Nuclear cystography offers three main advantages over fluoroscopic VCUG: increased detection of VUR (up to an additional 20%) (Fig. 111.8), frequent detection of a higher grade of VUR,[30,31] and reduced radiation dose (approximately 10–25-fold).[32] Disadvantages of nuclear cystography include a lack of detailed anatomic visualization of the urethra and collecting systems and limited identification of bladder abnormalities (such as periureteric diverticula); in addition, the classification of VUR with nuclear cystography is less refined than that with VCUG. The nuclear cystography VUR grades of low, intermediate, and high roughly correspond to the fluoroscopic grades of 1 (low), 2 or 3 (intermediate), and 4 or 5 (high).[27]

## Diuretic Renography

Diuretic renography is used to distinguish obstructive from nonobstructive hydronephrosis.[33] It attempts to quantify urinary obstruction based on the relative function of the hydronephrotic kidney compared with the normal kidney and the rate of urinary excretion of radiotracer (MAG-3 or DTPA) from the renal pelvis (and, in the presence of hydroureter, from the ureter) after a diuretic challenge (typically 1 mg/kg IV furosemide). The graphic presentation of renal excretion using a time versus intensity curve is termed a *renogram* (e-Fig. 111.9); normal, equivocal, and obstructed patterns of excretion after a diuretic challenge, termed *washout*, have been described[33] (Fig. 111.10). Additionally, the time required for half the tracer in the collecting system to pass across the ureteropelvic junction after the administration of furosemide, termed *diuretic* $T_{1/2}$, is stratified to indicate a normal (0–10 minutes), equivocal (10–20 minutes), or obstructed (>20 minutes) pattern.[34,35] These values are useful in distinguishing obstructive from nonobstructive hydronephrosis in older children and adults. However, application of these guidelines can lead to the misdiagnosis of obstruction in a large number of young infants with hydronephrosis demonstrated on routine prenatal sonography (e-Fig. 111.11).[36] The high capacitance of the dilated renal pelvis and relatively low renal urine output in young infants limit the accuracy of this test in the setting of hydronephrosis in children younger than 2 years.[35] Increasing hydronephrosis, decreasing split renal function of the hydronephrotic kidney, and a worsening washout curve all suggest the possibility of significant obstruction (Fig. 111.12).

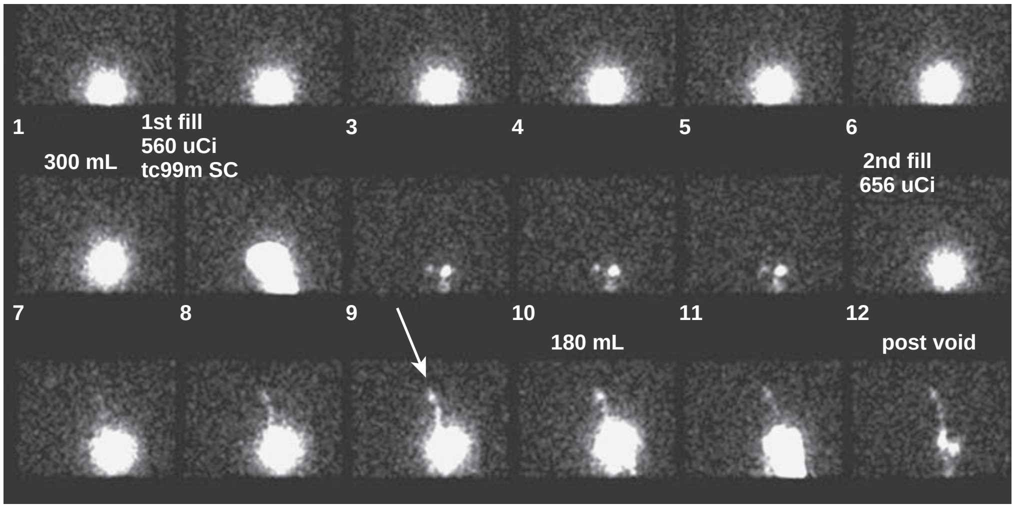
## Cortical Scintigraphy

A renal cortical scan is performed for the assessment of acute pyelonephritis or its sequela, atrophic pyelonephritic scarring, or for the identification and characterization of functioning renal tissue. A cortical scan also can be used to identify renal anomalies of fusion or location, although sonography is the examination of choice because of its lack of ionizing radiation, increased availability, better anatomic detail, and lower cost.

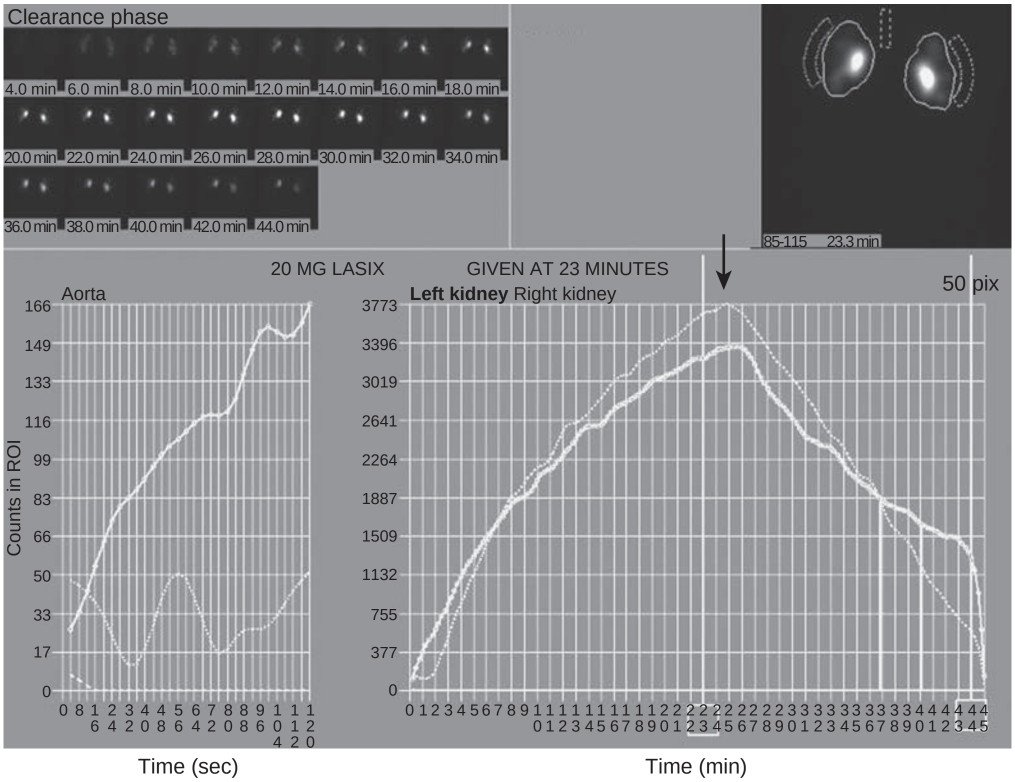
The renal cortical scan typically is performed with technetium-99m–labeled dimercaptosuccinic acid (DMSA) or glucoheptonate. These agents are extracted by and then bind to cells of the proximal convoluted tubule. It does not accumulate in the medulla or collecting system, thus accounting for the scan appearance of cortical uptake with relative central photopenia of the medulla and renal sinus (Fig. 111.13). Imaging typically occurs 2 to 3 hours after injection and should be performed with pinhole collimation or single photon emission CT acquisition with a dual-headed camera.[37,38] The accuracy in demonstrating acute pyelonephritis exceeds 95%.[39] A defect that appears as a vague area of photopenia not associated with volume loss is more consistent with acute pyelonephritis, whereas a triangular, well-demarcated photopenic focus with volume loss typically is considered an atrophic scar (Fig. 111.14), although it also may be related to focal renal dysplasia. Most areas of infection resolve without residual scarring, especially in older children, but resolution may not occur until 6 months or longer after the acute event. Therefore a definitive diagnosis of a scar requires a follow-up study at least 6 months after the acute infection.[40] Rounded defects identified with cortical scintigraphy should be further characterized with ultrasound to assess for a cyst or mass (e-Fig. 111.15).

## Miscellaneous Renal Nuclear Studies

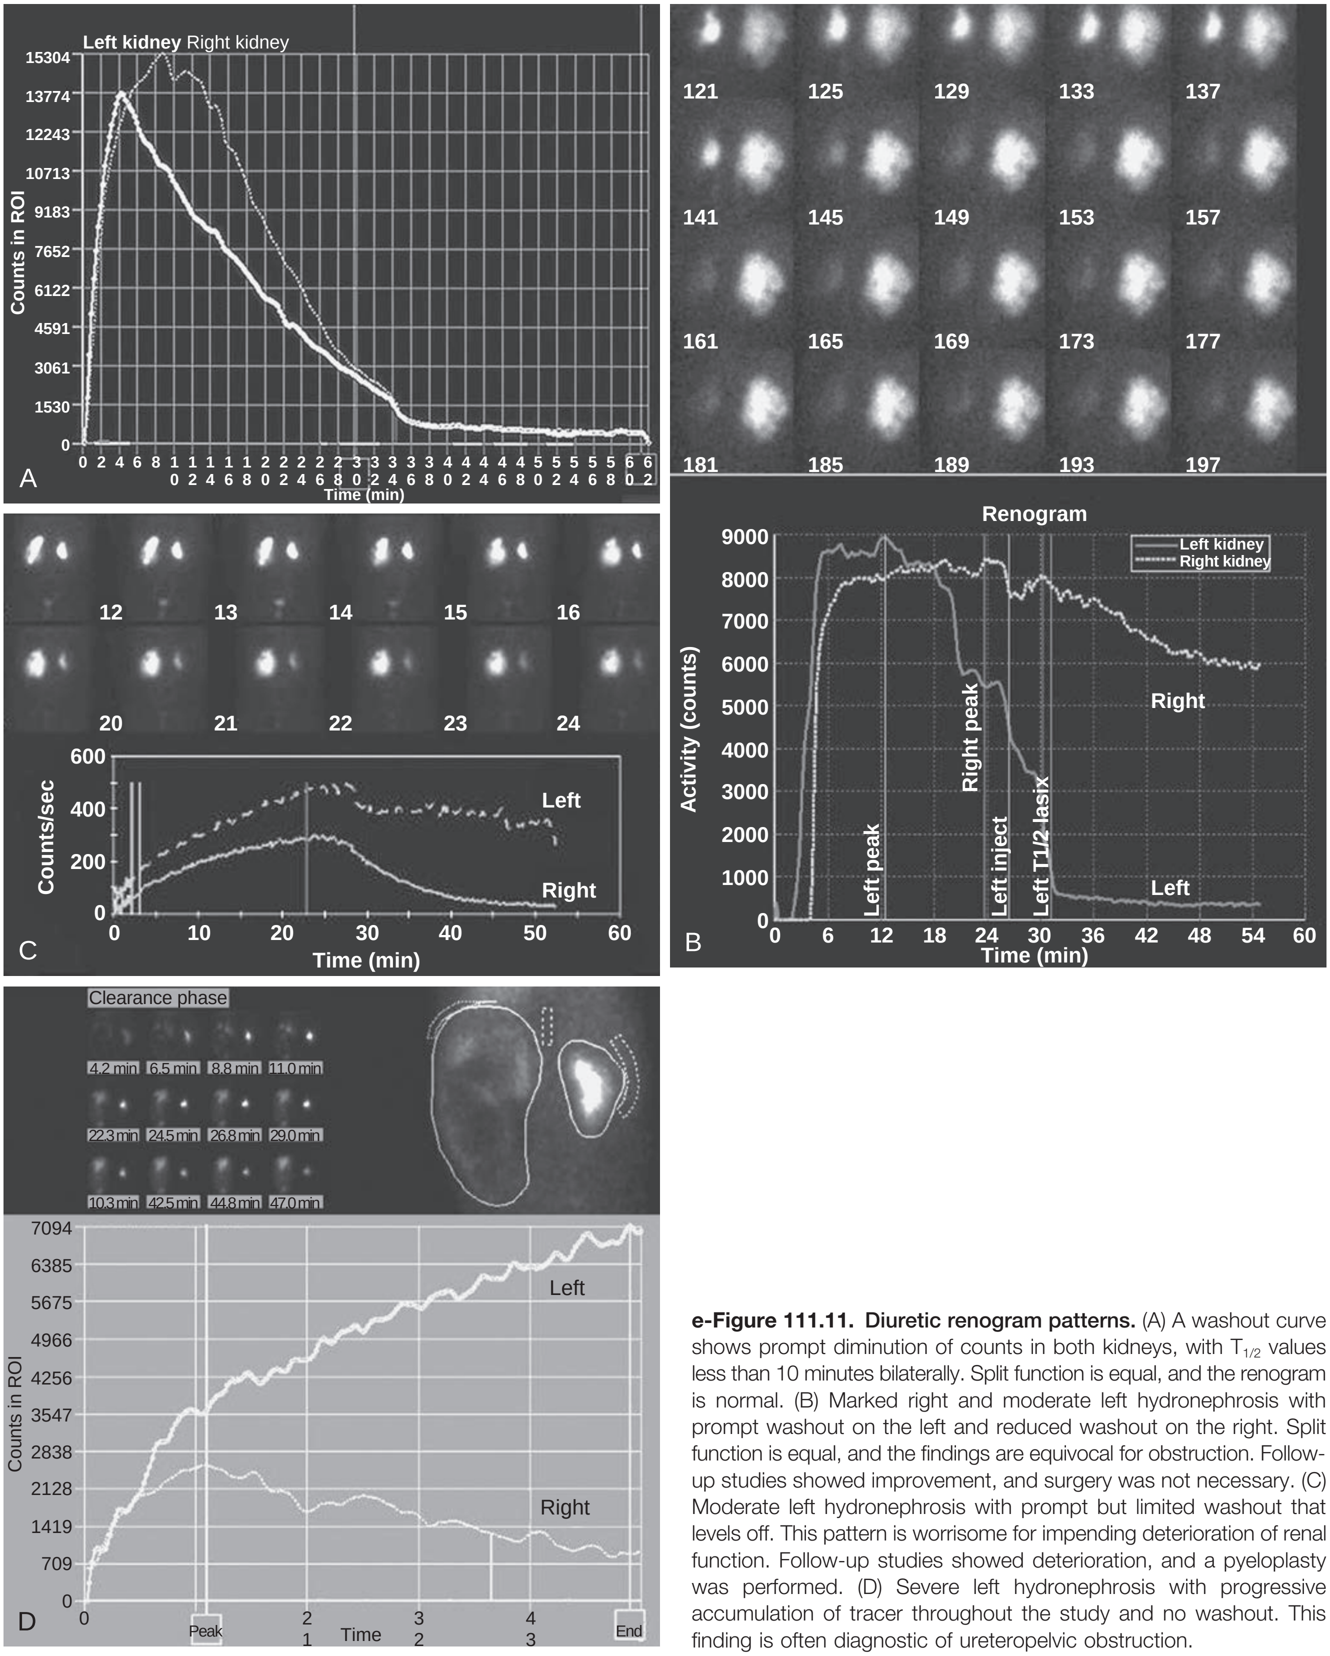
Quantitation of renal function is possible with nuclear imaging techniques.[41] The relative function of each kidney can be assessed during renography before tracer exits the renal pelvis or with cortical scintigraphy. Regions of interest for each kidney are drawn



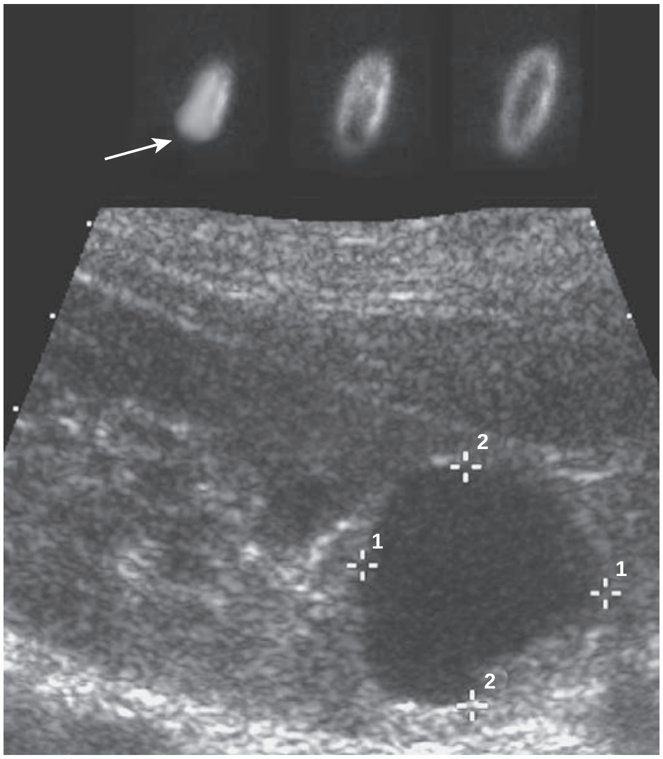
**e-Figure 111.7. Vesicoureteral reflux.** A cyclic nuclear cystogram demonstrates a normal first cycle, with intermediate-grade left reflux present on the second cycle only *(arrow)*.



**e-Figure 111.9.** Time versus activity graph shows a steady accumulation of tracer in the renal region of interest until washout occurs, starting 3 minutes after injection of a diuretic agent *(arrow)*. Note the superolateral background region of interest adjacent to both kidneys. Also note mild urinary stasis and hydronephrosis, with no spontaneous excretion until after administration of a diuretic agent. The diuretic $T_{1/2}$ is approximately 10 minutes, which is considered normal in the presence of mild hydronephrosis.



**e-Figure 111.11. Diuretic renogram patterns.** (A) A washout curve shows prompt diminution of counts in both kidneys, with $T_{1/2}$ values less than 10 minutes bilaterally. Split function is equal, and the renogram is normal. (B) Marked right and moderate left hydronephrosis with prompt washout on the left and reduced washout on the right. Split function is equal, and the findings are equivocal for obstruction. Follow-up studies showed improvement, and surgery was not necessary. (C) Moderate left hydronephrosis with prompt but limited washout that levels off. This pattern is worrisome for impending deterioration of renal function. Follow-up studies showed deterioration, and a pyeloplasty was performed. (D) Severe left hydronephrosis with progressive accumulation of tracer throughout the study and no washout. This finding is often diagnostic of ureteropelvic obstruction.



**e-Figure 111.15. Renal cyst.** Sagittal single photon emission computed tomography dimercaptosuccinic acid images show a rounded, photopenic defect in the lower pole *(arrow)*, which was shown to be a cyst on follow-up ultrasound.

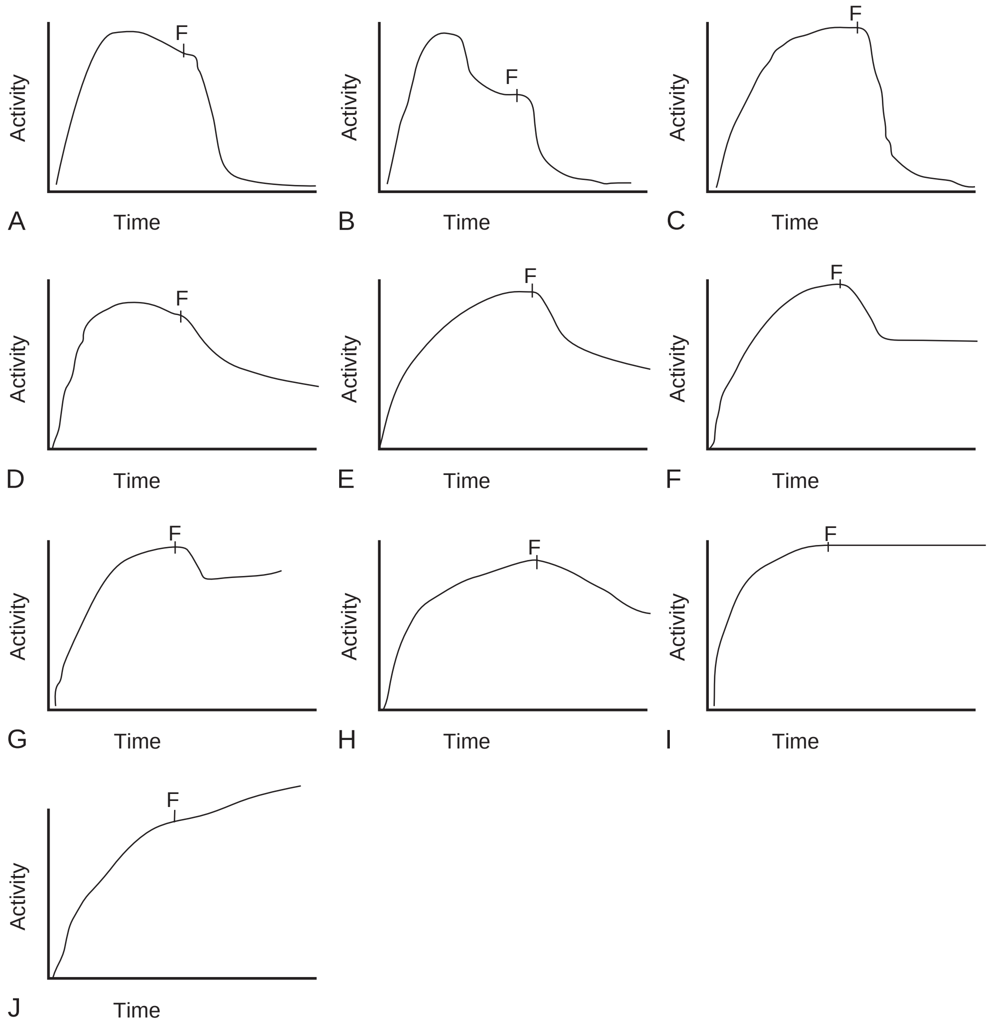


**Figure 111.10. Diuretic renogram patterns.** Patterns (A–C) are typically indicative of nonobstructed systems. Patterns (D and E) are equivocal in older children but usually indicate no obstruction in neonates and young infants with hydronephrosis. Patterns (F and G) often indicate flow-related obstruction. Patterns (H–J) typically indicate obstruction in older children but are seen frequently in neonates and infants with nonobstructive hydronephrosis. *F,* Furosemide injection.

from a posterior image, and relative function is given in terms of a percentage of total renal counts. The normal value is 50% ± 5%. Absolute renal function quantitation in terms of glomerular filtration rate or effective renal plasma flow can be performed with technetium-labeled DTPA and MAG-3, respectively, but these techniques require one to four blood samples.[41] Renal function increases rapidly in the first 2 years of life and reaches adult values, when normalized to body surface area, by age 2 years (normal values range from 80 to 140 mL/min/1.73 $m^2$).[41]

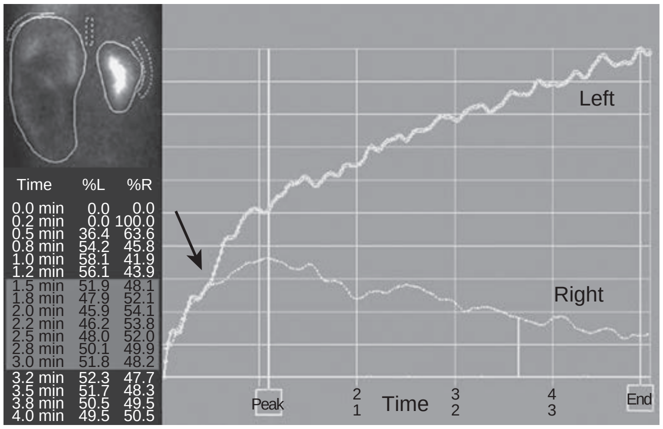
## COMPUTED TOMOGRAPHY

CT is one of our most powerful imaging tools. High-quality CT can be performed in patients of all ages and sizes and is not limited by bone or bowel gas. Relative immobility is required, and in children, reassurance, explanation of the procedure, the presence of a parent, sedation, and immobilization all contribute to a successful diagnostic study. Multidetector scanners that operate quickly obviate the need for sedation in many patients. Multiplanar reformatting, especially in the coronal plane, can aid in the depiction of the urinary tract.[42–44]

Noncontrast imaging is performed for calcifications or nephrolithiasis, but most CT imaging of the genitourinary system is performed with IV contrast material. Contrast enhancement is required for the evaluation of renal lesions and the vessels of the abdomen. Delayed imaging is useful for assessing the integrity of the collecting system (such as after trauma), assessing the course of the ureter, and evaluating certain renal masses and cystic lesions. CT radiation doses should be optimized based on patient size and the purpose of the study. Scanning begins based on the speed of the particular CT scanner and the information being sought. By showing the progression of contrast enhancement of the cortex, medulla, and collecting system of the kidneys, CT provides some assessment of renal function and anatomy.[45–50]

## MAGNETIC RESONANCE IMAGING

MRI has excellent tissue characterization, multiplanar capabilities, and the ability to gather functional and anatomic information. Meticulous attention to patient preparation and scanning technique is essential to reliably obtain high-quality images. Urine in the collecting system and ureter has low signal intensity on T1-weighted images and high signal intensity on T2-weighted scans. The kidney is easily visualized with intermediate signal on T1-weighted sequences and typically high signal on T2-weighted sequences. The renal cortex and medulla may demonstrate slightly different signal intensities on MRI (thus allowing visualization of corticomedullary differentiation), depending on the echo and repetition times chosen (Fig. 111.16).[51–58] A common indication for renal MRI in the pediatric population is the characterization of renal masses and cystic lesions.



| Time | %L | %R |
|---|---|---|
| 0.0 min | 0.0 | 0.0 |
| 0.2 min | 0.0 | 100.0 |
| 0.5 min | 36.4 | 63.6 |
| 0.8 min | 54.2 | 45.8 |
| 1.0 min | 58.1 | 41.9 |
| 1.2 min | 56.1 | 43.9 |
| 1.5 min | 51.9 | 48.1 |
| 1.8 min | 47.9 | 52.1 |
| 2.0 min | 45.9 | 54.1 |
| 2.2 min | 46.2 | 53.8 |
| 2.5 min | 48.0 | 52.0 |
| 2.8 min | 50.1 | 49.9 |

| 3.8 min | 50.5 | 49.5 |
| 4.0 min | 49.5 | 50.5 |

**Figure 111.12. Hydronephrosis.** A markedly enlarged left kidney with central photopenic regions consistent with marked hydronephrosis. The renogram shows tracer accumulation and retention throughout, with no discernible washout after administration of a diuretic. Note that the renogram tracings of the two kidneys are superimposed during the first few minutes after injection of the tracer *(arrow)*, which indicates nearly equal split renal function, as shown on the function table between 1.5 and 3 minutes.

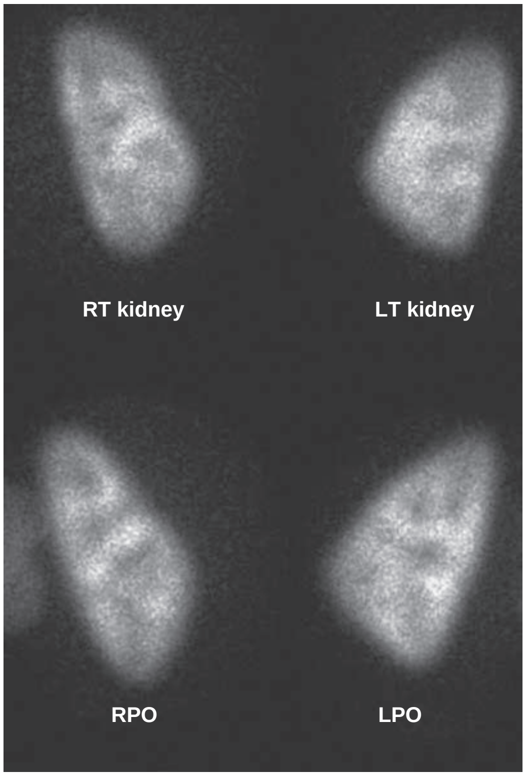

**Figure 111.13. Normal dimercaptosuccinic acid cortical scan.** Note the relative photopenia of the medulla due to a lack of uptake by the deeper portions of the loop of Henle. Also note the decreased intensity of the polar regions as a result of the relatively thinner polar cortex when compared with the midpolar region. *LPO,* Left posterior oblique; *LT,* left; *RPO,* right posterior oblique; *RT,* right.

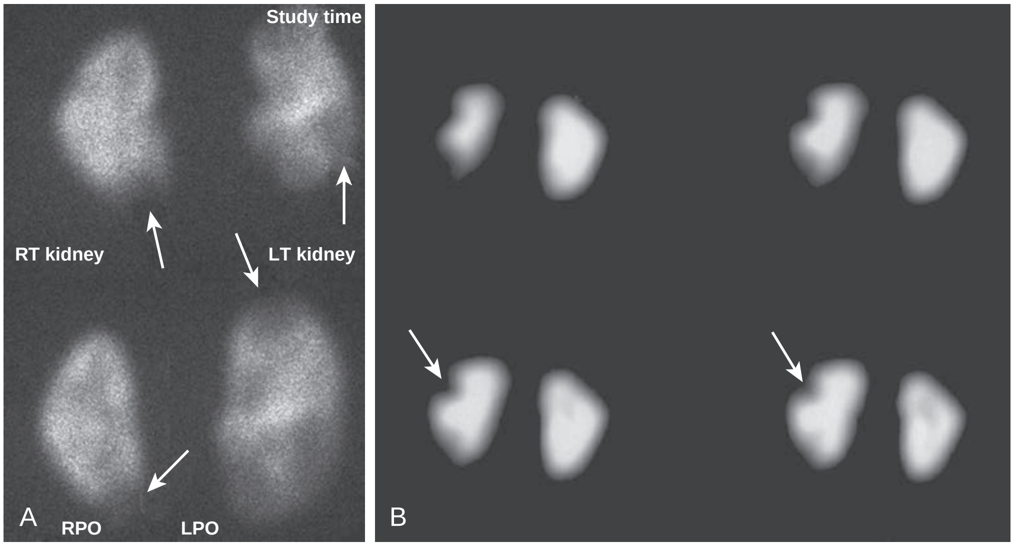

**Figure 111.14. Pyelonephritis versus scarring.** (A) Pinhole dimercaptosuccinic acid (DMSA) images obtained for split uptake assessment show bilateral photopenic defects that are rather poorly defined and not associated with renal parenchymal volume loss *(arrows)* indicating pyelonephritis. (B) Coronal single photon emission computed tomography glucoheptonate images show sharply defined wedge-shaped defects *(arrows)* indicative of renal scars. Glucoheptonate has been largely replaced by DMSA for cortical scintigraphy because of better binding characteristics. *LPO,* Left posterior oblique; *LT,* left; *RPO,* right posterior oblique; *RT,* right.

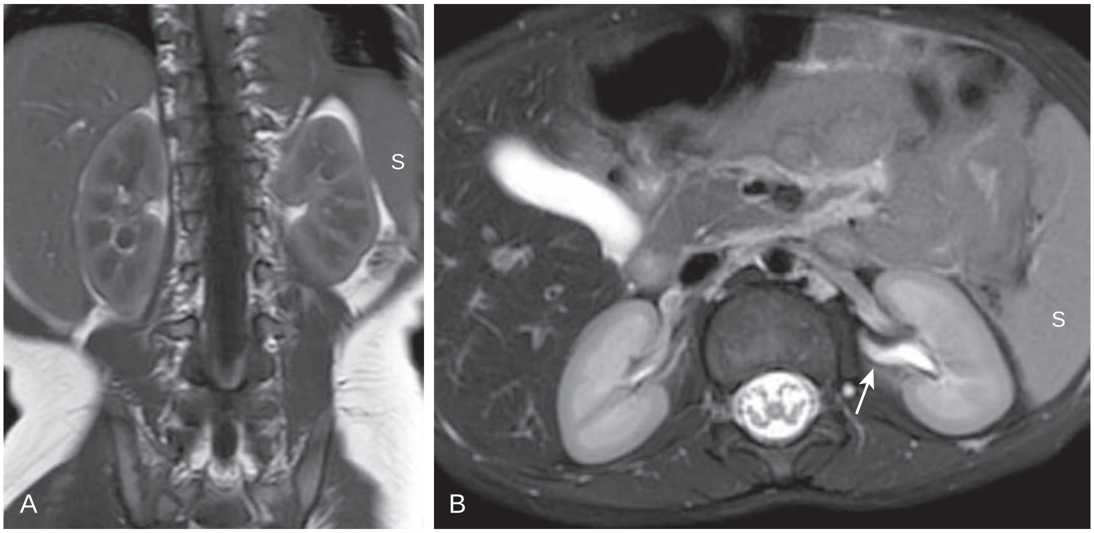

**Figure 111.16. Normal renal magnetic resonance image in a 1-year-old.** (A) A coronal T1-weighted fast spin-echo image shows that the renal cortex is near-isointense to the adjacent spleen *(S)* and the medulla is hypointense relative to the cortex. (B) An axial T2-weighted fast spin-echo fat-saturated image shows renal parenchyma is slightly hyperintense relative to the spleen *(S)*, with the medulla appearing brighter than cortex and the urine in the central pelvis appearing quite hyperintense *(arrow)*.

## Magnetic Resonance Urography

Magnetic resonance urography (MRU) represents the next stage in the evolution of uroradiology, fusing superb anatomic and functional imaging into a single test that does not use ionizing radiation (Fig. 111.17).[59–65] In addition to conventional T1- and T2-weighted images, dynamic imaging is performed in conjunction with the injection of a gadolinium-based contrast agent to assess the concentrating and excretory functions of the kidney (e-Fig. 111.18). The evaluation of the contrast dynamics is similar to renal scintigraphy but with the important distinction that the signals originating from the renal parenchyma can be separated from those originating from the collecting system. The primary indication for MRU is in the evaluation of hydronephrosis (e-Fig. 111.19). Other evolving indications for MRU include evaluation of renal scarring and dysplasia, identification of ectopic ureters in children with urinary incontinence, and characterization of complex urinary tract anatomy.

### Hydronephrosis and Obstructive Uropathy

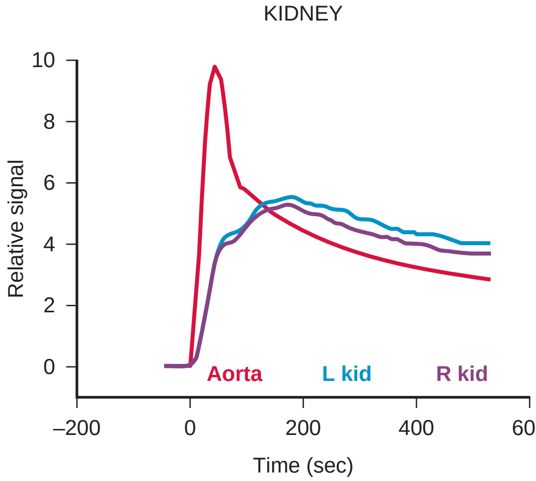
Hydronephrosis is the most common indication for MRU in infants and children.[66] Ureteropelvic junction obstruction is the most common cause of neonatal hydronephrosis. Obstructive uropathy occurs in a subset of children with hydronephrosis and refers to obstruction that results in an injury to the kidney.[67] The kidney damage is not simply a result of mechanical impairment of urine flow but rather occurs as a result of a complex syndrome caused by the interaction of a variety of vasoactive factors and cytokines, leading to alterations of both glomerular hemodynamics and tubular function.[68] It is necessary to try to determine if the degree of obstruction present will lead to either a loss of renal function in the future or, in the case of children, will limit the future development of the kidney.

In children, obstruction is usually both chronic and partial. The partial obstruction results in equilibrium between urine production, impaired urine outflow, and pelvic reservoir capacity.[69] A steady state is reached between the amount of urine produced and the volume of the renal pelvis so that the pressure in the renal pelvis is in the normal range. This dynamic balance may be upset during diuresis or when the obstruction is exacerbated. The loss of balance results in a transient increase in pelvic pressure. It is unclear whether it is the frequency, duration, or severity of these transitory elevations in renal pelvic pressure that are responsible for renal damage and progressive loss of renal function.

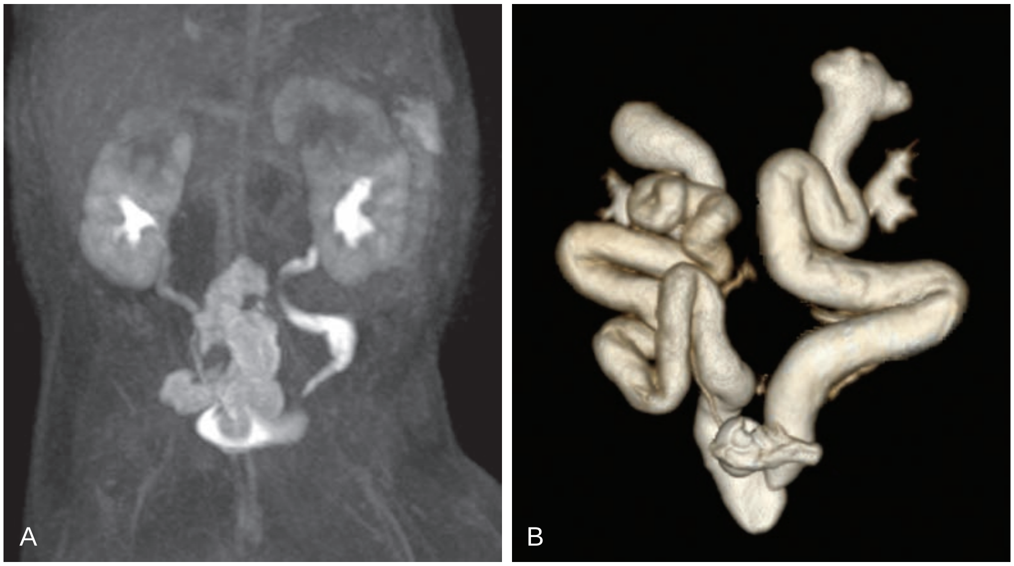
One of the key strengths of MRU (also known as *functional MRU*, or fMRU) is its ability to dynamically assess signal intensity changes occurring within the renal parenchyma after administration of contrast material and in response to a fluid and diuretic challenge. Changes in renal physiology can be evaluated rapidly by examining how the perfusion, filtration, and concentration affect the handling of the contrast agent by the kidney.

With MRU, the hydronephrotic kidney is subjected to both a fluid challenge (IV hydration) and a diuretic challenge (IV furosemide administered ~15 minutes before the administration of contrast material). The response of the kidney to this challenge determines the appearance of the MR nephrogram. If symmetric changes in the signal intensity of the nephrogram occur, the hydronephrosis is classified as a compensated hydronephrotic system—that is, the fluid challenge has been accommodated without increasing the pressure in the pelvicalyceal system. However, when the signal intensity changes are asymmetric, they most often indicate acute or chronic obstruction—that is, the fluid challenge has exceeded the capacity for renal drainage, and the pressure in the collecting system rises. This hydronephrosis is classified as a decompensated hydronephrotic system. Signs associated with decompensation include parenchymal edema on the T2-weighted images, delayed calyceal transit time, and a delayed and increasingly dense (intense) nephrogram (Fig. 111.20). These two patterns have different prognostic implications; little improvement in renal function can be expected after pyeloplasty in compensated kidneys, but significant improvement is seen in decompensated systems.[70]

The quality of the renal parenchyma is assessed both on the high-resolution T2-weighted images and during the parenchymal phase of the nephrogram. Signs that suggest underlying uropathy and permanent damage include architectural disorganization with loss of the corticomedullary differentiation, small cysts,



**e-Figure 111.18. Time intensity curves for the patient shown in Fig. 111.17.** These curves allow assessment and comparison of renal perfusion, concentration, and excretion similar to the time activity curves generated with diuretic renal scintigraphy.



**e-Figure 111.19. Hydronephrosis and poor renal function.** Postcontrast T1-weighted maximum intensity projection (A) and 3D T2-weighted volume-rendered (B) MRU images show the anatomy and morphology of hydronephrotic and poorly functioning systems. Both kidneys are duplex with poorly functioning upper poles and associated megaureters. The lower pole ureters are seen on both the contrast-enhanced and the T2-weighted images. The ureters of the upper poles are only seen on the T2-weighted volume-rendered image, whereas the T1-weighted MIP only shows poorly enhancing parenchyma of the upper pole. The anatomy and insertion of the megaureters can be assessed on the T2-weighted urogram.

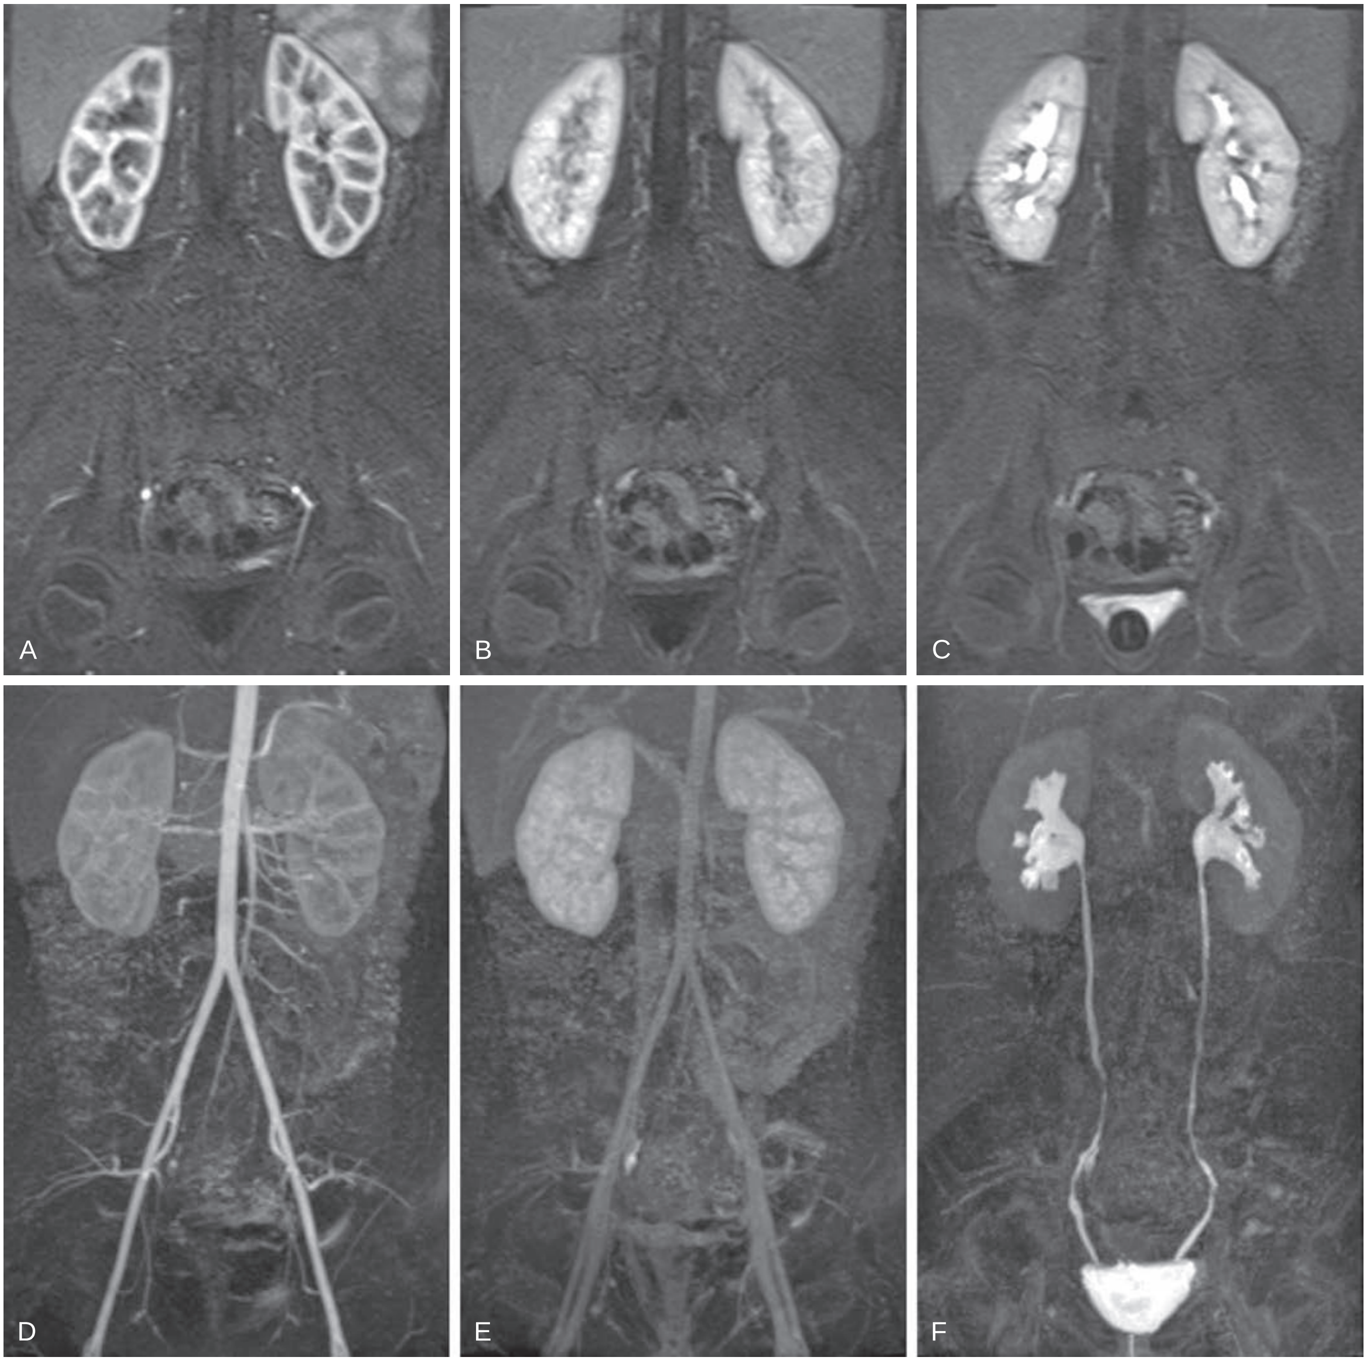


**Figure 111.17. Normal magnetic resonance urogram in an 8-year-old girl.** Images (A–C) show the same slice from three volume acquisitions acquired at time points corresponding to the cortical (arterial), parenchymal (nephrographic), and excretory phases of renal function, respectively. Images (D–F) are maximum intensity projections derived from the total volume for the three same time points.

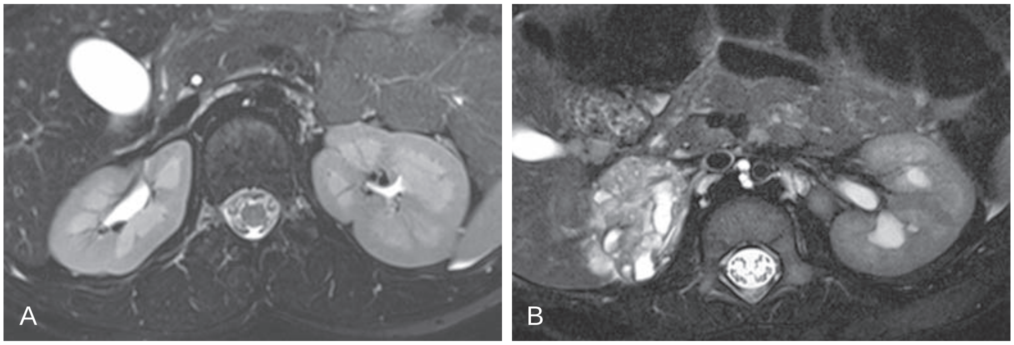
and low cortical T2-weighted signal intensity (e-Fig. 111.21). The nephrogram in these cases usually shows dim and patchy contrast enhancement reflecting damage to the microvasculature, as well as to the glomeruli and tubules. These imaging findings probably reflect the histologic changes of renal damage based on reduced glomerular number, glomerular hyalinization, cortical cysts, and interstitial inflammation and fibrosis.[71] In contrast to uropathic kidneys, edematous kidneys typically show increased signal intensity on the T2-weighted images, as well as a delayed hyperintense nephrogram. The edematous pattern typically is seen either with decompensated hydronephrosis or acute pyelonephritis.

Anatomic information includes grading the hydronephrosis, identification of transition in the caliber of the ureter, and evaluation of underlying causes such as kinks, strictures, or crossing vessels.[72,73] Both the T2-weighted and delayed postcontrast images are used to define the pelvicalyceal and ureteric anatomy. The T2-weighted images (magnetic resonance [MR] hydrography) are particularly helpful in children with severe hydronephrosis and/or poorly functioning systems. Volumetric T2-weighted and



**e-Figure 111.21. Renal dysplasia.** High-resolution T2-weighted MR images show a patient with normal renal anatomy (A), whereas part (B) shows a patient with right renal dysplasia. MRU allows assessment of both the renal cortex and medulla and detection of cysts, scarring, edema, and architectural disorganization.

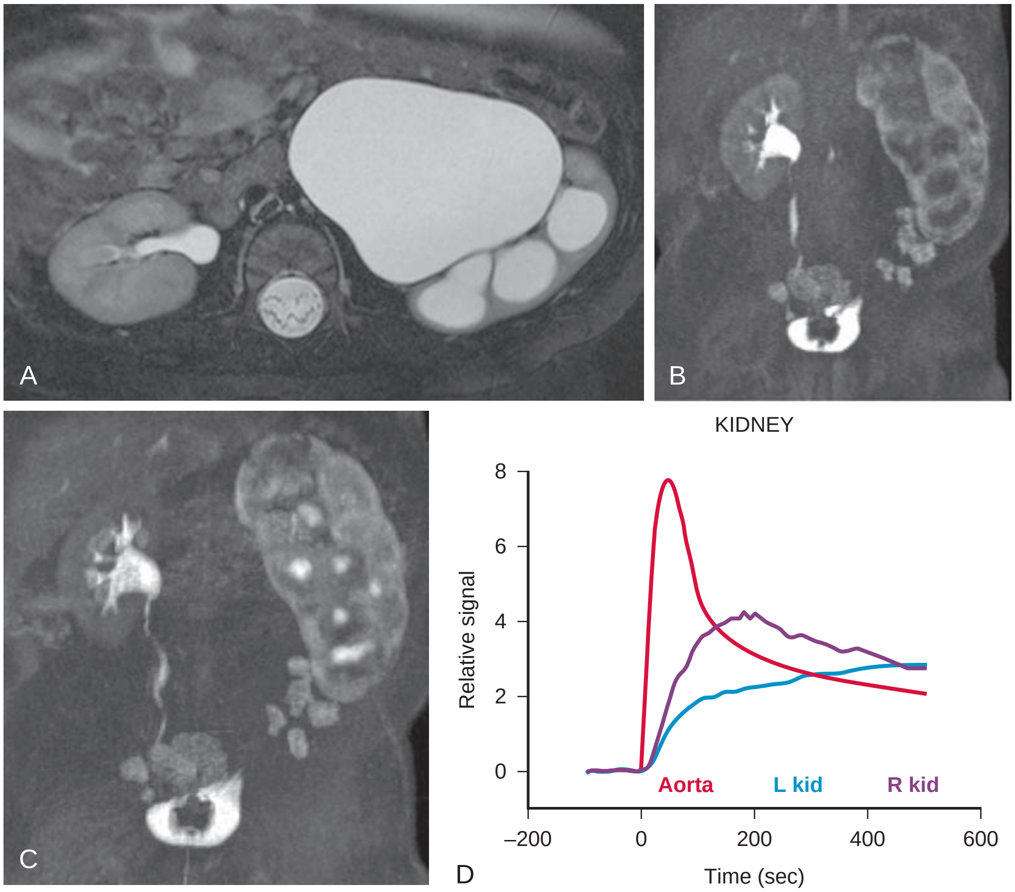


**Figure 111.20. Decompensated ureteropelvic junction obstruction in a 3-month-old girl.** (A) The axial T2-weighted MR image demonstrates marked hydronephrosis of the left kidney with ballooning of the calyces and thinning of the renal parenchyma. After administration of contrast material, calyceal excretion of contrast material is delayed on the left side (B), and an increasingly dense (intense) nephrogram is seen (C). The signal intensity versus time curve (D) shows delayed peak enhancement with gradual accumulation of signal within the parenchyma of the left kidney. *L,* Left; *R,* right.

postcontrast images can be used to generate exquisite volume-rendered and maximum intensity projection images of the pelvicalyceal systems and ureters.

## Congenital Malformations, Renal Scarring, and Dysplasia

Anomalies of renal fusion, position, and rotation are clearly demonstrated with MRU. Horseshoe and ectopic kidneys easily can be separated from the background and overlying tissues. Pelvic kidneys in particular are clearly demonstrated with MRU. Hypoplastic kidneys associated with ureteric ectopia and supernumerary kidneys usually can be demonstrated even if minimal renal function exists. MRU is the method of choice in the evaluation of incontinence associated with ectopic insertion of the ureter (Fig. 111.22).[74]

MRU enables identification of the acquired segmental scars most often associated with pyelonephritis and differentiation of areas of acute pyelonephritis from developed scars on the basis of mass effect and inflammatory changes. Acute pyelonephritis is associated with edema, mass effect, and swelling of the kidney. Mature scars are characterized by volume loss and contour defects of the kidney on T2-weighted images and perfusion defects on the dynamic contrast-enhanced images, and they exhibit dilatation of the adjacent calyx, indicating transmural parenchymal loss. Affected regions demonstrate no appreciable contrast enhancement, reflecting fibrosis and microvascular damage (Fig. 111.23).

The typical imaging features associated with dysplastic kidneys include small size, disorganized architecture with loss of normal corticomedullary differentiation, small cysts, decrease in signal intensity on T2-weighted images, poor perfusion, a dim and patchy nephrogram, and dysmorphic calyces.

### KEY POINTS

- Ultrasound is generally the first-line test for evaluating the kidneys and urinary tract in children.
- Antegrade VCUG is the examination of choice for detailed anatomic evaluation of the bladder, study of the anatomy of the male urethra, and identification of VUR.
- Nuclear cystography is performed as an alternative to VCUG for the assessment of VUR. Advantages include continuous imaging, which increases detection of VUR, reduced radiation dose, and detection of higher-grade VUR. Disadvantages include lack of detailed anatomic information and decreased information about the grade of VUR.
- Contrast-enhanced voiding urosonography sensitivity for VUR detection is comparable with that of standard techniques.

*Continued*

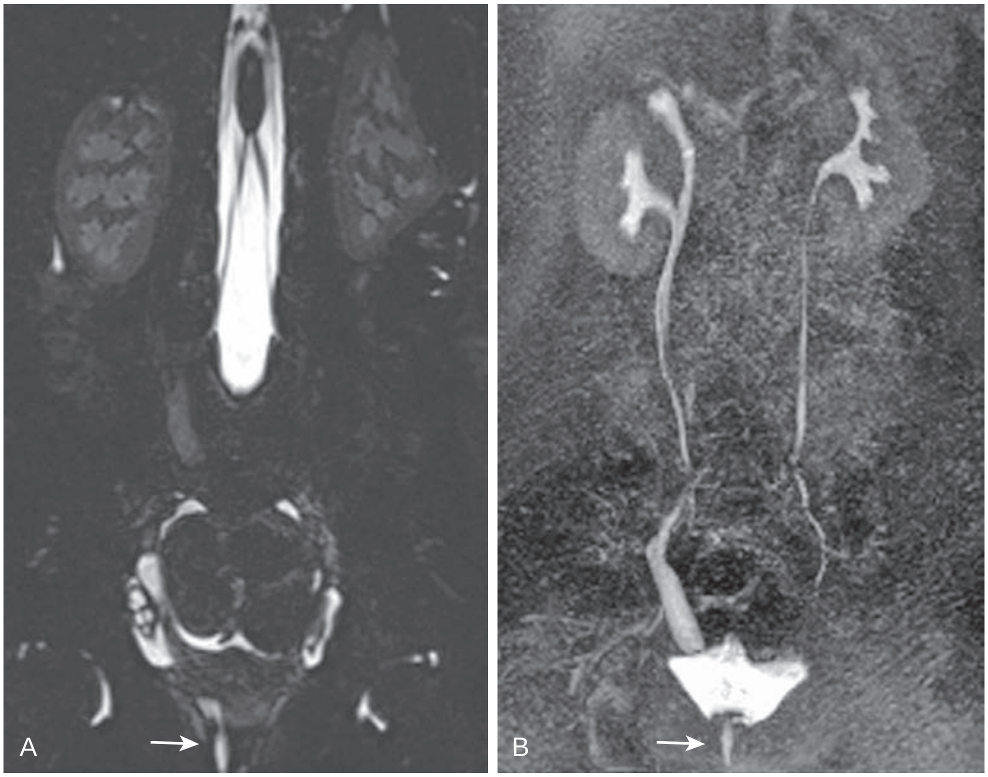

**Figure 111.22. Ectopic ureteric insertion in a 9-year-old girl with incontinence.** The T2-weighted MR image (A) shows a small cystic and dysplastic right upper pole moiety with a dilated ureter seen extending below the bladder base. On the delayed postcontrast maximum intensity projection image (B), the dilated ectopic ureter is seen inserting distally into the vagina *(arrows)*.

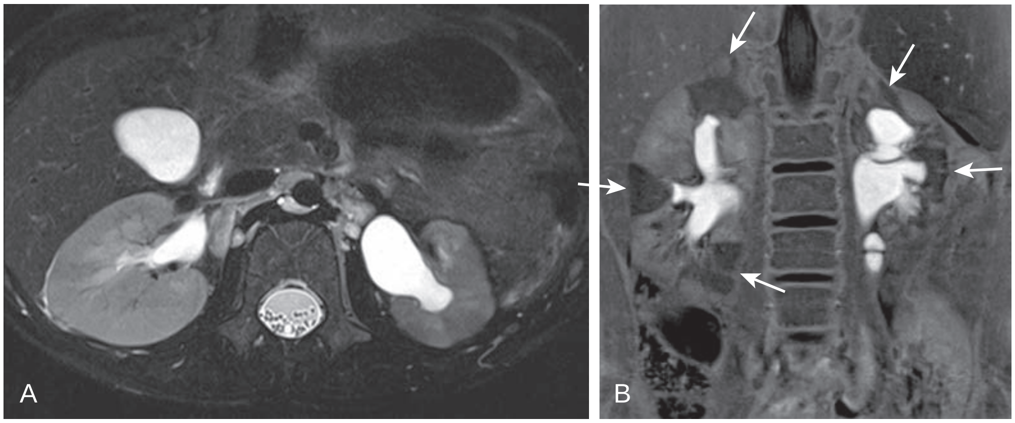

**Figure 111.23. Renal scarring in a 5-year-old girl with a history of a recurrent urinary tract infection.** An axial T2-weighted image (A) shows a smaller left kidney with disorganization of the renal parenchyma and focal areas of low signal intensity. Minimal abnormality is seen on the right. The inversion recovery image after administration of contrast material (B) shows triangular areas of decreased intensity with associated deformity of the renal contour bilaterally *(arrows)*. The scars are seen adjacent to the calyces.

- Cyclic voiding studies increase the detection of VUR in infants.
- Diuretic nuclear renography distinguishes obstructive from nonobstructive hydronephrosis based on the characteristics of the renogram generated, including differential renal function, renal extraction of radiotracer, and washout of radiotracer from the urinary collecting system. The examination is less accurate in young infants because of a high capacitance renal pelvis and relatively low urine output.
- The ability of MRU to provide a more complete characterization of renal anatomy and physiology has provided insights into the pathophysiology of hydronephrosis and the complex interaction of renal development, dysplasia, and scarring. MRU has the potential to revolutionize the imaging approach to renal disease in children.
- MRU is the method of choice in the evaluation of incontinence associated with ectopic insertion of the ureter.

## OVERVIEW

Fetal genitourinary system abnormalities encompass a wide spectrum of disorders varying in degrees of severity and include developmental anomalies, obstructive lesions in the urinary tract, and renal parenchymal diseases. The prenatal evaluation of the genitourinary system includes assessment of the amniotic fluid, the kidneys, the bladder, and associated anomalies. Amniotic fluid is important for normal fetal development, particularly the fetal lungs. In the first trimester, amniotic fluid forms as a dialysate of maternal serum. Fetal urine production begins by 12 weeks of gestation and becomes the major source of amniotic fluid by 16 weeks. Fetal urine production is typically 120 mL/day at 20 weeks and increases gradually to 1200 mL/day by term. The fetus voids every 30 to 60 minutes. The bladder should be visualized at least once during a prenatal imaging examination.[1,2]

Identification of the fetal urinary bladder is attempted in the first trimester ultrasound, and more detailed evaluation of the kidneys and bladder is a fundamental part of the second trimester fetal anatomic assessment. Complex cases, such as bladder exstrophy, confusing duplex collecting systems, and obstructive masses, may be further evaluated by fetal magnetic resonance imaging (MRI).[3–5] Sonographic fetal anatomic assessment may be limited in the setting of oligohydramnios, and MRI may be particularly useful. Prenatal findings may influence the further pursuit of genetic and laboratory testing or surgical intervention and may guide the delivery plan.

## NORMAL FETAL GENITOURINARY TRACT

***Overview and Imaging.*** Fetal kidneys can be identified at 13 weeks of gestation. Normal renal sizes through gestation (mean kidney length in millimeters is slightly longer than weeks of gestation) are shown in Table 112.1.[6,7] Corticomedullary differentiation is apparent by 20 weeks of gestation (Fig. 112.1). Renal calyces and ureters typically are not seen on ultrasound unless they are pathologically dilated,[8] and the renal pelvis is only readily visualized once the anterior-posterior diameter exceeds 2 mm.[9] The fetal bladder can be visualized at 10 weeks of gestation. The bladder wall should not measure more than 3 mm. Bladder wall thickening may be a sign of outlet obstruction.[10,11]

Amniotic fluid volume can be a reflection of renal health. Oligohydramnios (defined by an amniotic fluid index less than 8 cm)[12] may be seen in the setting of placental insufficiency, intrauterine growth retardation, chromosomal abnormality, premature rupture of membranes, post-dates gestation, or urologic pathology (Box 112.1).[13]

## RENAL PARENCHYMAL DISORDERS

***Overview.*** Fetal renal echogenicity may be abnormally increased as a normal variant but more often reflects an underlying abnormality. The fetal kidney is considered echogenic if it is brighter than the fetal liver. Echogenic kidneys are observed in approximately 1 to 2 per 1000 fetal ultrasounds, and approximately 10% of cases of renal malformations include echogenic kidneys.[14,15] Etiologic considerations for the echogenic kidney are summarized in Box 112.2.[16–24] If echogenic kidneys are identified and the amniotic fluid volume is normal, the findings suggest nonlethal renal disease. Echogenic kidneys with oligohydramnios are highly concerning for a poor outcome.[25]

## CYSTIC RENAL DISEASE

***Overview.*** Congenital cystic renal diseases occur in about 2 to 4 in 1000 live births and include autosomal dominant and autosomal recessive polycystic kidney disease (Fig. 112.2 and Video 112.1), multicystic dysplastic kidney (Fig. 112.3), cystic glomerulopathies, and other cystic renal dysplasias. The complex pathogenesis of these disorders involves an abnormal orchestration of transcription and growth factor expression (Table 112.2), as well as ciliopathies affecting the renal tubule primary cilium (Table 112.3).[26–29] Structural and functional abnormalities in primary cilia contribute to various cystic phenotypes that involve the kidney and liver.[27]

***Imaging.*** These types of renal cystic abnormalities may be demonstrated in the fetus either by ultrasound or MRI.[27,30–36] Fetal sonographic evaluation of the kidneys should include renal length,

**TABLE 112.1** Normal Fetal Renal Lengths

| Gestational Age (wk) | Mean Kidney Length (cm) | 95% Confidence Interval (cm) |

**BOX 112.1** Renal Etiologies for Oligohydramnios

- Bilateral renal agenesis
- Bilateral multicystic dysplastic kidney
- Bilateral severe ureteropelvic junction obstruction
- Bilateral renal disease with one kidney each involved with items 1, 2, or 3 above
- Severe prune-belly syndrome
- Severe autosomal recessive polycystic kidney disease
- Severe renal dysplasia as a result of posterior urethral valves or urethral atresia

## Abstract:

Fetal genitourinary system abnormalities including congenital malformations, obstructive lesions in the urinary tract, and renal parenchymal diseases may be identified by prenatal ultrasound. The prenatal evaluation of the genitourinary system includes assessment of the amniotic fluid, the kidneys, the bladder, and associated anomalies. Fetal magnetic resonance imaging (MRI) adds to the sonographic evaluation in the setting of oligohydramnios or in complex or confusing cases. Prenatal findings may influence the further pursuit of genetic and laboratory testing or surgical intervention, and may guide the delivery plan. In this chapter, the normal sonographic and MRI appearance of the genitourinary system is reviewed. Abnormalities of renal parenchyma, including renal masses, as well as urinary tract dilatation and its appropriate management are discussed. Lower urinary tract outlet obstruction and potential prenatal surgical interventions are reviewed as well.

## Keywords:

Fetal MRI

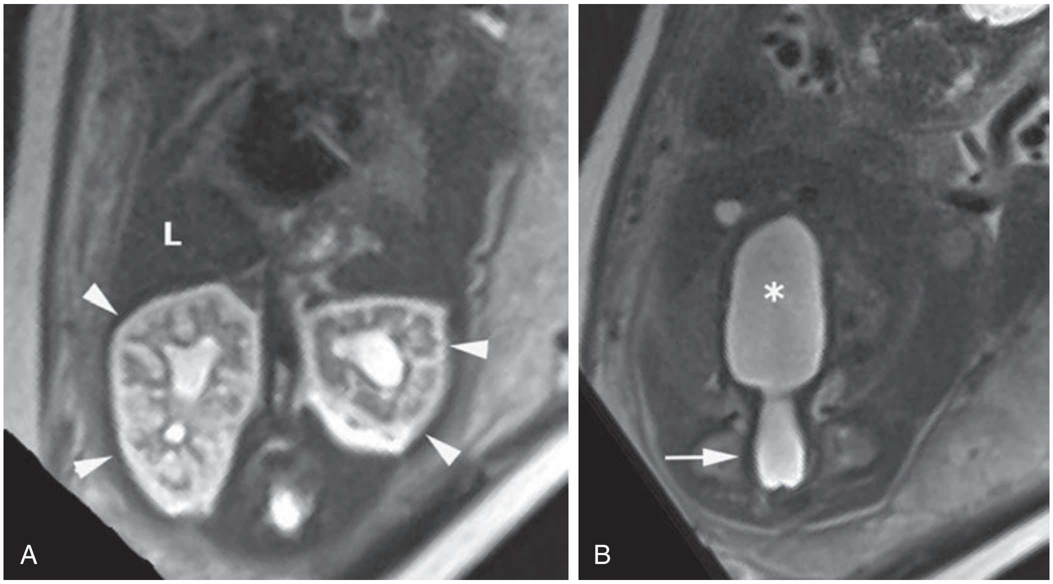
overall echogenicity, preservation of corticomedullary differentiation, and presence of macroscopic cysts. Renal size may be considered abnormally increased if it is greater than or equal to 2 standard deviations (moderately enlarged) or greater than or equal to 4 standard deviations (markedly enlarged) greater than expected for gestational age.[6] Renal echogenicity greater than that of the liver or spleen is abnormal (Fig. 112.4), and corticomedullary differentiation may be lost or reversed if renal parenchymal disease is present.[27] MRI also readily shows abnormalities in renal size and detects renal cysts. Dysplastic parenchyma typically increases the T2-weighted signal intensity (e-Fig. 112.5).

***Approach to Diagnosis.*** A differential diagnostic approach to fetal echogenic renal cystic diseases is summarized in Table 112.4. If macroscopic cysts are observed without abnormal renal echogenicity, possible etiologies will depend on the number of cysts observed. Visualization of a single renal cyst should prompt consideration of a cystic tumor, a duplex collecting system with cystic dysplasia of the upper pole, urinoma, asymmetric presentation of autosomal dominant polycystic kidney disease (ADPKD), or an isolated cyst in an otherwise normal kidney. Multiple cysts may be seen with multicystic dysplastic kidney, ADPKD, tuberous sclerosis complex, and *TCF2* gene mutation–associated nephropathy.

## RENAL TUMORS

***Overview and Imaging.*** A solid, round echogenic mass in the fetal kidney (Fig. 112.6) is most likely to be a congenital mesoblastic nephroma (CMN), also known as a *leiomyomatous hamartoma* or a *fetal renal hamartoma*, although a Wilms tumor may present in the fetus as well.[37] Both tumor types can replace the kidney or be localized. Tumors may be vascular with cystic areas as a result of hemorrhage and cystic degeneration. Polyhydramnios may occur (seen in 40% of renal tumor cases) and may lead to premature



**e-Figure 112.5. Abnormal intensity of renal parenchyma on fetal MRI.** (A) Coronal T2-weighted single-shot fast spin-echo MR image through the abdomen of a fetus at 27 weeks' gestational age shows markedly hyperintense renal cortices *(arrowheads)* bilaterally. Urinary tract dilatation is evident bilaterally. (B) Coronal image through the fetal pelvis shows an abnormally dilated urinary bladder *(asterisk)* and dilated posterior urethra *(small arrow)*, with urinary bladder wall thickening, consistent with urinary bladder outlet obstruction by posterior urethral valves. Note the absence of amniotic fluid.

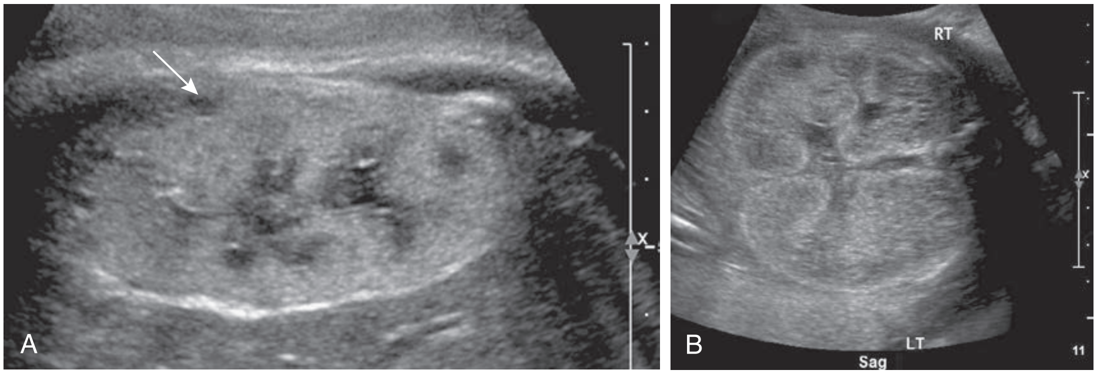


**Figure 112.2. Autosomal dominant polycystic kidney disease (ADPKD) and autosomal recessive polycystic kidney disease (ARPKD).** (A) Longitudinal sonogram of a fetus at 36 weeks' gestational age shows an enlarged echogenic kidney measuring more than 6 cm in length with small peripheral cysts *(arrow)*. The contralateral kidney also was large and echogenic. Amniotic fluid remained normal throughout the pregnancy. The father also had ADPKD. (B) Coronal sonogram of both kidneys of a different fetus at 23 weeks' gestational age shows marked nephromegaly and diffusely increased echogenicity with poor corticomedullary differentiation. This appearance is created by the innumerable acoustic reflections by dilated tubules. *LT*, Left kidney; *RT*, right kidney.

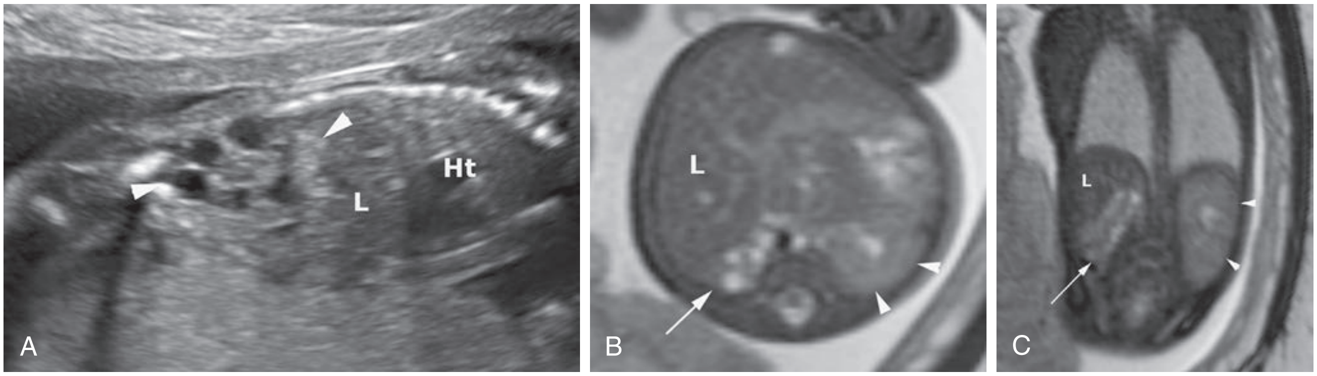

**Figure 112.3. Multicystic dysplastic kidney.** (A) Longitudinal sonogram of the right kidney in a fetus at 20 weeks' gestational age shows an enlarged kidney (outlined by *arrowheads* at superior and inferior poles) with macroscopic cysts not communicating with the collecting system. There is minimally discernible renal parenchyma that is echogenic and disorganized. (B) Axial and (C) coronal steady-state free precession MR image of the same fetus at 31 weeks' gestational age shows decreased size of the multicystic mass *(arrow)* in the right renal fossa with no normal renal tissue. Left kidney *(arrowheads)* is normal. *Ht*, Heart; *L*, liver.

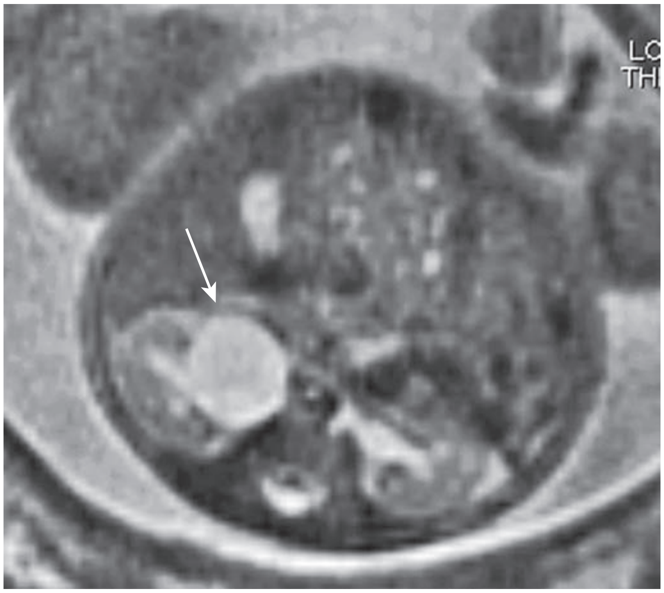
Renal length is normal for this gestational age, and the amniotic fluid volume is normal. *Sp*, Spine.

labor, and fetal renal tumor patients have increased perinatal complications.[38] Although CMN is generally benign, resection is recommended as a small percentage exhibit aggressive or malignant behavior.

## ANTENATAL HYDRONEPHROSIS

***Overview.*** Pyelectasis (dilatation of the fetal renal collecting system) is seen in 1% to 5% of screened fetuses.[39–45] Numerous factors influence renal pelvis dilation, including maternal hydration, fetal bladder filling, or the presence of an extrarenal pelvis (e-Fig. 112.7). Fetuses with trisomy 21 have an increased incidence of mild pyelectasis (>4 mm in the second trimester).[46] If mild pyelectasis is observed, other anomalies or risk factors should be present before pursuing cell-free fetal DNA testing, because the specificity of aneuploidy with isolated pyelectasis is low.[47–49] Most fetuses with mild pyelectasis are normal (approximately 90% or more).[42,45,50,51] Apart from the risk for chromosomal aneuploidy,



**e-Figure 112.7. Extrarenal pelvis versus ureteropelvic junction obstruction.** Axial single-shot fast spin-echo T2-weighted MR image of both fetal kidneys shows a large extrarenal pelvis on the right *(arrow)*. The renal cortex remains thick. Postnatal imaging (not shown here) confirmed a mildly dilated extrarenal pelvis without obstruction.

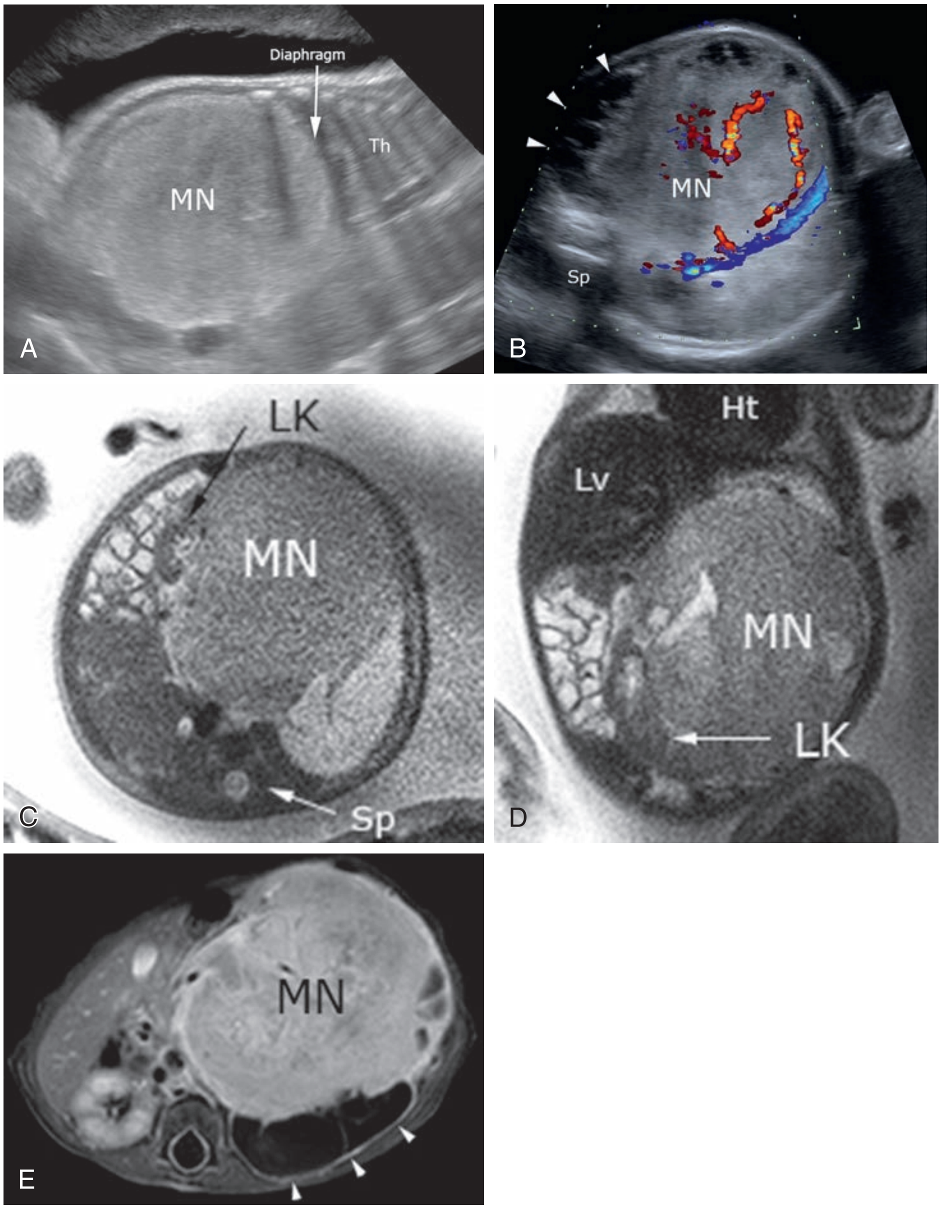


**Figure 112.6. Fetal mesoblastic nephroma.** (A) Longitudinal gray-scale and (B) transverse color Doppler prenatal ultrasound images at 36 weeks' gestational age show a large left retroperitoneal echogenic vascular mass with marginal anechoic spaces *(white arrowheads)* consistent with cystic components. Subsequent single-shot fast spin-echo fetal 3T MR images in (C) axial and (D) coronal planes show mass displacing the left renal parenchyma *(LK)* anteriorly. (E) Postnatal contrast-enhanced MR image in axial plane shows enhancing solid tissue with rim-enhancing marginal cystic components *(arrowheads)*. Pathology was confirmed after nephrectomy. *Ht*, Heart; *Lv*, liver; *MN*, mesoblastic nephroma; *Sp*, spine; *Th*, thorax. *(Images courtesy Dr. Pinar Karakas-Rothey, Benioff Children's Hospital Oakland, Oakland, California.)*

pyelectasis in the fetus may signify either obstruction or vesicoureteral reflux, so follow-up later in gestation and postnatally must be considered. Causes of bilateral hydronephrosis are presented in Box 112.3.

***Imaging.*** In 2014 a consensus classification system for urinary tract dilatation (UTD) was established by eight relevant societies.[45] The UTD Classification System applies to both prenatal and postnatal diagnosis. The severity of the urinary tract dilation is based on six categories: (1) anterior-posterior renal pelvic diameter (APRPD); (2) calyceal dilation; (3) renal parenchymal thickness; (4) renal parenchymal appearance; (5) bladder abnormalities; and (6) ureteral abnormalities. The classification system is stratified based on gestational age (16–27 weeks vs. 28 weeks or greater). Antenatal urinary tract dilation is declared as either low risk (UTD A1) or increased risk (UTD A2-3). If the APRPD is 4 to less than 7 mm at 16 to 27 weeks gestational age (GA) or 7 to less than 10 mm at 28 weeks or greater, and if no other abnormality of the urinary tract is present (Fig. 112.8), then the UTD is classified as A1 (low risk). However, if the APRPD is greater than or equal to 7 mm at 16 to 27 weeks or greater than or equal to 10 mm at 28 weeks or greater, or if any additional abnormality is present (unexplained oligohydramnios, peripheral caliectasis,

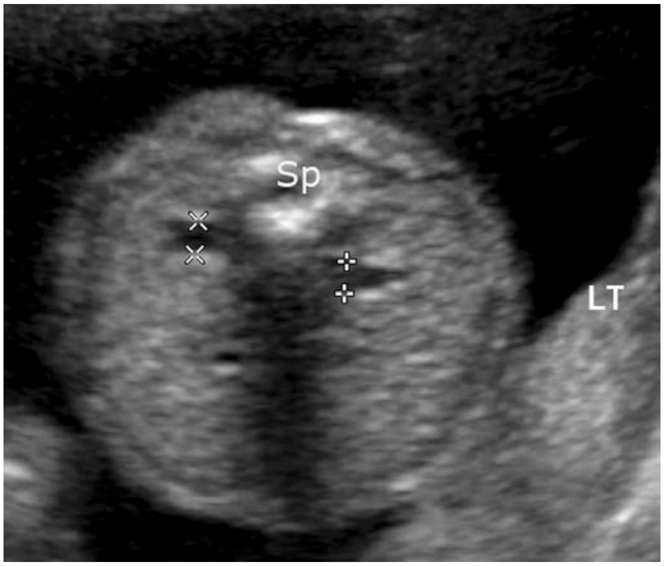

**Figure 112.8. Fetal urinary tract dilatation, low risk (UTD A1).** A transverse ultrasound image of a fetus at 20 weeks' gestational age shows calipers marking the anterior-posterior diameter of both renal pelves, measuring between 4 to 7 mm. The renal parenchyma is normal, and ureters and urinary bladder were normal *(not shown)*. This mild degree of UTD is classified as low risk. *LT,* Left; *Sp,* spine.

renal parenchymal abnormality, ureterectasis, or urinary bladder abnormality), then the UTD is classified as increased risk (A2-3) (Box 112.4 and Fig. 112.9).

Management recommendations based on the UTD classification are also proposed.[45] The main goals of follow-up imaging are to identify fetal kidneys at risk for renal failure or infection, and to identify fetuses that may benefit from fetal surgical intervention (discussed later in this chapter). For UTD A1 diagnosed before 32 weeks, a follow-up prenatal ultrasound is recommended at greater than or equal to 32 weeks. If the repeat ultrasound at greater than or equal to 32 weeks shows resolution of the UTD and no abnormality of the renal parenchyma, bladder, and ureters, then no further prenatal or postnatal follow-up is necessary. However, if there is persistent UTD A1 or UTD A2-3, evaluation after birth is recommended.

Postnatal evaluation should include two ultrasound evaluations. The first ultrasound usually is performed at least 2 days after birth to avoid underestimating collecting system dilatation as a result of physiologic oliguria in the first 48 hours of life and within 1 month after birth; the second ultrasound study is then performed 1 to 6 months later.[45,52,53] Follow-up should be performed sooner for suspected obstructive uropathies, such as posterior urethral valves (as suggested by a thick-walled bladder with persistent urinary tract dilation and/or posterior urethral dilation on prenatal ultrasound) or for bilateral conditions.[45]

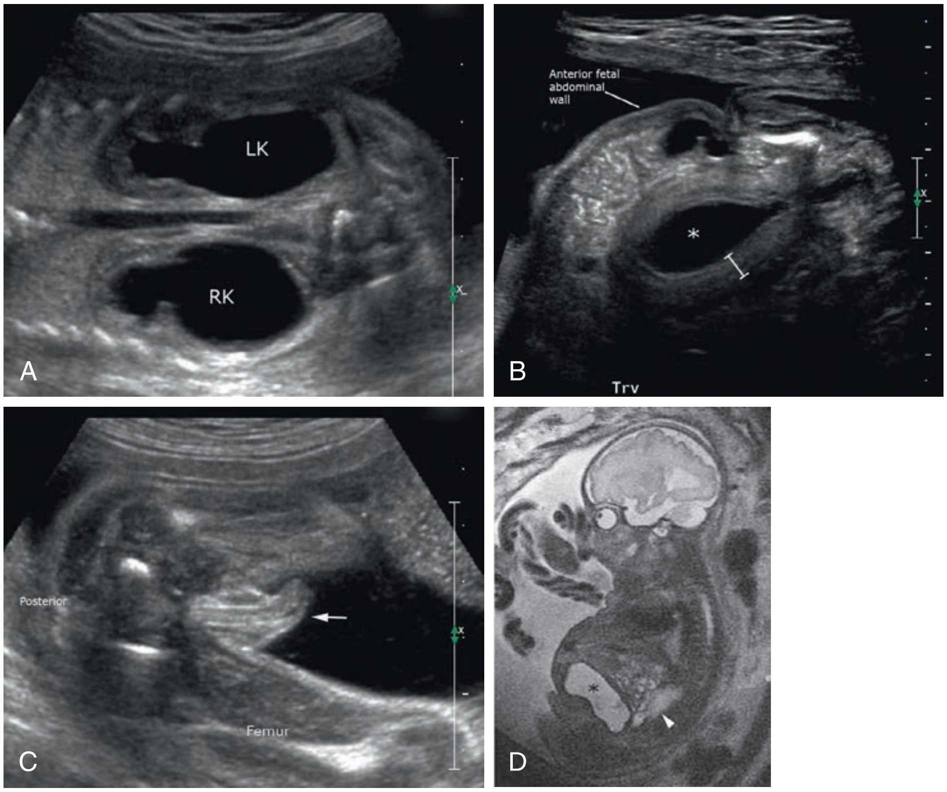
Counseling patients about the significance of antenatally detected pyelectasis is based on a large number of studies reviewing outcomes of otherwise normal fetuses found to have varying degrees of UTD.[40–45,54] A meta-analysis[44] combining the findings 1678 cases of antenatal hydronephrosis gathered from 17 independent studies found that even mild degrees of prenatally diagnosed hydronephrosis may indicate pathology requiring postnatal management (11.9%). Prenatal consultation with a pediatric urologist and/or pediatric nephrologist is recommended in situations where there is substantial risk for surgery or renal dysfunction.[45]

## MEGACYSTIS

***Overview and Imaging.*** An abnormally large bladder, or megacystis, manifests in the first trimester in approximately 1 : 330 to 1 : 1800 pregnancies.[55–59] A longitudinal bladder diameter greater than 7 mm during the second or third trimester is considered abnormal.[55–58] Early diagnoses of megacystis may resolve later in pregnancy.[11,55–59] An enlarged fetal bladder observed by ultrasound or MRI may simply reflect normal variation in bladder filling, although if bilateral hydroureteronephrosis is observed, then pathologies such as obstruction or functional emptying abnormalities must be considered. If an abnormal longitudinal bladder diameter persists after 23 weeks gestational age, the prognosis is more likely to be poor.[59] Potentially severe abnormalities include posterior urethral valves (Fig. 112.10), prune-belly syndrome (Eagle-Barrett syndrome) (e-Fig. 112.11), and megacystis-microcolon-intestinal hypoperistalsis syndrome. An enlarged fetal bladder also merits close evaluation of the spine, given that caudal regression and neural tube defects may present with a neurogenic bladder.[60]

## FETAL BLADDER OUTLET OBSTRUCTION: SURGICAL INTERVENTIONS

***Overview.*** At a minimum, management of urinary tract outlet obstruction in the fetus involves serial ultrasounds through the second and third trimester and may merit delivery of the fetus at a tertiary care center. The role for procedural intervention in the fetus with bladder outlet obstruction has been well investigated during the past few decades, especially in identifying the appropriate fetal population that would benefit from intervention. Although the



**e-Figure 112.11. Fetal prune-belly (Eagle-Barrett syndrome).** (A) Coronal sonogram through the kidneys in a fetus at 24 weeks' gestational age shows bilateral marked urinary tract dilatation. (B) Transverse sonogram through the fetal urinary bladder *(asterisk)* shows marked thickening of the urinary bladder wall (denoted by *caliper*). Abnormal contour of the anterior abdominal wall is also appreciable. (C) Normal male phallus is observed *(arrow)*. Amniotic fluid index is normal. (D) Sagittal T2-weighted single-shot fast spin-echo MR image performed later at 30 weeks' gestational age shows abnormal urinary bladder *(asterisk)* enlargement and abnormal abdominal wall contour. Volume-averaging of partially viewed dilated renal collecting system is noted by *arrowhead*. *LK*, Left kidney; *RK*, right kidney.

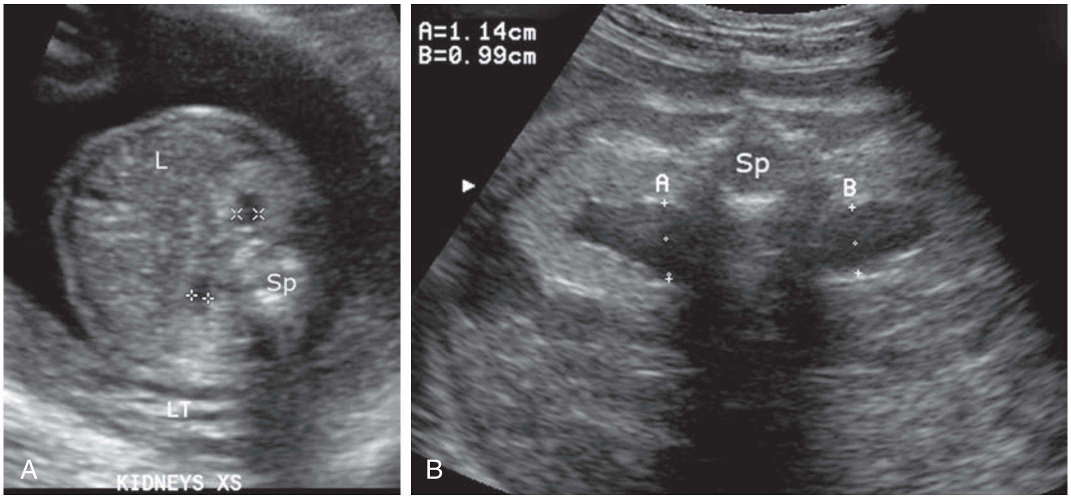


**Figure 112.9. Fetal urinary tract dilatation, high risk (UTD A2-3).** (A) Transverse sonogram of a fetus at 23 weeks' gestational age shows a mildly dilated right renal pelvis, measuring 4.4 mm. Because of increased renal echogenicity, the UTD classification is A2-3 (high risk). (B) Transverse sonogram of a different fetus at 35 weeks' gestational age shows abnormal dilatation of the bilateral kidneys, with anterior-posterior renal pelvis diameters measuring 10 mm and 11 mm. Renal echogenicity is mildly echogenic as well. Urinary bladder was normal *(not shown)*. In the third trimester, this degree of urinary tract dilatation is classified as A2-3. *L*, Liver; *Sp*, spine.

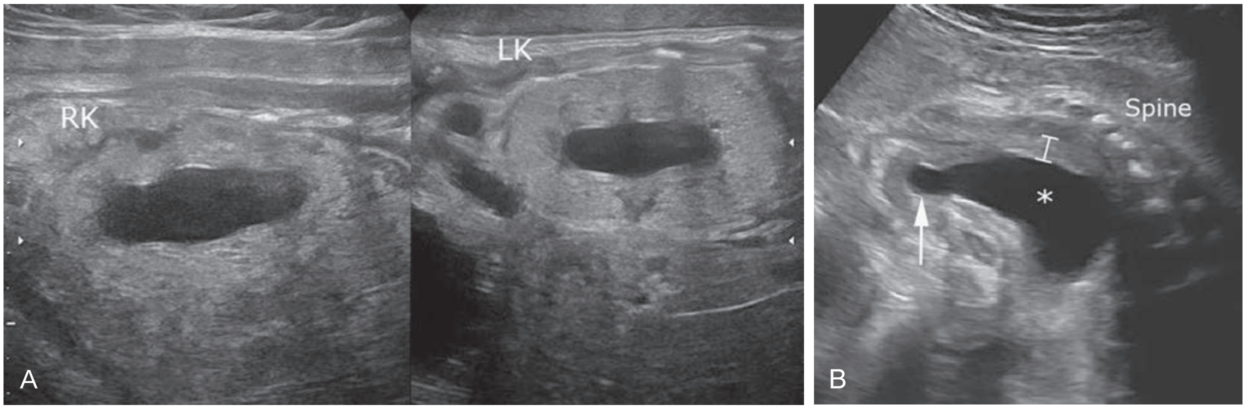

**Figure 112.10. Posterior urethral valves and oligohydramnios.** (A) Longitudinal sonogram at 32 weeks' gestational age shows echogenic kidneys. The renal pelves measured 13 mm on left and 7 mm on right (not shown). With the increased renal echogenicity, the UTD classification is A2-3 (high risk). (B) The fetal bladder *(asterisk)* is abnormally large with distension of the posterior urethra *(arrow)* in a configuration called the *keyhole* sign. Bladder wall thickening is noted by caliper. *LK*, Left kidney; *RK*, right kidney.

fetus with a high-grade bladder outlet obstruction may progress during pregnancy and be accompanied by development of renal dysplasia, second trimester cases have been reported that spontaneously improve and later manifest only a low-grade obstruction with normal amniotic fluid volume.[61,62] Further, animal studies have shown that the severity of renal damage from obstruction depends on numerous factors, including the timing, duration, and severity of the obstruction.[62–64] The primary challenge is to identify the fetuses for intervention that have severe enough obstruction that renal function and pulmonary development would be compromised by progression of disease but that maintain the potential for improved renal development after the obstruction is relieved.

Monitoring the function of fetal kidneys primarily requires assessing amniotic fluid volume and the sonographic appearance of the kidneys; more eloquent measurements include sampling various fetal urine electrolytes and proteins after 20 weeks' gestational age. Many investigators have evaluated the potential of fetal urine electrolyte concentrations in identifying renal functional prognosis.[65–67] Fetuses with obstructive uropathy and a subsequent poor outcome are "salt wasters," and fetuses with a decent outcome have hypotonic urine.[68] Nicolini et al.[67] found that elevated fetal urinary calcium levels was the most sensitive (100%) predictor of renal dysplasia (specificity 60%), and elevated urinary sodium levels were the most specific (80%) predictor of renal dysplasia. Urinary phosphate, creatinine, and urea were not useful in predicting the likelihood of renal dysplasia. Elevated levels of the protein β2-microglobulin within fetal urine also has been shown to be useful in the prediction of postnatal renal function,[68] particularly in identifying fetuses at risk for renal damage by obstruction even when amniotic fluid volume remains normal.

***Treatment and Complications.*** Surgical intervention for bladder outlet obstruction and decreasing amniotic fluid volume or oligohydramnios is considered in the fetus with a good prognostic electrolyte panel (i.e., Na <100 mEq per liter, Cl <90 mEq per liter, and osmolarity <210 mEq per liter) and no evidence of renal dysplasia by ultrasound.[69,70] Surgical interventions to treat bladder outlet obstruction include vesicoamniotic shunt, fetoscopic valve ablation, fetoscopic urethral stent placement, and open fetal surgery for vesicostomy.

The vesicoamniotic shunt is placed percutaneously under ultrasound guidance to allow for emptying of the obstructed bladder directly into the amniotic cavity. Seven nonrandomized, controlled clinical series in the literature[66,71–76] offer the combined experience of 195 treated fetuses. A meta-analysis[77] incorporating studies of both controlled series and additional case studies pooled the odds ratios to summarize measures of effect of this procedure. This analysis found that bladder drainage markedly improved perinatal survival, specifically in the subgroup of fetuses with a poor predicted prognosis (based on urine electrolytes and amniotic fluid volume). The procedure, when successful, restores amniotic fluid volume and allows for improved development of the fetal lungs. Although the vesicoamniotic shunt has the potential to improve pulmonary development, the shunt does not necessarily benefit the kidneys. Further, shunt placement does not address the severe bladder dysfunction seen with outlet obstruction, and animal studies have shown that decompressing a normal fetal bladder by shunting leads to a fibrotic and noncompliant bladder wall.[78] The bladder dysfunction is a potential obstacle to renal transplantation. Complication rates from vesicoamniotic shunt placement are as high as 60%[79,80] and include inadequate shunt drainage, shunt migration, premature labor, urinary fetal ascites, chorioamnionitis, and iatrogenic gastroschisis.

Only one randomized control trial (RCT) has been performed to evaluate the effective outcomes of this procedure.[81] The percutaneous shunting in lower urinary tract obstruction (PLUTO) RCT included 31 patients and sought to determine the effectiveness of vesicoamniotic shunting (VAS) as a treatment for lower urinary tract obstruction.[81] Survival seemed to be higher in the fetuses receiving vesicoamniotic shunting, but because of poor recruitment, the study was closed early and the benefit could not be definitively proven. The authors concluded that the chance of newborn infants surviving with normal renal function is very low irrespective of whether vesicoamniotic shunting is done,[81] as suggested in previous studies.[82] A follow-up study reported on the remaining patients in the PLUTO registry who did not wish to be randomly assigned to a treatment group and who instead chose their own management plan (either conservative management or VAS).[83] There was a higher number of voluntary terminations of pregnancy than the authors had expected. Of 144 total patients in the registry, 68 patients pursued termination, 31 patients were enrolled in the RCT, and the remaining 45 patients were compared with the RCT. The authors observed no difference in live-birth rates for those who received either VAS or conservative management, highlighting the poor prognosis when lower urinary tract obstruction (LUTO) is associated with pulmonary hypoplasia. The chance of the infant surviving with normal renal function was also higher in the group that registered for conservative management than in those who were randomized. Those in the registry who elected to pursue conservative management were less likely to have presented at an earlier age and were less likely to have low amniotic fluid volume; given the prediction for a poor outcome when either early GA or low amniotic fluid volume are present, it is likely that the apparent difference in findings could be explained by these confounding patient cohort factors. More recently published retrospective single center studies, however, demonstrate that VAS may still be a valid treatment option in adequately selected cases.[54,84]

As an alternative to VAS, fetal cystoscopy may allow for diagnosis of the obstructive lesion and for intervention, such as by ablation of posterior urethral valves, fenestration of ureterocele, or placement of a stent across a stenotic urethra.[84–95] This method also avoids the need for amnioinfusion and some of the potential risks associated with vesicoamniotic shunt migration.[86] Recent experience shows that laser fulguration and hydroablation are the best option for disruption of posterior urethral valves, with neonatal survival rates of approximately 70% to 75%.[89,90] There is a lack of evidence for the effectiveness of fetal cystoscopy over VAS for LUTO. Sananes et al suggest the main advantage of the fetal cystoscopy over VAS is that it provides the correct diagnosis of the etiology of LUTO and consequently to allow a better selection of candidates for fetal therapy that contribute to better long-term outcome related to renal function.[92]

Open fetal surgery for vesicostomy (bladder marsupialization) is the only approach that completely decompresses the entire urinary tract and eliminates the transmission of pressure to the kidney. Candidates for this procedure are male fetuses with posterior urethral valves less than 24 weeks' gestational age presenting with oligohydramnios, normal fetal urine electrolytes, and no evidence of renal cystic dysplasia or abnormally increased renal echogenicity, and who have normal karyotypes. Only a small amount of clinical experience exists in this advanced arena of fetal surgical intervention, and vesicostomy currently carries a 50% neonatal mortality.[96–98]

## KEY POINTS

- The prenatal evaluation of the genitourinary system includes assessment of the amniotic fluid, the kidneys, the bladder, and associated anomalies.
- Fetal urine production begins by 12 weeks of gestation.
- The fetal kidney is considered echogenic if it is brighter than the fetal liver. Echogenic kidneys with oligohydramnios portend a poor prognosis.
- Visualization of a single renal cyst should prompt consideration of a cystic tumor, duplex collecting system with cystic dysplasia of the upper pole, urinoma, asymmetric presentation of ADPKD, or an isolated cyst in an otherwise normal kidney. Multiple cysts may be seen with multicystic dysplastic kidney, ADPKD, tuberous sclerosis complex, and TCF2 gene mutation–associated nephropathy.
- A solid, rounded echogenic mass in the fetal kidney is most likely to be a CMN.
- If at 32 weeks, the anterior-posterior renal pelvic diameter of the renal pelvis remains less than 7.0 mm, then parents can be counseled regarding the association with a good postnatal outcome.
- If an enlarged fetal bladder is associated with bilateral hydroureteronephrosis, a serious obstruction or functional emptying abnormality must be considered. These abnormalities include posterior urethral valves, prune-belly syndrome (Eagle-Barrett syndrome) and megacystis-microcolon-intestinal hypoperistalsis syndrome.
- Complex cases such as bladder exstrophy, confusing duplex collecting systems, and obstructive masses may be evaluated further by fetal MRI.
- Surgical intervention for bladder outlet obstruction and decreasing amniotic fluid volume or oligohydramnios is considered in the fetus with a good prognostic electrolyte panel (Na <100 mEq per liter, Cl <90 mEq per liter, and osmolarity <210 mEq per liter) and no evidence of renal dysplasia by ultrasound.
- Fetal surgical interventions to treat bladder outlet obstruction include a vesicoamniotic shunt, fetoscopic valve ablation, fetoscopic urethral stent placement, and open fetal surgery for vesicostomy.

## KIDNEY AND URETER

### Multicystic Dysplastic Kidney

***Overview, Etiology, and Clinical Presentation.*** A multicystic dysplastic kidney (MCDK) is the most common form of cystic renal dysplasia. With high-grade obstruction or atresia of the upper urinary tract (renal pelvis and/or ureter) during early renogenesis, disordered parenchymal development results in an MCDK.[1] Two types of MCDK exist: the pelvoinfundibular type (common) and the hydronephrotic type (uncommon).[2,3] MCDK can occur in half of a duplex kidney (usually the upper moiety) or in renal fusion anomalies, such as a horseshoe kidney and crossed fused renal ectopia. MCDK is sporadic in most cases, although familial cases have been described.[1,4] Vesicoureteral reflux (VUR) (both ipsilateral [into an atretic ureter] and contralateral) and contralateral ureteropelvic junction (UPJ) obstruction are associated with this anomaly, and Müllerian anomalies may coexist in girls.[1,5,6] Long-term sequelae (e.g., infection and hypertension) are rare, because most affected kidneys either partially or completely involute on their own over time.[7–11]

***Imaging.*** On ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI), a classic MCDK is characterized by multiple cysts of various sizes (ranging from 1 mm to several cm) that do not communicate, with no identifiable normal renal parenchyma (Fig. 113.1). The size of the affected kidney may be small, normal, or enlarged.[1] Compensatory hypertrophy of the contralateral kidney often is present.[12] The hydronephrotic form has cysts that communicate, mimicking pelvicaliectasis, but no normal functioning renal tissue.[2] The diagnosis of both pelvoinfundibular and hydronephrotic MCDK can be confirmed by diuretic renal scintigraphy (e-Fig. 113.2) or magnetic resonance urography (MRU) (e-Fig. 113.3). A voiding cystourethrogram (VCUG) may reveal VUR into a blind-ending ureter on the side of the MCDK.[13,14]

***Treatment.*** Follow-up ultrasound typically demonstrates involution of the cysts over time, eventually resulting in remnant dysplastic renal tissue that may be difficult to visualize (e-Fig. 113.4).[15,16] Resection of an MCDK is rarely indicated[17] and is usually reserved for cases in which there is increasing kidney size rather than involution. In the past, routine nephrectomies were performed due to a fear of malignant degeneration. Current evidence discounts this possibility, and, if no other complication exists, surgery is not indicated and limited radiologic follow-up may be appropriate.[11]

### Autosomal Dominant Polycystic Kidney Disease

***Overview and Etiology.*** Autosomal dominant polycystic kidney disease (ADPKD), the most common form of inherited renal cystic disease, is now recognized to be a ciliopathy (disorder of the primary cilia) and is seen in about 1 in 800 live births.[18–20] Two types of ADPKD exist, each with clearly defined chromosomal mutations. The more severe form (PKD1) accounts for about 85% to 90% of cases, whereas the milder phenotype (PKD2) presents later in life, results in less morbidity, and is less common.[18,21] Cysts arise from both the renal cortex and the medulla.[18,22]

***Clinical Presentation.*** Systemic hypertension, hematuria, and slowly progressive chronic kidney disease are the typical clinical manifestations.[1,23] ADPKD is very rarely detected prenatally because fewer than 5% of nephrons are cystic before birth.[1] Diagnosis of ADPKD early in life portends a poor prognosis; 43% of affected persons die in the first year of life, hypertension develops in 67%, and some affected children progress rapidly to end-stage renal disease.[23] Because in some instances it can be difficult to delineate between autosomal recessive and autosomal dominant forms of polycystic kidney disease, screening of siblings and parents may be helpful. ADPKD can coexist with tuberous sclerosis as a "contiguous gene syndrome," and the recognition of this specific syndromic form has implications for management.[24]

***Imaging.*** The diagnosis of ADPKD usually is made on the basis of ultrasound (Fig. 113.5), although CT or MRI also can suggest it. While the kidneys may be normal during the first decade of life, they also may contain one or more simple cysts (Fig. 113.6).[18,25] The kidneys may be abnormally enlarged and echogenic, mimicking autosomal recessive polycystic kidney disease (ARPKD) in early life[18,26] Although it is typically a bilateral process, imaging findings may be asymmetric, and in young children they can manifest as a unilateral abnormality.[18,25,27] Microscopic cysts, as well as larger cysts that can be detected by cross-sectional imaging techniques, can involve the liver and less frequently other organs.[22,28] Nephrolithiasis may be seen at ultrasound or CT.[29] The remainder of the urinary tract is usually normal.

***Treatment.*** Although renal function is generally maintained during childhood, ADPKD is responsible for the need for chronic dialysis in 10% to 12% of adult dialysis patients.[1] Hypertension should be managed medically to prevent long-term complications. While 12% to 15% of patients with ADPKD have an intracranial aneurysm,[22,27,30,31] screening magnetic resonance (MR) angiography usually is not performed in childhood because aneurysm rupture is rare in this period.

### Autosomal Recessive Polycystic Kidney Disease

***Overview and Etiology.*** ARPKD is a rare disorder that is seen in about 1 : 20,000 live births and that is also recognized to be a ciliopathy.[32,33] Genetic studies have localized the inheritance of ARPKD to chromosome 6p.[33,34] The *PKHD1* gene is expressed in fetal and adult kidneys and livers, the two major sites affected by the disease.[34] Approximately 1 in 70 persons is a carrier for this condition.[32,33] Histologically, the kidneys have a spongelike appearance, replaced by myriad mostly minute 1- to 2-mm cysts of relatively uniform size, representing dilated and elongated collecting ducts.[1,33] These cysts radiate from the hilum toward the surface of the kidney without a clear demarcation between the medulla and cortex; fibrosis is present in the renal interstitium.

***Clinical Presentation.*** ARPKD has been subdivided into categories based on clinical presentation. The perinatal and neonatal forms, which have the poorest prognosis, are associated with severe renal dysfunction, and affected patients may die of the disease early in life.[33,35] While the degrees of renal and hepatic abnormalities

## Abstract:

There are numerous congenital anomalies and developmental conditions that can affect the kidneys, ureters, and urinary bladder. These abnormalities are frequently detected *in utero* or during the neonatal period. Some of these conditions are quite common (e.g., multicystic dysplastic kidney, ureteropelvic junction obstruction, upper urinary tract duplication), while other conditions are quite rare (e.g., congenital megacalyces, megacystis-microcolon-intestinal hypoperistalsis-malrotation syndrome, cloacal exstrophy). In this chapter, we will review the etiology, clinical presentation, and imaging features of several common and less common genitourinary congenital and neonatal abnormalities.

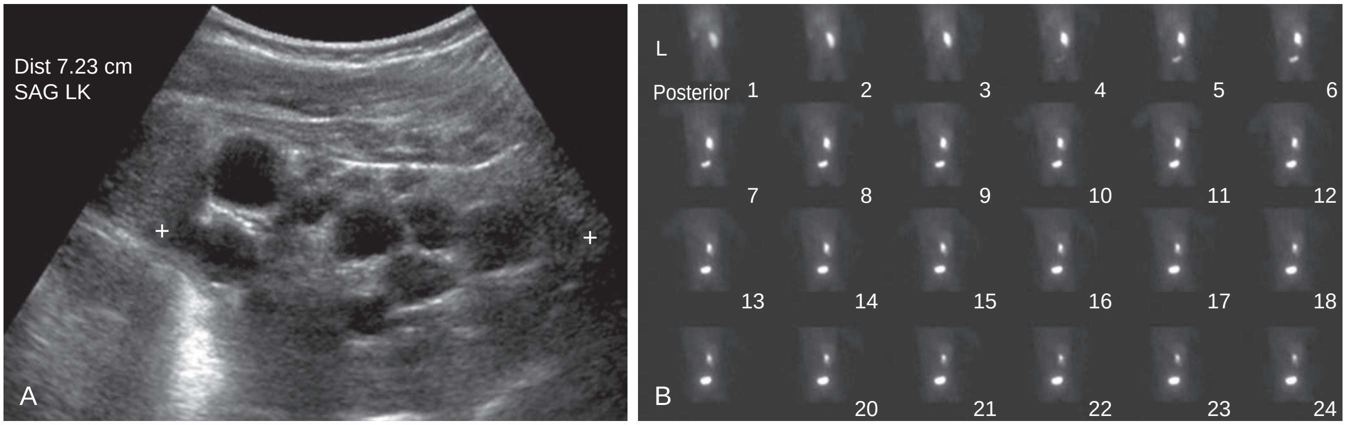
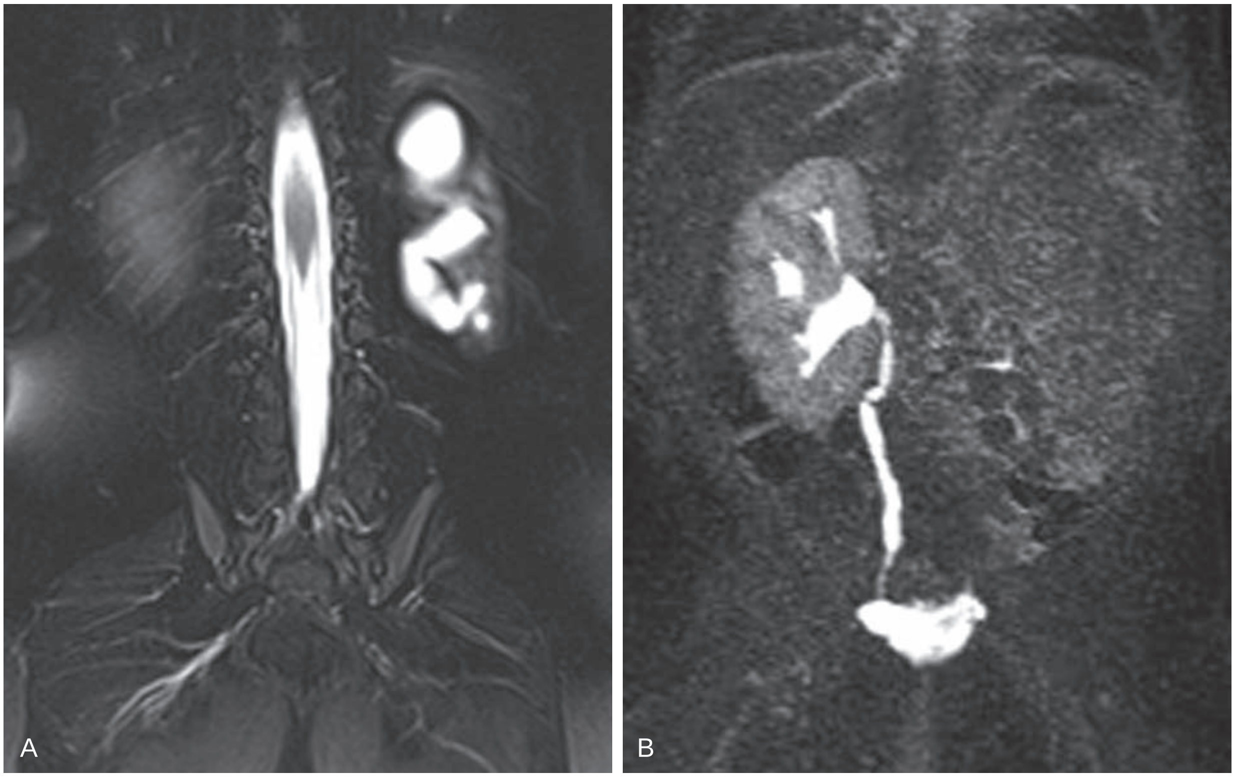
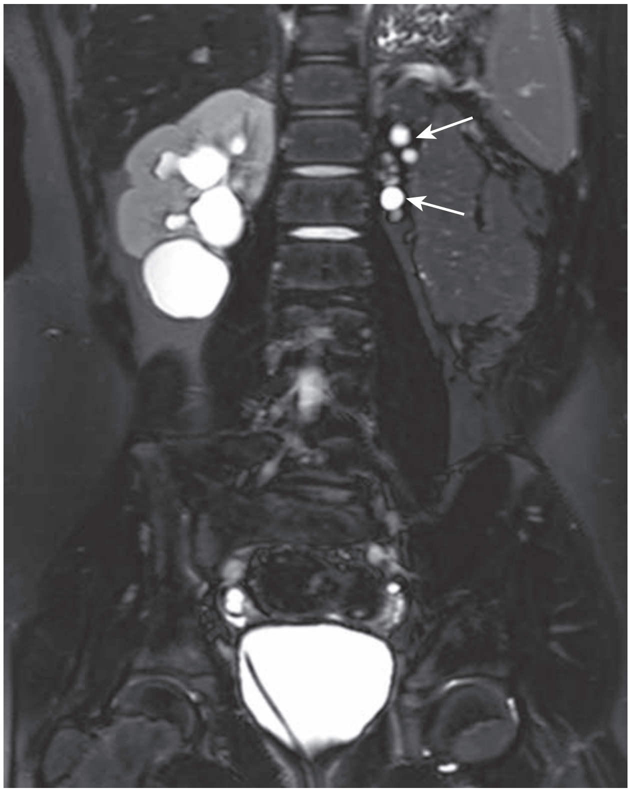
Urinary Bladder



**e-Figure 113.2. A multicystic dysplastic kidney in a 6-month-old boy.** (A) Longitudinal ultrasound image of the left kidney shows multiple noncommunicating cysts of variable size. Visualized renal parenchyma is abnormally echogenic. (B) Posterior diuretic renal scintigraphy images show no appreciable left kidney function with no uptake or excretion of radiotracer. Right kidney function is normal.



**e-Figure 113.3. Multicystic dysplastic kidney and MRI, hydronephrotic form.** (A) A coronal T2-weighted MR image with fat saturation shows a fluid signal within the left kidney that has a configuration similar to that of the renal collecting system. Only a small amount of left kidney parenchyma is present. (B) A coronal T1-weighted maximum intensity projection (MIP) MR image obtained 15 minutes after contrast material injection confirms the absence of the left kidney function. The right kidney is normal.



**e-Figure 113.4. Involuting multicystic dysplastic kidney.** A coronal T2-weighted MR image with fat saturation from a 14-year-old girl shows multiple small hyperintense cysts in the left renal fossa *(arrows)*, consistent with an involuting multicystic dysplastic kidney. This kidney was no longer visible by ultrasound. The right kidney is duplex in structure, with severe lower moiety parenchymal thinning due to ureteropelvic junction obstruction as well as multiple areas of upper moiety scarring.

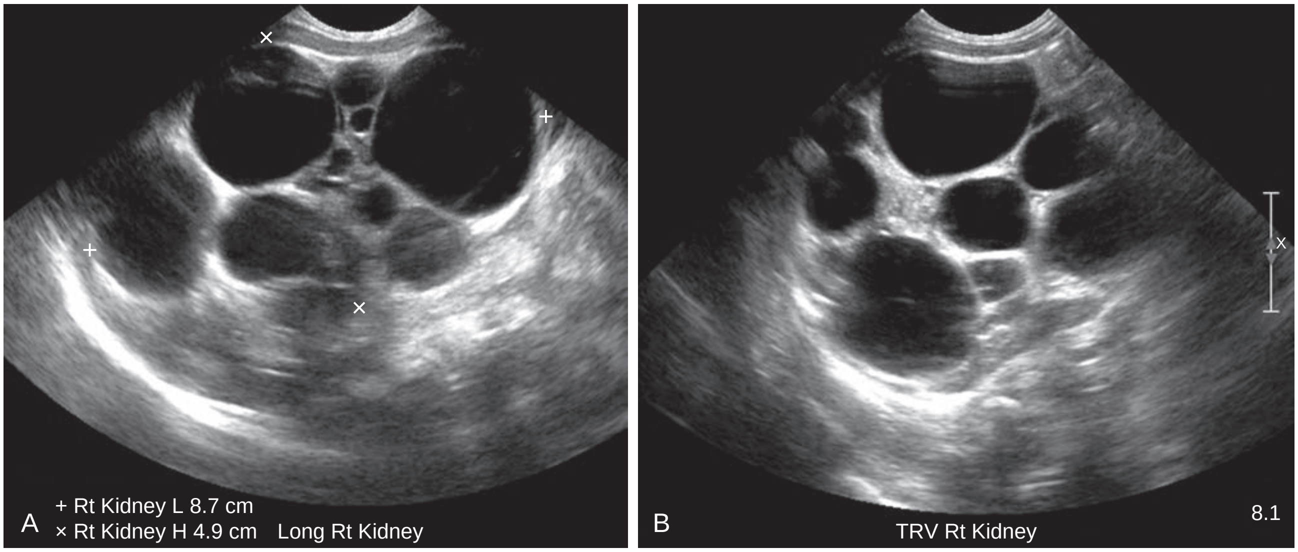


**Figure 113.1. Multicystic dysplastic kidney in a 1-day-old boy.** (A) Longitudinal ultrasound image of an enlarged left kidney shows multiple noncommunicating simple cysts of variable size, mimicking hydronephrosis. The very small amount of remaining renal parenchyma is abnormally echogenic. (B) A transverse ultrasound image shows similar findings.

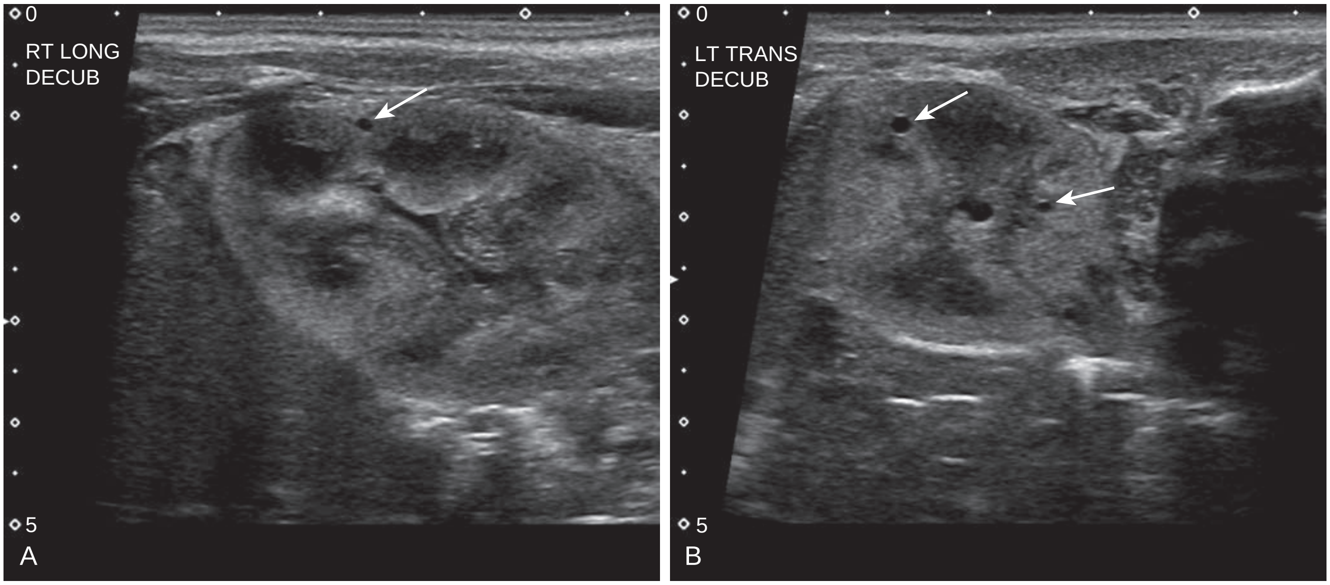

**Figure 113.5. Autosomal dominant polycystic kidney disease in a newborn.** (A) Longitudinal right kidney and (B) transverse left kidney ultrasound images show small bilateral simple renal cysts *(arrows)*. The renal cortex appears echogenic as well. There was a documented history of maternal and maternal grandfather autosomal dominant polycystic kidney disease.

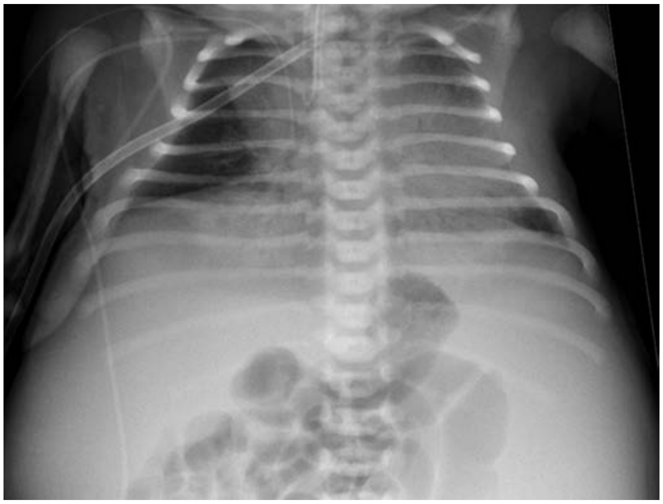
historically have been considered to be inversely proportional,[19,33] a recent study suggests that the severity of renal and liver involvement are independent.[36] Liver involvement may be the cause of clinical presentation in a minority of affected children due to ductal plate malformations (e.g., congenital hepatic fibrosis and intrahepatic bile duct ectasia, or Caroli syndrome) and associated complications, such as portal hypertension and cholangitis.[33,36]

***Imaging.*** Abdominal radiography in the neonatal period commonly reveals bilateral abdominal or flank masses with centralized gas-filled bowel loops. The lungs may appear small because of a combination of pulmonary hypoplasia and mass effect from marked nephromegaly (e-Fig. 113.7).[33] On ultrasound, affected neonatal kidneys tend to be smoothly enlarged (frequently more than four standard deviations above the mean expected length for age), are hyperechoic as a result of the multiple acoustic interfaces at the walls of the dilated ducts, and have poor corticomedullary differentiation (Fig. 113.8).[1,33,35,37] On occasion, discrete cysts (solitary or multiple) of variable size (most commonly <1 cm) may be seen (Fig. 113.9).[32,37] A sonolucent rim may be seen at the periphery of the kidney as a result of cortical compression and relative sparing.[32,33] Contrast-enhanced CT (Fig. 113.10), while rarely performed, can show delayed opacification of the renal parenchyma with a prolonged and striated nephrogram. When studied with MRI, the dilated tubules in affected kidneys can appear linear and



**e-Figure 113.7. Autosomal recessive polycystic kidney disease in a newborn boy.** Anteroposterior chest radiograph shows small lungs due to pulmonary hypoplasia. Bulging of the flanks and centralization of bowel gas is due to bilateral nephromegaly.

hyperintense on T2-weighted imaging, radiating from the medulla toward the cortex giving rise to a "spoke wheel" appearance (Fig. 113.11).[38] Ultrasound and MRI are most often used to evaluate for liver involvement, typically showing altered liver echogenicity and signal intensity due to congenital hepatic fibrosis, dilated intrahepatic bile ducts (sometimes appearing cystic and showing the central dot sign), and splenomegaly (e-Fig. 113.12).

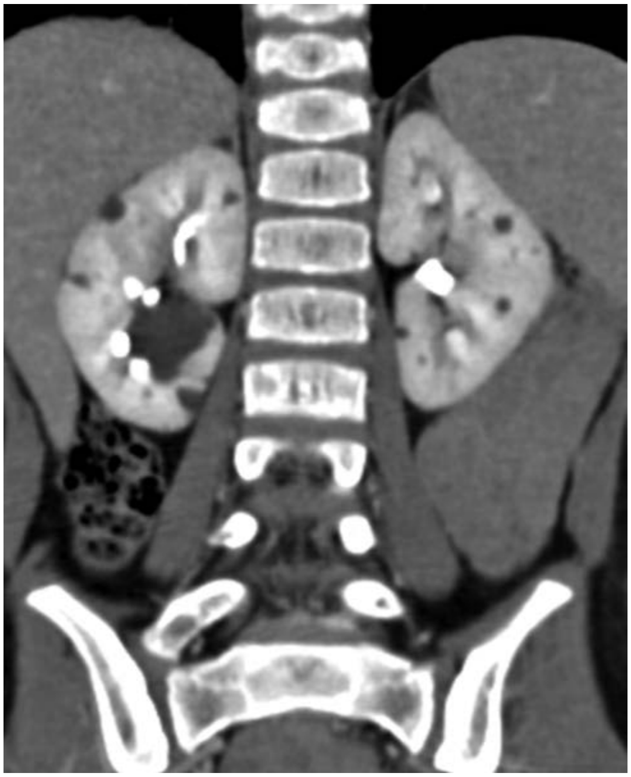


**Figure 113.6. Autosomal dominant polycystic kidney disease in an 8-year-old girl.** Coronal reformatted contrast-enhanced CT image shows multiple low attenuation lesions in both kidneys due to the presence of cysts.

***Treatment.*** Eighty-six percent of patients who survive beyond 1 month of age are alive at 1 year, and 67% are alive at 15 years.[39] Bilateral nephrectomy and renal replacement therapy may be required in neonates or infants when renal enlargement is massive and causes symptomatic mass effect or pulmonary compromise.[40] In infants who have initially adequate (although not normal) renal function, the disease may not be detected until later in the first decade. Systemic renovascular hypertension may occur and require medical management.[19,33] Many patients with ARPKD eventually will require renal replacement therapy, either dialysis or renal transplantation; combined liver-kidney transplantation may be performed in some children.[41]

## Other Renal Cystic Diseases in Children

Other uncommon genetic disorders (syndromes) are associated with renal cysts (Box 113.1). Recent studies suggest that several of these conditions are also due to genetic mutations that affect primary cilia or centromere function (sometimes referred to as *nephronopthisis*), with a variety of genes implicated.[20,28] Depending

**BOX 113.1** Other Causes of Renal Cystic Disease

- Tuberous sclerosis
- von Hippel-Lindau disease
- Trisomies 13 and 18
- Medullary cystic kidney disease
- Other ciliary disorders/nephronophthisis
  Asphyxiating thoracic dystrophy (Jeune syndrome)
  Bardet-Biedl syndrome
  Meckel-Gruber syndrome
  Joubert syndrome
  Oral-facial-digital syndrome type 1
  Short rib polydactyly
  Zellweger syndrome (cerebrohepatorenal syndrome)

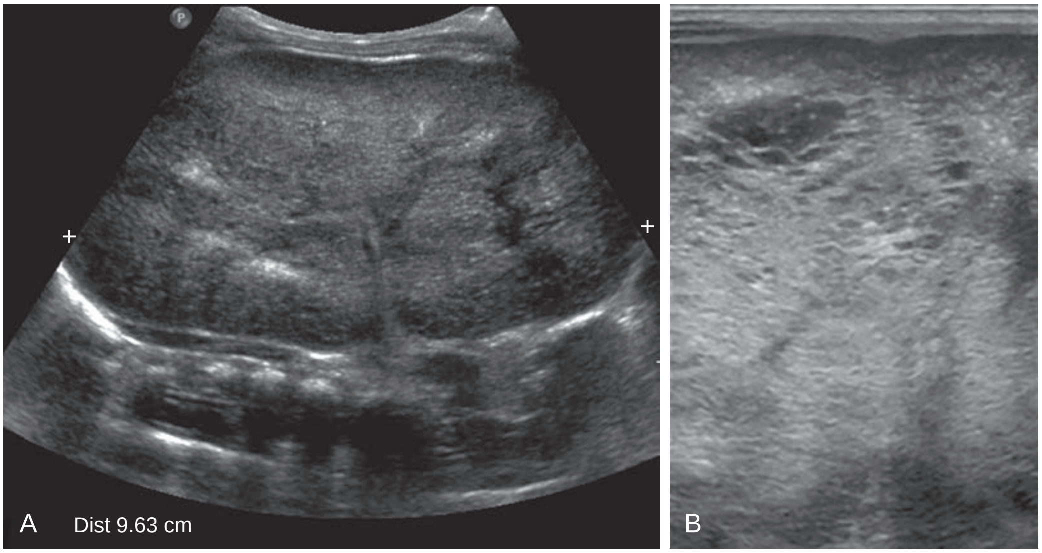

**Figure 113.8. Autosomal recessive polycystic kidney disease in a newborn girl.** (A) Longitudinal ultrasound image of the left kidney confirms the presence of a nephromegaly with loss of corticomedullary differentiation. The kidney is centrally echogenic and peripherally hypoechoic. (B) Linear high-frequency transducer ultrasound evaluation from a different newborn with autosomal recessive polycystic kidney disease reveals numerous tiny cystic structures within the kidney due to dilated ducts and tubules. The peripheral cortex is relatively hypoechoic.

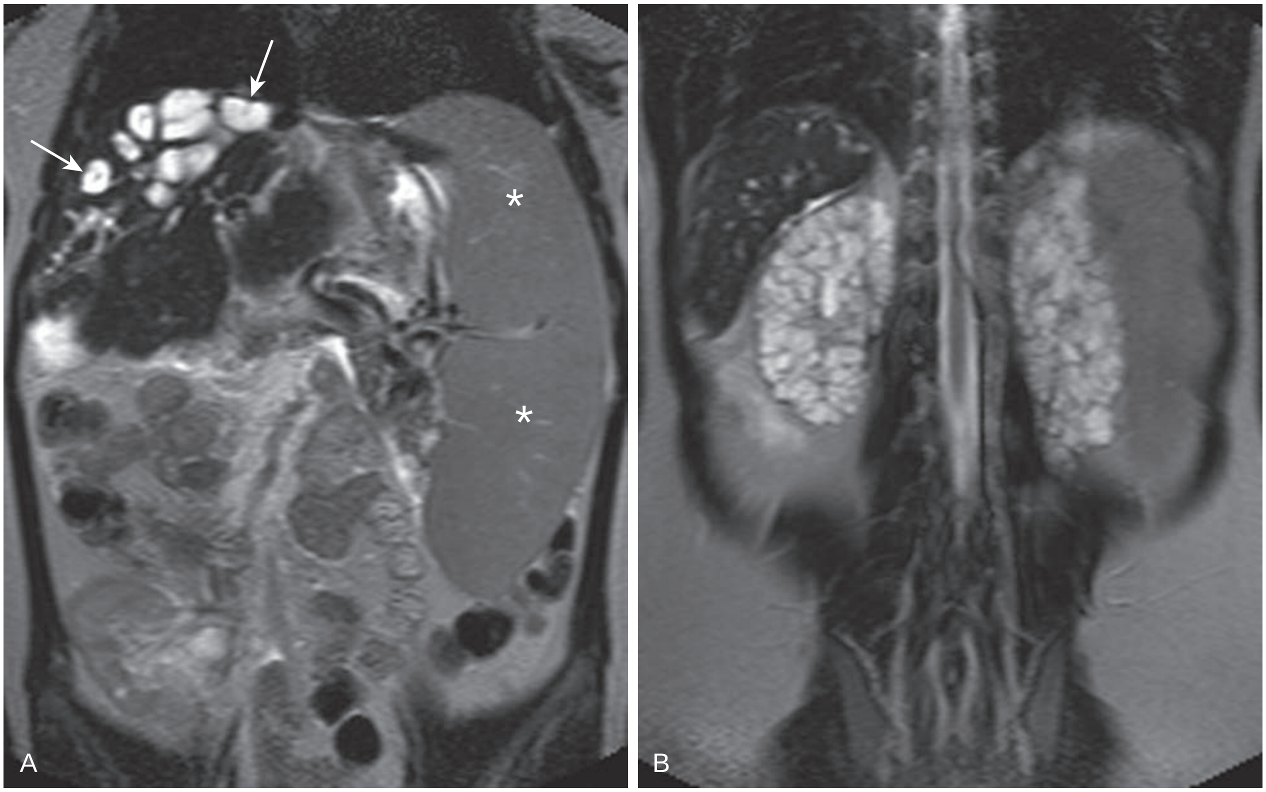

**e-Figure 113.12. Autosomal recessive polycystic kidney disease with severe liver involvement.** A coronal T2-weighted magnetic resonance (MR) image from a 14-year-old boy shows (A) shrunken appearance of the liver, multiple dilated intrahepatic bile ducts *(arrows)*, and splenomegaly *(asterisks)*. Findings suggest congenital hepatic fibrosis, Caroli syndrome, and portal hypertension. (B) More posterior image shows complete replacement of both kidneys by many small cysts.

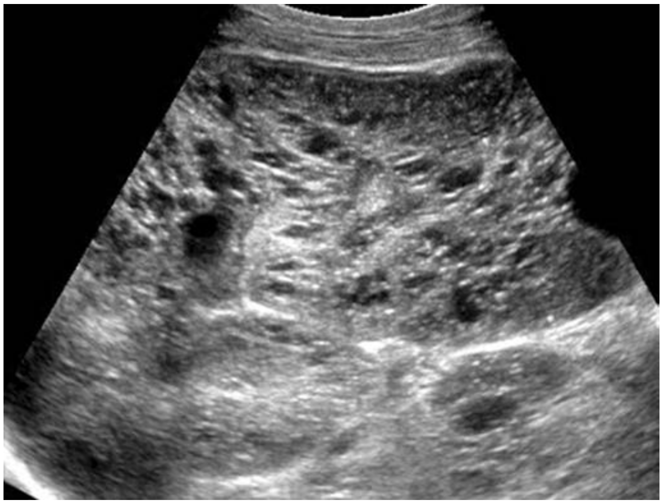

**Figure 113.9. Autosomal recessive polycystic kidney disease in a 6-month-old boy presenting with acute renal failure and bilateral flank masses.** Longitudinal ultrasound image of the right kidney shows nephromegaly, loss of normal corticomedullary differentiation, and many tiny cystic structures replacing the renal parenchyma.

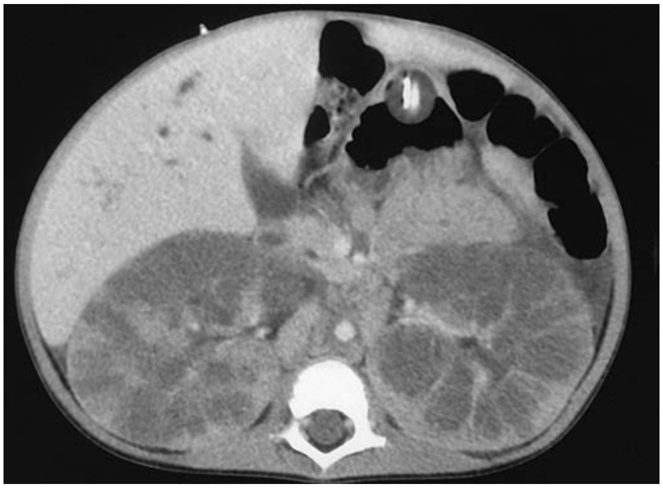

**Figure 113.10. Autosomal recessive polycystic kidney disease and CT.** A CT image shows that the pathologic process is primarily medullary. The dilated tubules have produced a linear pattern that can be seen clearly in a few regions. Areas of cortex appear spared.

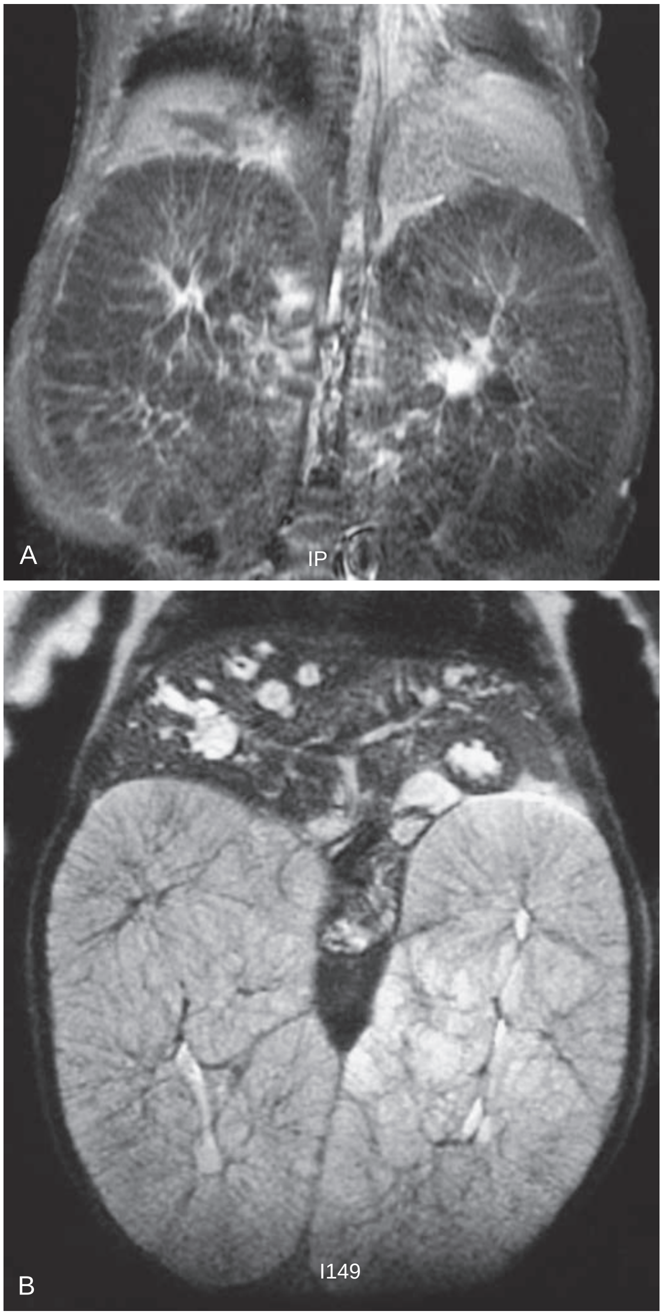

**Figure 113.11. Autosomal recessive polycystic kidney disease and MRI.** (A) T1-weighted and (B) T2-weighted MR images from an infant show that the kidneys are enormously enlarged and have a "spoke wheel" appearance. The patient also has intrahepatic biliary ectasia (Caroli syndrome), appearing as liver cysts on the T2-weighted image.

on the specific mutation, clinical presentation, associated anomalies, and age of presentation with regard to renal disease may vary.

## Calyceal Diverticulum

***Overview, Etiology, and Clinical Presentation.*** A calyceal diverticulum represents a focal outpouching of the renal collecting system that is located within the renal parenchyma and that contains urine.[42] This condition has an incidence of 3.3 to 4.5 : 1000 in children, based on excretory urography.[43–45] Calyceal diverticula are likely developmental in origin; they are lined with urothelium and surrounded by muscularis mucosa.[42,44] Although these structures most commonly are an incidental finding, they can be associated with pain as well as infection and calculus formation as a result of urinary stasis.[42,44,46,47]

***Imaging.*** Abdominal radiographs may be normal or may demonstrate one or more calculi (or milk of calcium) within a calyceal diverticulum.[44] On ultrasound, such diverticula may mimic a solitary renal cyst, appearing round, thin-walled, and anechoic.[43] They can vary in size ranging from a few millimeters to several centimeters (with a mean size around 11 mm),[44,46] and they most commonly occur within the upper pole of the kidney.[42] Calyceal diverticula can rarely be bilateral and/or multiple.[48] Upon excretory phase imaging (including MRI and CT), calyceal diverticula may fill with contrast material (Fig. 113.13). A thin connection, or neck, to an adjacent calyceal fornix may or may not be identified.[44]

***Treatment.*** A symptomatic calyceal diverticulum may require endoscopic or laparoscopic ablation.[47] Although both lithotripsy

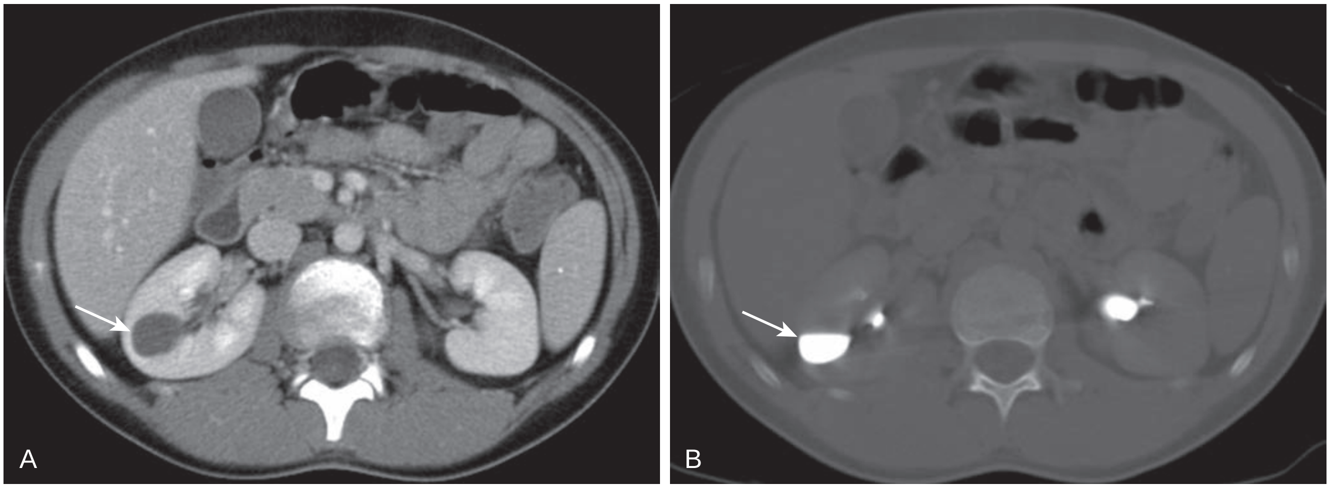

**Figure 113.13. Calyceal diverticulum in a 10-year-old girl.** (A) Axial contrast-enhanced CT image shows a low-attenuation cystic structure in the right kidney *(arrow)*. (B) An axial postcontrast excretory phase CT image shows excreted contrast material layering with this abnormality.

of calculi within the diverticulum and percutaneous ablation of the cavity have been described in adults,[46,49] such techniques have not been applied widely to children.

## Congenital Infundibulopelvic Stenosis

***Overview, Etiology, and Clinical Presentation.*** Congenital infundibulopelvic stenosis is a very rare congenital anomaly of the renal collecting system that presents as unilateral or bilateral caliectasis.[50] Although the exact etiology of this condition is uncertain, Lucaya et al[51] hypothesized that this abnormality is a milder manifestation of the process that results in MCDK. Affected children may be predisposed to urinary tract infections, and this condition may be associated with other renal and urinary tract anomalies.[50,51] Renal function may be normal to severely impaired.[50,51]

***Imaging.*** Upon contrast-enhanced excretory phase imaging studies (including excretory urography, MRU, and CT), this condition has a specific appearance: the renal collecting system infundibula are abnormally narrowed but not entirely obliterated, and the calyces appear abnormally rounded and dilated (Fig. 113.14). The renal pelvis also typically appears narrowed as a result of stenosis or hypoplasia. This condition may be unilateral or bilateral. Despite the cystlike appearance of the calyces on contrast-enhanced studies, the ultrasound appearance of the kidneys can be normal.

***Treatment.*** Most affected individuals demonstrate normal or stable impaired renal function and do not require treatment. Surgical approaches to manage this condition have been described, including multiple infundibuloplasties, ureterocalicostomy, and renal transplantation.[51] MRU with three-dimensional volumetric rendering can provide detailed anatomic depiction of the pelvocalyceal system and aid surgical planning.[50]

## Congenital Megacalyces (Megacalycosis)

***Overview, Etiology, and Clinical Presentation.*** Congenital megacalyces is a very rare anomaly of the renal collecting system that may be confused for obstructive hydronephrosis.[52] Calyceal involvement may be unilateral or bilateral. This abnormal calyceal dilatation is likely a result of underdevelopment/hypoplasia of the renal medullary pyramids.[53,54] Boys are more commonly affected than girls. Associated urinary stasis may predispose affected children to urinary tract infection and urolithiasis.[53]

***Imaging.*** Congenital megacalyces may appear similar to obstructive caliectasis by ultrasound. With excretory urography and MRU, however, this condition may be more readily identifiable because of the presence of abnormally dilated calyces that lack normal papillary impressions, have a polygonal or faceted shape, and appear to be increased in number (20 or more) (Fig. 113.15).[54] The renal parenchyma overlying affected calyces may appear thin. The renal pelvis can be normal in caliber or mildly dilated,[53] and classically, no related urinary tract obstruction should be present.

***Treatment.*** Congenital megacalyces usually is an incidental finding that requires no specific treatment.

## Ureteropelvic Junction Obstruction

***Overview.*** UPJ obstruction is the most common type of congenital urinary tract obstruction, occurring in about 3 per 1000 live births. Boys are more frequently affected than are girls, and the left kidney is more commonly involved than the right kidney. About 30% of cases are bilateral, although severity of obstruction and pelvicaliectasis may be asymmetric.[1]

***Pathophysiology.*** In the majority of cases, an intrinsic narrowing (e.g., smooth muscle deficiency, fibrosis/stricture, valve, kinking, or altered peristalsis) occurs at the level of the UPJ, leading to dilatation of the pelvicalyceal system.[1,55] Secondary intrinsic obstruction of the UPJ also can be caused by fibroepithelial polyps. On occasion, extrinsic narrowing can be seen from a crossing renal vessel, particularly in older children and adults.[56,57] UPJ obstruction can be found in association with other urinary tract anomalies, such as contralateral MCDK, upper urinary tract duplication,[58,59] VUR,[60] and ureterovesical junction obstruction.[61]

***Clinical Presentation.*** When UPJ obstruction is not detected prenatally, affected children can present with a palpable abdominal mass in the neonatal period. Older children may present with intermittent hydronephrosis and flank pain, often associated with crossing vessels. UPJ obstruction can be complicated by calculi, infection, forniceal rupture and urinoma, and posttraumatic hematuria, especially when diagnosis is delayed.[35]

***Imaging.*** On ultrasound, abnormal dilatation of the pelvicalyceal system of varying degrees is seen, whereas the ureter is generally normal in caliber.[1,35] Ultrasound findings suggestive of renal dysplasia may be present in cases of severe obstruction. Debris within the collecting system can represent infection or hemorrhage (Fig. 113.16). Careful interrogation of the UPJ region with Doppler

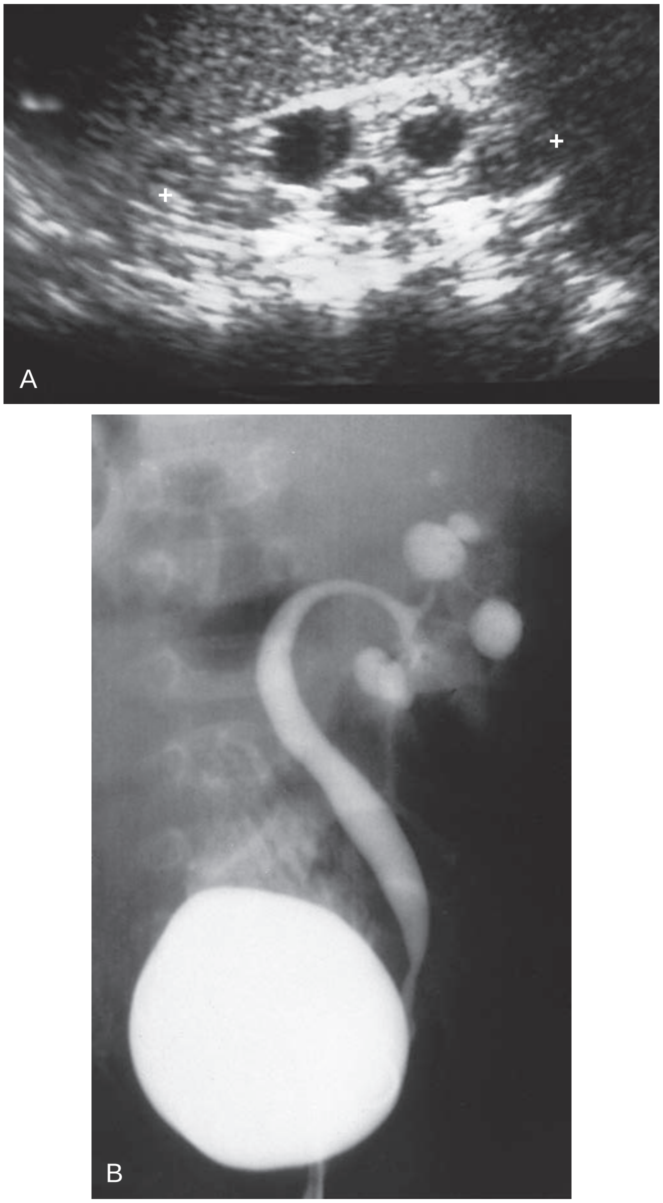

**Figure 113.14. Infundibulopelvic stenosis simulating cystic kidney disease.** (A) Longitudinal ultrasound image shows multiple “cysts” scattered throughout the kidney in this child with VACTERL association. (B) A voiding cystourethrogram shows vesicoureteral reflux into the abnormal pelvocalyceal system. The ureter has a greater caliber than the renal pelvis, infundibula, and calyces. The most peripheral portion of each calyx is rounded, producing the cystic spaces seen with ultrasound.

ultrasound may identify a crossing vessel, when present.[62] Frequently, separating dilated nonobstructed from dilated obstructed renal collecting systems is difficult by ultrasound alone.

Abdominal radiographs may show soft tissue fullness, bulging of the flank, and displacement of bowel loops from the affected side (e-Fig. 113.17). While not typically performed for pediatric UPJ obstructions, contrast-enhanced excretory phase CT commonly demonstrates delayed enhancement and excretion of contrast material.[55] CT angiography with multiplanar reformatted and three-dimensional images as well as MRU may be used to depict suspected crossing vessels as a cause of UPJ obstruction in older children and adults (Fig. 113.18).[57,63,64]

Diuretic renal scintigraphy is most often used to evaluate renal function (including perfusion and differential function) and drainage in the setting of suspected or known UPJ obstruction (e-Fig. 113.19).[65,66] Functional MRU is an increasingly important tool in the evaluation of untreated and treated UPJ obstructions.[67] This imaging technique currently allows for the detailed assessment of urinary tract anatomy, while also providing information regarding differential renal function and the presence or absence of obstructive uropathy (Fig. 113.20).[67–69] Both retrograde and antegrade pyelography may be performed to establish the level of upper urinary tract obstruction, if clinically necessary.

***Treatment.*** Recent literature has emphasized the conservative management of neonates with pelvocalyceal dilatation and suspected UPJ obstruction, especially with preserved renal function shown by biochemical parameters and imaging.[1,70–72] A substantial number of cases that are identified prenatally with pelvocalyceal dilation resolve spontaneously without requiring surgery.[70–72] Indications for surgery include reduced renal function, considerably delayed excretion of contrast material or radiotracer, sustained increase in pelvicalyceal dilation, breakthrough infections, a solitary kidney, and severe bilateral hydronephrosis.[72,73] Treatment, when necessary, usually is accomplished with a dismembered pyeloplasty (open, laparoscopic, or robotic).[1]

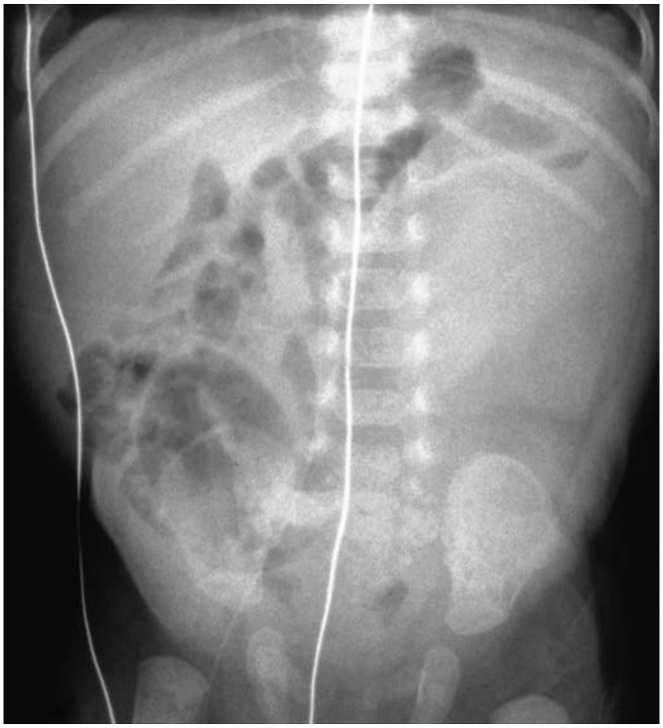
## Upper Urinary Tract Duplication

***Overview and Etiology.*** A duplex kidney consists of a single renal unit that is drained by two collecting systems. If two ureteric buds are present or the ureteric bud bifurcates before meeting the metanephric blastema, duplication of the renal collecting system and/or ureter occur.[74] Possibilities include a simple bifid renal pelvis, a bifid ureter (i.e., incomplete ureteral duplication), complete ureteral duplication, an ectopic ureter, and an ectopic ureterocele. Incomplete duplication of the upper urinary tract is more common than is complete duplication. Even when two ureters are present distally, they frequently enter the bladder via a common sheath.

In cases of complete ureteral duplication, one ureter takes up a near-normal position within the urinary bladder, and the other moves inferiorly with the mesonephric (wolffian) duct into an abnormal location (e.g., the bladder neck, urethra, vagina, or perineum in girls or the ejaculatory system in boys).[74] The Weigert-Meyer rule, which is applied only to complete duplications, states that the ureter that drains the upper moiety inserts inferior and medial to the lower moiety ureter (Fig. 113.21). In addition, the ectopic ureter is more likely to be obstructed, whereas the lower moiety ureter is more likely to reflux. Extravesical ureter insertion is far more common in girls than in boys. Extravesical ureter insertions in boys are above the sphincter mechanism; they can be below the sphincter mechanism in girls and present with urinary incontinence. On occasion, ectopic ureteroceles may be detected in the setting of a diminutive pelvicalyceal system, the so-called “ureterocele disproportion.”[74,75]

***Clinical Presentation.*** Clinically, incomplete duplication of the upper urinary tract may be asymptomatic or may present with urinary tract infections as a result of ureteroureteral reflux and stasis (so-called “yo-yo” reflux).[74] Children with complete duplication may present in a variety of manners, including hydronephrosis, urinary tract infection, and bladder outlet obstruction due to a large ureterocele.[74,76] Complete duplications in girls also may present with enuresis (both daytime and nocturnal wetness) as a result of insertion of the ectopic ureter into the urethra below the level of the sphincter mechanism or vagina.[74] In boys, complete duplications may complicated by infection (e.g., urinary tract or epididymitis) or pelvic pain.

***Imaging.*** Ultrasound may identify a prominent renal parenchymal column that appears to completely separate the sinus fat, providing indirect evidence of collecting system duplication (Fig. 113.22). More commonly, complete duplications present with



**e-Figure 113.17. Ureteropelvic junction obstruction.** Abdominal radiograph reveals mass effect in the central and left abdomen, displacing bowel to the right.

**e-Figure 113.19. Ureteropelvic junction obstruction in a 7-year-old with gross hematuria after a fall.** (A) Axial contrast-enhanced CT image demonstrates marked left pelvicaliectasis *(asterisks)* and renal parenchymal thinning *(arrows)*. The left ureter was normal in caliber. (B) Diuretic renal scintigraphy demonstrates decreased perfusion of the left kidney. The left kidney shows substantially delayed uptake and excretion of radiotracer despite intravenous furosemide administration, a pattern consistent with obstruction. *CTS,* Counts; *LT,* left; *RT,* right.

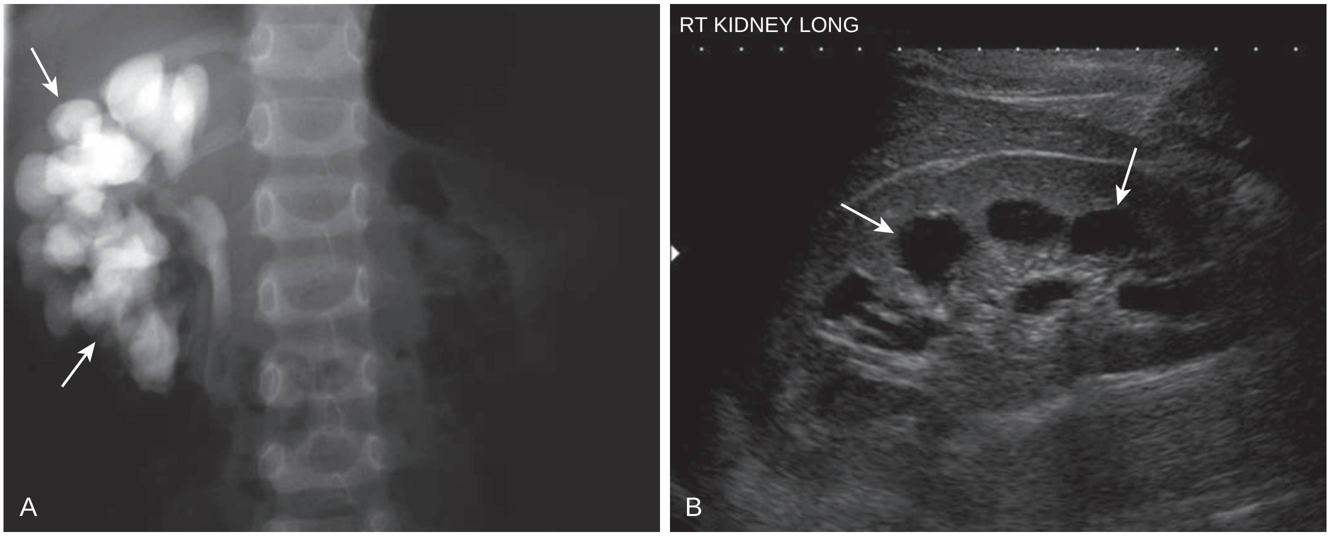

**Figure 113.15. Congenital megacalyces in a 5-year-old boy.** (A) An excretory urography image demonstrates contrast material filling an increased number of right kidney polygon-shaped calyces *(arrows)*, confirming the diagnosis of congenital megacalyces. The right renal pelvis is normal in diameter. (B) A longitudinal ultrasound image of the right kidney shows multiple dilated calyces that appear as cysts *(arrows)* with overlying parenchymal thinning.

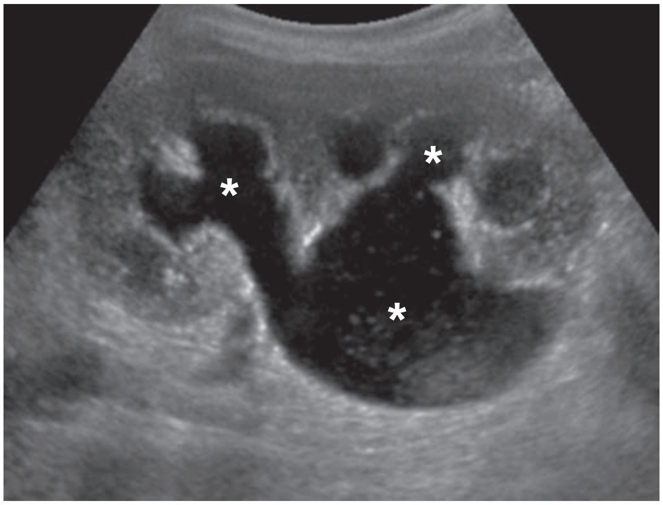

**Figure 113.16. Ureteropelvic junction obstruction in a newborn boy with a typical ultrasound appearance.** Longitudinal image of the left kidney shows moderate to severe dilatation of the pelvicalyceal system *(asterisks)*, with the renal pelvis being more dilated that the calyces. The proximal ureter could not be seen. Debris is present in the renal pelvis.

upper moiety hydronephrosis. Dilatation of the lower moiety can be due to VUR or, less often, concomitant UPJ obstruction (e-Fig. 113.23).[58,74] Ultrasound of the urinary bladder may show a thin-walled intraluminal cystic structure, consistent with a ureterocele (Fig. 113.24).[1] Ureteroceles vary in size and may appear septated or multiloculated, and when they are located in the midline, it may be difficult to establish the exact side from which they arise.[76]

In the early bladder filling phase of a VCUG examination, a smooth, round filling defect is consistent with a ureterocele (Fig. 113.25). Ureteroceles become more difficult to visualize as the urinary bladder distends with contrast material because of obscuration, flattening, or even eversion.[74,76] VUR into the lower moiety collecting system of a duplex kidney commonly reveals too few calyces and has a “drooping lily” appearance as a result of abnormal long-axis orientation (Fig. 113.26).[74] The normal long axis of the renal collecting system should parallel that of the ipsilateral psoas muscle. On occasion, VUR may be noted involving the upper moiety of a duplicated system (in about 11% of children), sometimes only after ureterocele incision.[74,77] VUR also can be used to separate incomplete from complete ureteral duplications (Fig. 113.27).

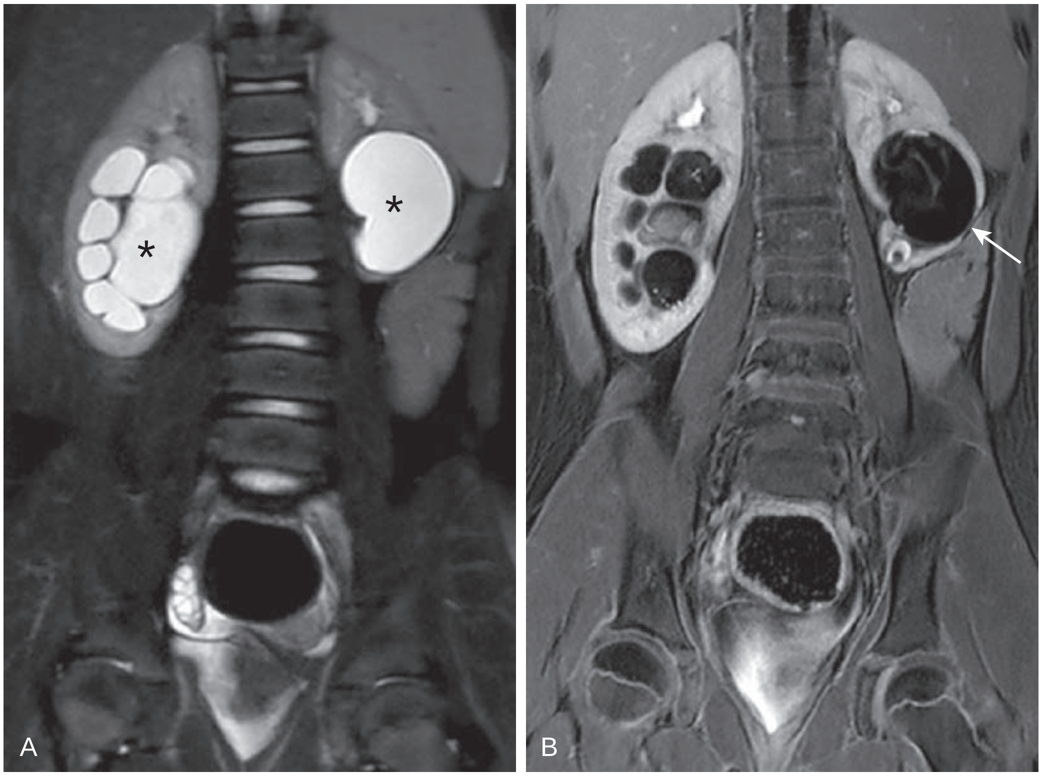
MRU provides a precise assessment of duplicated upper urinary tract anatomy (Figs. 113.28 and 113.29).[78] A variety of T2-weighted imaging techniques can be used to image urine-filled structures without exogenous contrast material. MRU also can evaluate renal function, detect evidence of obstructive uropathy and dysplasia, and confidently identify ectopic ureteric insertions (Fig. 113.29).[74,79]

***Treatment.*** Incomplete duplications of the upper urinary tract are frequently asymptomatic and require no specific treatment. Treatments for upper moiety obstruction include endoscopic puncture or excision of an obstructing ureterocele, ureteroureterostomy, and upper moiety heminephrectomy in the setting of poor or absent function.[74,80,81] Lower moiety dilatation due to VUR may require ureteral reimplantation, whereas dilatation due to UPJ obstruction may require pyeloplasty. Multicystic dysplastic upper moieties may involute over time without need for intervention.[82]

## URINARY BLADDER

### Prune-Belly Syndrome (Eagle-Barrett Syndrome)

***Overview, Etiology, and Clinical Presentation.*** Prune-belly syndrome, also known as *Eagle-Barrett* or *triad syndrome*, includes the constellation of bilateral cryptorchidism, anterior abdominal wall muscular deficiency, and a variety of urinary tract anomalies, including megacystis and hydroureteronephrosis.[83,84] The appearance of the abdominal wall on physical examination and radiographs has a characteristic appearance. Although the pathogenesis of prune-belly syndrome is controversial, two main theories have been suggested: (1) bladder outlet obstruction early in utero and (2) a primary mesodermal defect.[83–85] This condition is usually nonhereditary (although familial cases have been reported), usually affects boys (3%–5% of cases occur in girls), and is present in



**e-Figure 113.23. Bilateral upper urinary tract duplication with bilateral lower moiety ureteropelvic junction obstructions in an 8-year-old girl.** (A) Coronal T2-weighted fat-saturated MR image shows bilateral duplex kidneys with bilateral lower moiety pelvicaliectasis *(asterisks)*. (B) A coronal postcontrast excretory phase T1-weighted MR image shows delayed passage of contrast material into the bilateral lower moiety collecting systems due to ureteropelvic junction obstructions. There is severe left lower moiety parenchymal thinning *(arrow)*. There was timely excretion of contrast material into the bilateral upper moiety collecting systems.

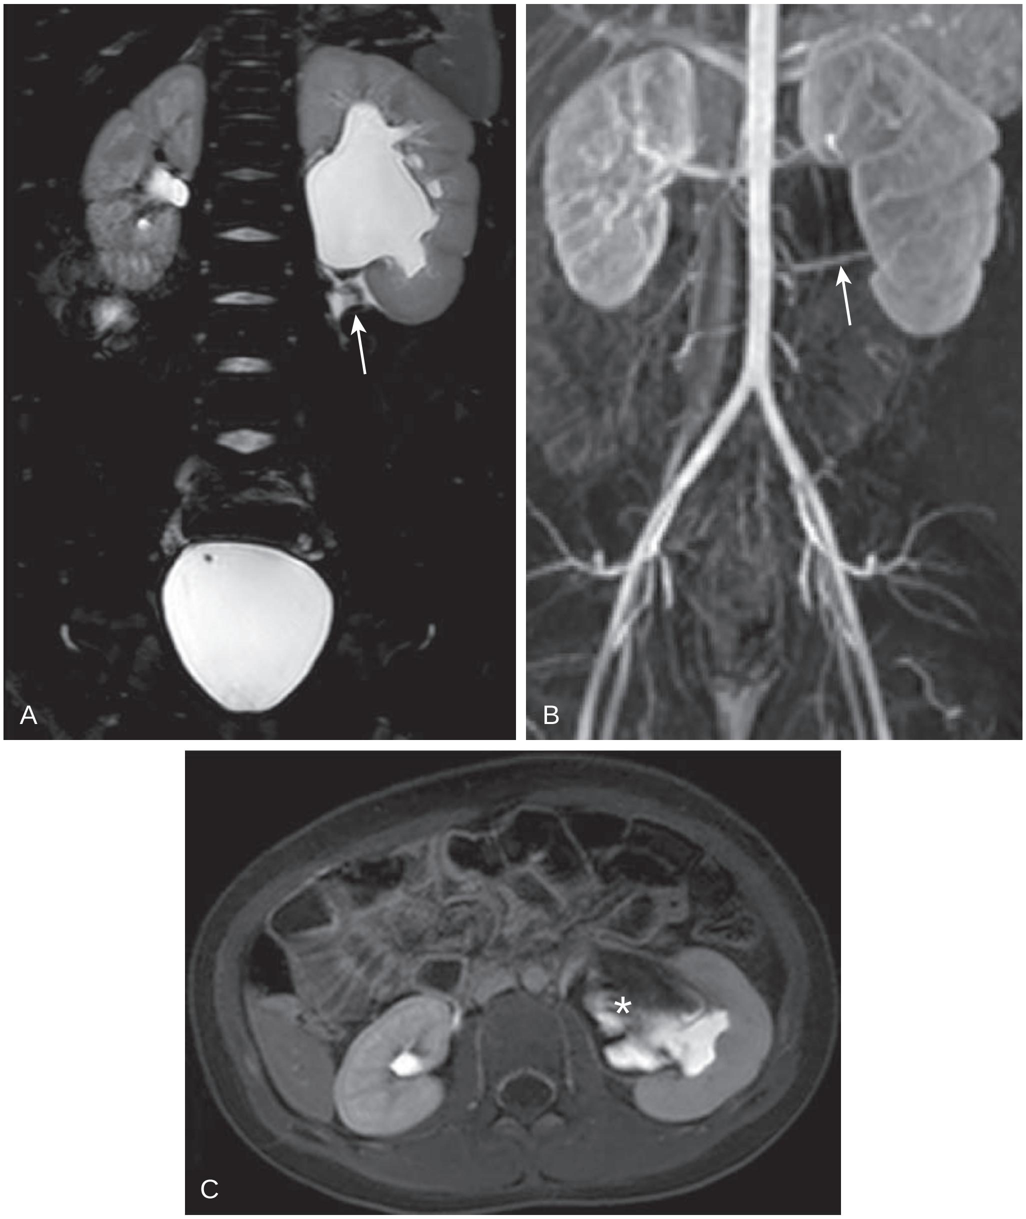


**Figure 113.18. Ureteropelvic junction obstruction due to surgically confirmed crossing vessel.** (A) Coronal T2-weighted fat-saturated magnetic resonance (MR) image shows left pelvicaliectasis; fluid *(arrow)* adjacent to the left renal collecting system is likely due to diuretic challenge and related forniceal rupture or transudation of urine. (B) Coronal postcontrast arterial phase T1-weighted maximum intensity projection (MIP) MR image shows slight hypoenhancement of the left kidney as well as an accessory left renal artery *(arrow)* crossing the left ureteropelvic junction region. (C) Axial postcontrast T1-weighted MR image shows delayed excretion of contrast material into the left renal collecting system *(asterisk)*.

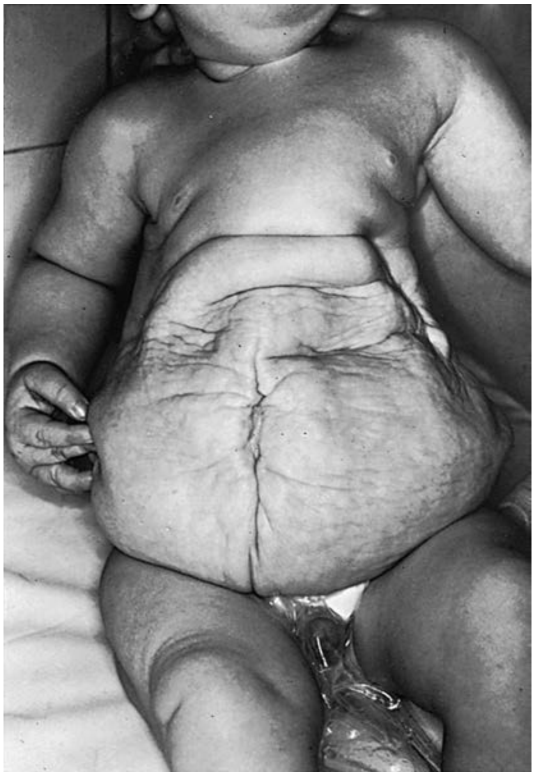
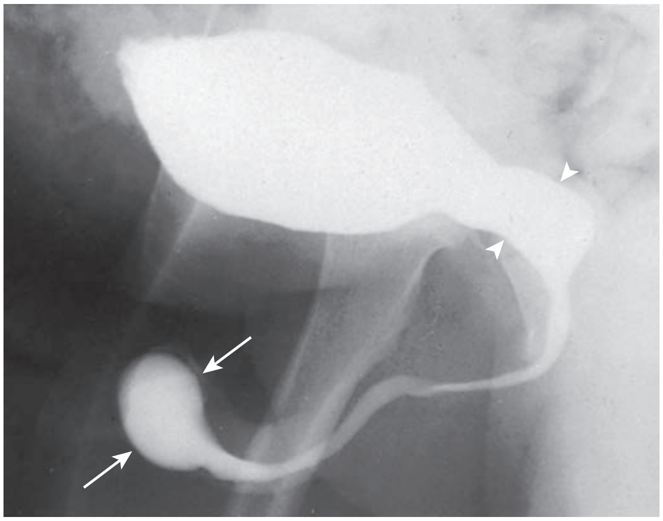
1:29,000 to 1:50,000 live births.[83,84] Associated anomalies of the cardiovascular, musculoskeletal, and gastrointestinal systems also may be present.[86]

***Imaging.*** On physical examination and radiographs, the abdominal wall of affected neonates has a characteristic wrinkled appearance with bulging of the flanks resulting from muscular deficiency (e-Fig. 113.30). VCUG allows depiction of the urinary bladder and urethral anatomy, identifies VUR, and determines whether a urachal anomaly is present. Markedly dilated, tortuous ureters are common because of a combination of muscular deficiency and VUR, which is present in approximately 75% of patients with prune-belly syndrome (Fig. 113.31).[84] Upper urinary tract obstruction typically is not present. The urinary bladder usually has a smooth wall and an increased capacity (megacystis) and may contain multiple diverticula. Urethral findings include dilatation and elongation of the prostatic urethra (e-Fig. 113.32), an enlarged utricle, megalourethra (see e-Fig. 113.32), and rarely urethral atresia.[83] A minority of patients with prune-belly syndrome have urethral obstruction due to an obstructing membrane or valve.[83] The primary role of ultrasound in the neonatal period is to establish the status of the kidneys. The kidneys commonly show findings compatible with renal dysplasia, including small size, abnormally



**e-Figure 113.30. Prune-belly syndrome in a newborn boy.** There is marked abdominal wall laxity. The testes were undescended, and flank masses representing huge ureters were easily palpated.



**e-Figure 113.32. Neonatal boy with prune-belly syndrome.** A voiding cystourethrogram image shows an elongated and dilated nonobstructed posterior urethra *(arrowheads)* as well as localized dilatation of the distal segment of the urethra *(arrows)*, consistent with a localized form of fusiform megalourethra.

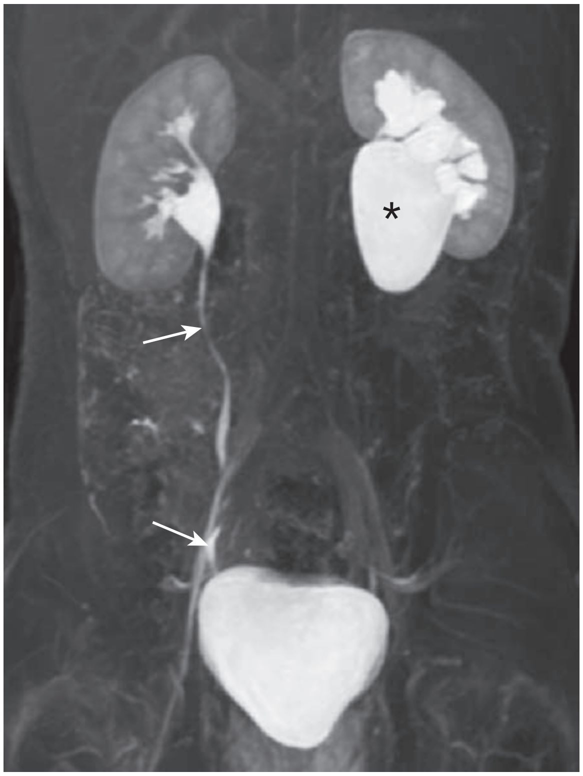


**Figure 113.20. Ureteropelvic junction obstruction in an 8-year-old girl.** Coronal postcontrast excretory phase T1-weighted maximum intensity projection (MIP) MR image shows dilated left renal collecting system *(asterisk)* and delayed passage of contrast material into the left ureter. The right upper urinary tract is normal in caliber, with contrast filling the right ureter *(arrows)*.

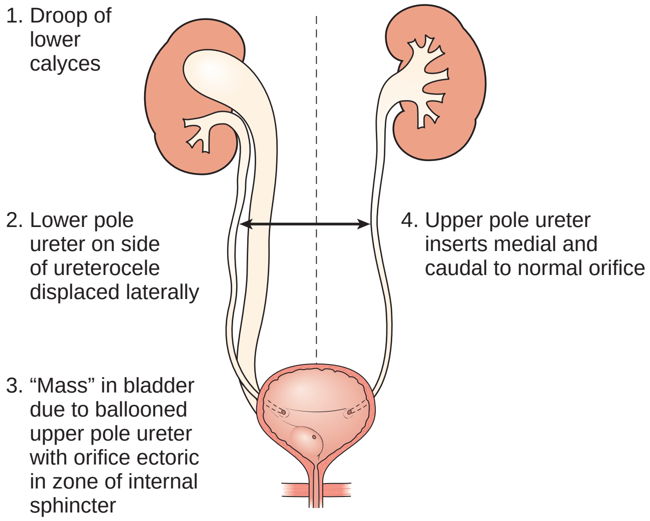

1. Droop of lower calyces
2. Lower pole ureter on side of ureterocele displaced laterally
3. "Mass" in bladder due to ballooned upper pole ureter with orifice ectoric in zone of internal sphincter
4. Upper pole ureter inserts medial and caudal to normal orifice

**Figure 113.21.** Diagram of the Weigert-Meyer rule. *(Redrawn from Berdon WE, Baker DH, Becker JA, et al. Ectopic ureterocele.* Radiol Clin North Am*. 1968;6:205–214.)*

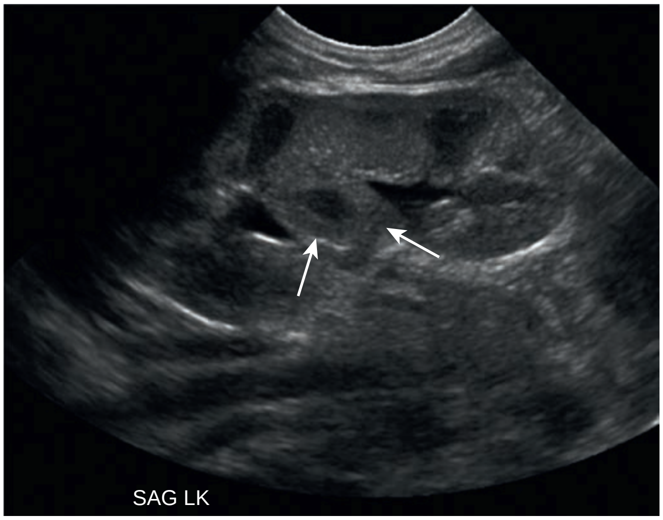

**Figure 113.22. Upper urinary tract duplication in a 1-month-old girl.** A longitudinal ultrasound image through the left kidney shows a prominent column *(arrows)* separating upper and lower moiety collecting systems.

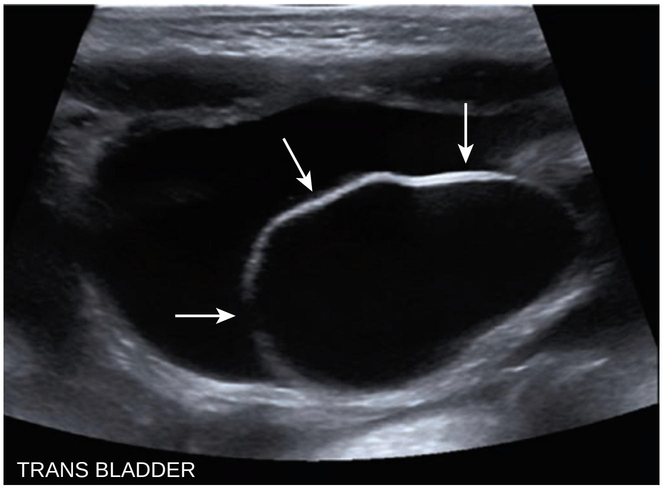

**Figure 113.24. Upper urinary tract duplication in a 6-week-old girl.** Transverse ultrasound image through the bladder confirms the presence of a large left ureterocele *(arrows)*.

increased parenchymal echogenicity, loss of corticomedullary differentiation, and cortical cysts.

***Treatment.*** Children with prune-belly syndrome may require multiple surgical procedures. The testes should be relocated from the abdomen to the scrotum (orchiopexy) to minimize the risk of future testicular torsion and neoplasm.[83] Any urethral obstruction should be surgically addressed. VUR and poor upper urinary tract drainage may be managed with chronic antibiotic prophylaxis or surgical reimplantation of the ureters to attempt to preserve renal function. Megacystis and poor urinary bladder emptying may be treated with reduction cystoplasty or vesicostomy.[87] In more severe cases, anterior abdominal wall surgical reconstruction (abdominoplasty) is performed and may improve urinary bladder emptying.[83,87] Because of renal dysplasia and chronic kidney disease, affected children eventually may require renal transplantation or dialysis therapy.[86]

## Megacystis-Microcolon-Intestinal Hypoperistalsis Syndrome

***Overview, Etiology, and Clinical Presentation.*** The name "megacystis-microcolon-intestinal hypoperistalsis syndrome" describes the pertinent clinical and radiologic findings.[88] Originally termed *Berdon syndrome*, features of this syndrome may overlap

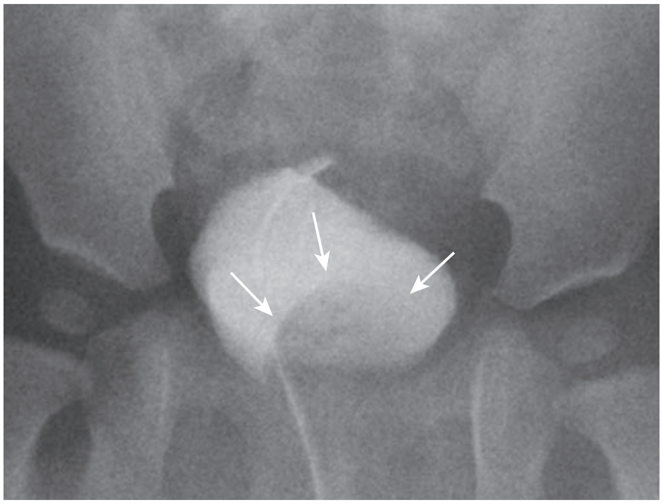

**Figure 113.25. Left upper urinary tract duplication in a 1-year-old girl.** Voiding cystourethrogram image demonstrates a large urinary bladder filling defect *(arrows)*, indicating a ureterocele. No vesicoureteral reflux was visualized.

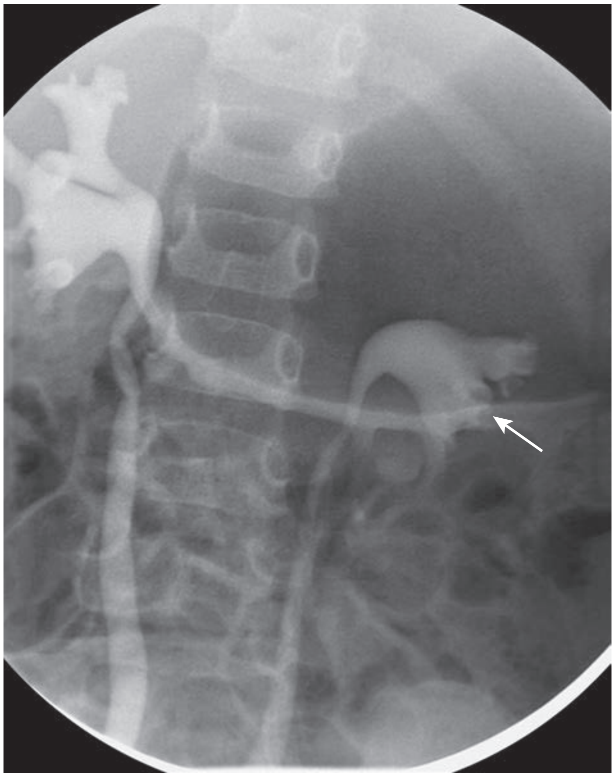

**Figure 113.26. Left upper urinary tract duplication in a 2-year-old girl.** Voiding cystourethrogram image shows bilateral vesicoureteral reflux. The left renal collecting system has too few calyces and its axis is abnormally oriented, giving rise to the "drooping lily" appearance *(arrow)*.

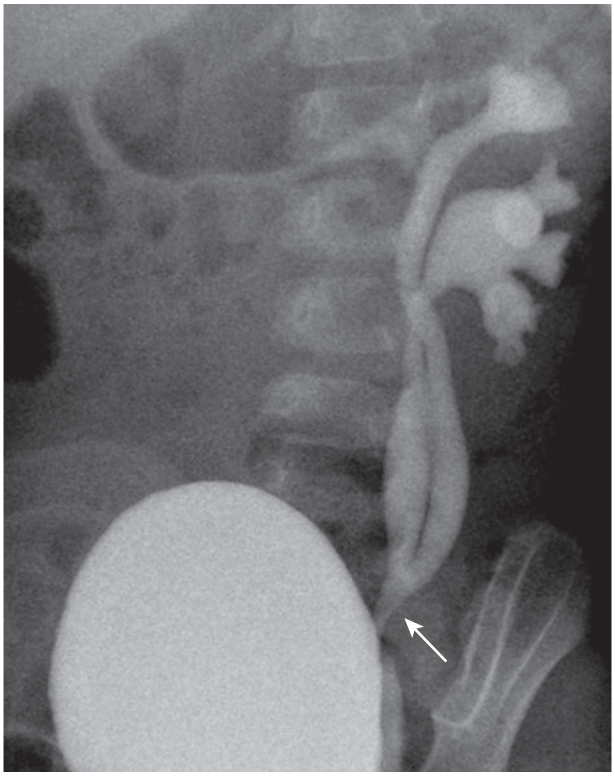

**Figure 113.27. Incomplete duplication of the left upper urinary tract in a 1-year-old girl.** A voiding cystourethrogram image shows reflux of contrast material into two separate left renal collecting systems and proximal/mid ureters. The ureters join distally *(arrow)*, above the left ureterovesical junction.

with prune-belly syndrome. This syndrome is an autosomal recessive disorder seen mostly in girls.[89] It presents clinically with severe abdominal distention during the neonatal period because of functional bowel obstruction and severe urinary bladder distention; prenatal detection also has been described.[90,91]

***Imaging.*** Abdominal radiography may demonstrate a large, round mass emanating from the pelvis because of megacystis; ultrasound and VCUG can confirm marked urinary bladder distention (Fig. 113.33) and, in most cases, hydroureteronephrosis.[91] Urinary bladder emptying is abnormal, although no anatomic obstruction is found. Contrast enema examination reveals a severe microcolon and diminished or absent colonic peristalsis (Fig. 113.34).[90,91] Upper gastrointestinal (GI) series and small bowel follow-through can be used to document malrotation and hypoperistaltic small bowel.[88,92]

***Treatment.*** This syndrome is often fatal in the first year of life because of malnutrition or sepsis, unless the patient receives parenteral nutrition and aggressive supportive care.[90,91,93,94] Bowel transplantation has been attempted as a treatment option.[95] A cutaneous vesicostomy or suprapubic cystostomy may assist urinary bladder drainage.[91]

## Bladder Exstrophy

***Overview, Etiology, and Clinical Presentation.*** Deficiency of the anterior abdominal wall with an open, everted, incompletely formed urinary bladder is called *bladder exstrophy*. The anterior wall of the urinary bladder and overlying skin are absent, and the rectus abdominis muscles are separated inferiorly.[1,96] The remaining posterior urinary bladder wall is continuous with the skin.[96] Failure of migration of mesenchymal cells between ectoderm and cloaca during the fourth week of fetal life leads to incomplete closure of the midline lower anterior abdominal wall in utero.[1,96,97] This rare, unpredictable, congenital defect occurs in 1:10,000 to 1:40,000 live births and is more common in boys.[1] Epispadias in boys and bifid clitoris in girls often are noted as well.[96] Other skeletal, spinal, scrotal, and anorectal anomalies also may be present,[1,96] whereas renal anomalies are relatively uncommon.[98]

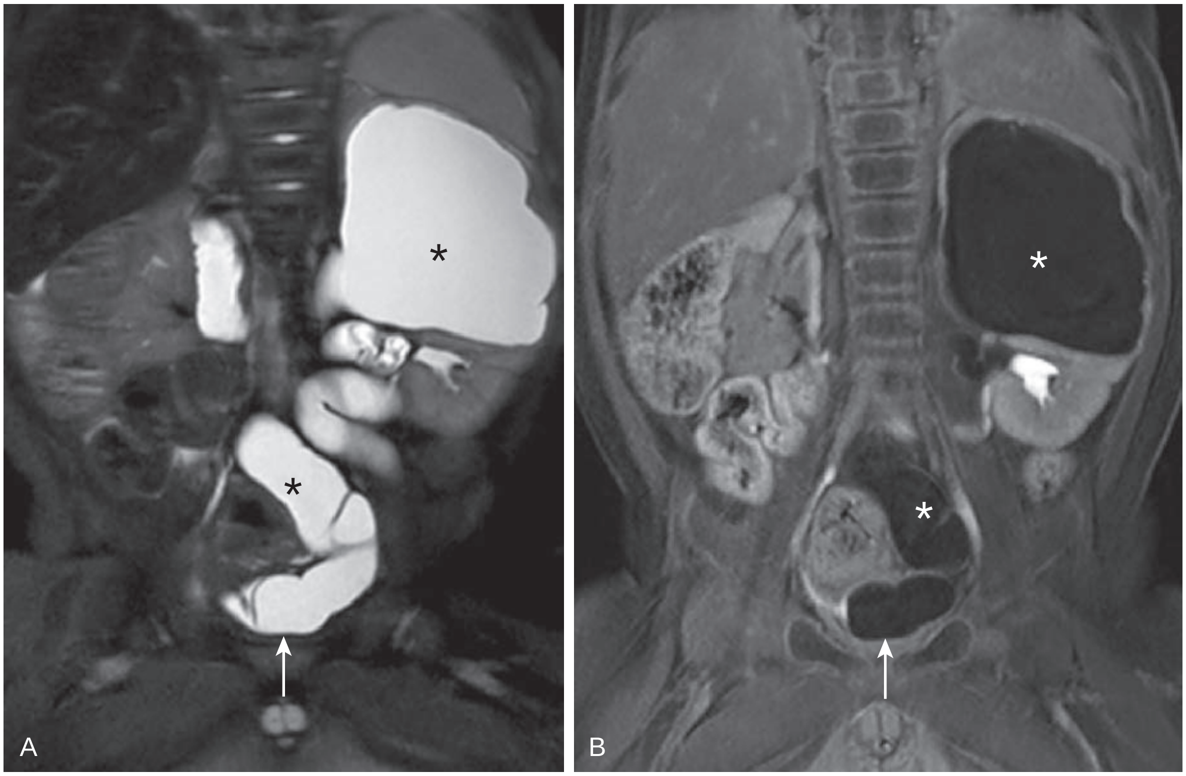

**Figure 113.28. Complete duplication of the left upper urinary tract in a 6-month-old boy.** Coronal (A) T2-weighted fat-saturated and (B) postcontrast excretory phase T1-weighted MR images show severely dilated left upper moiety collecting system and ureter *(asterisks)* due to an obstructing ureterocele *(arrows)*. There is severe left upper moiety parenchymal thinning. The left lower moiety collecting system has a "drooping lily" appearance, and the left lower moiety urinary tract is nonobstructed and normal in caliber.

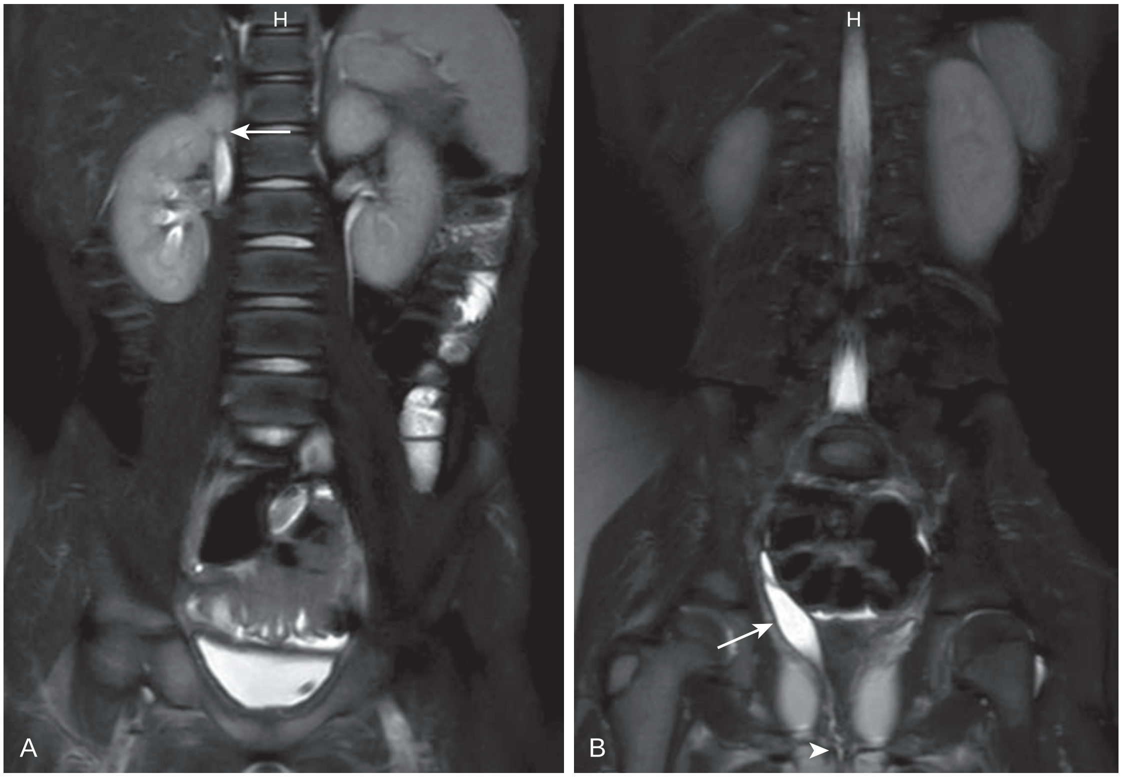

**Figure 113.29. Upper urinary tract duplication and an ectopic ureter in a 6-year-old girl with enuresis.** (A) A coronal T2-weighted fat saturated MR image shows duplication of the right upper urinary tract, which was not appreciated at ultrasound. A single upper moiety calyx was identified *(arrow)*. (B) A more posterior image shows that the right upper moiety ureter is dilated distally *(arrow)*, before narrowing as it passes through the pelvic floor and opening onto the vaginal introitus *(arrowhead)*.

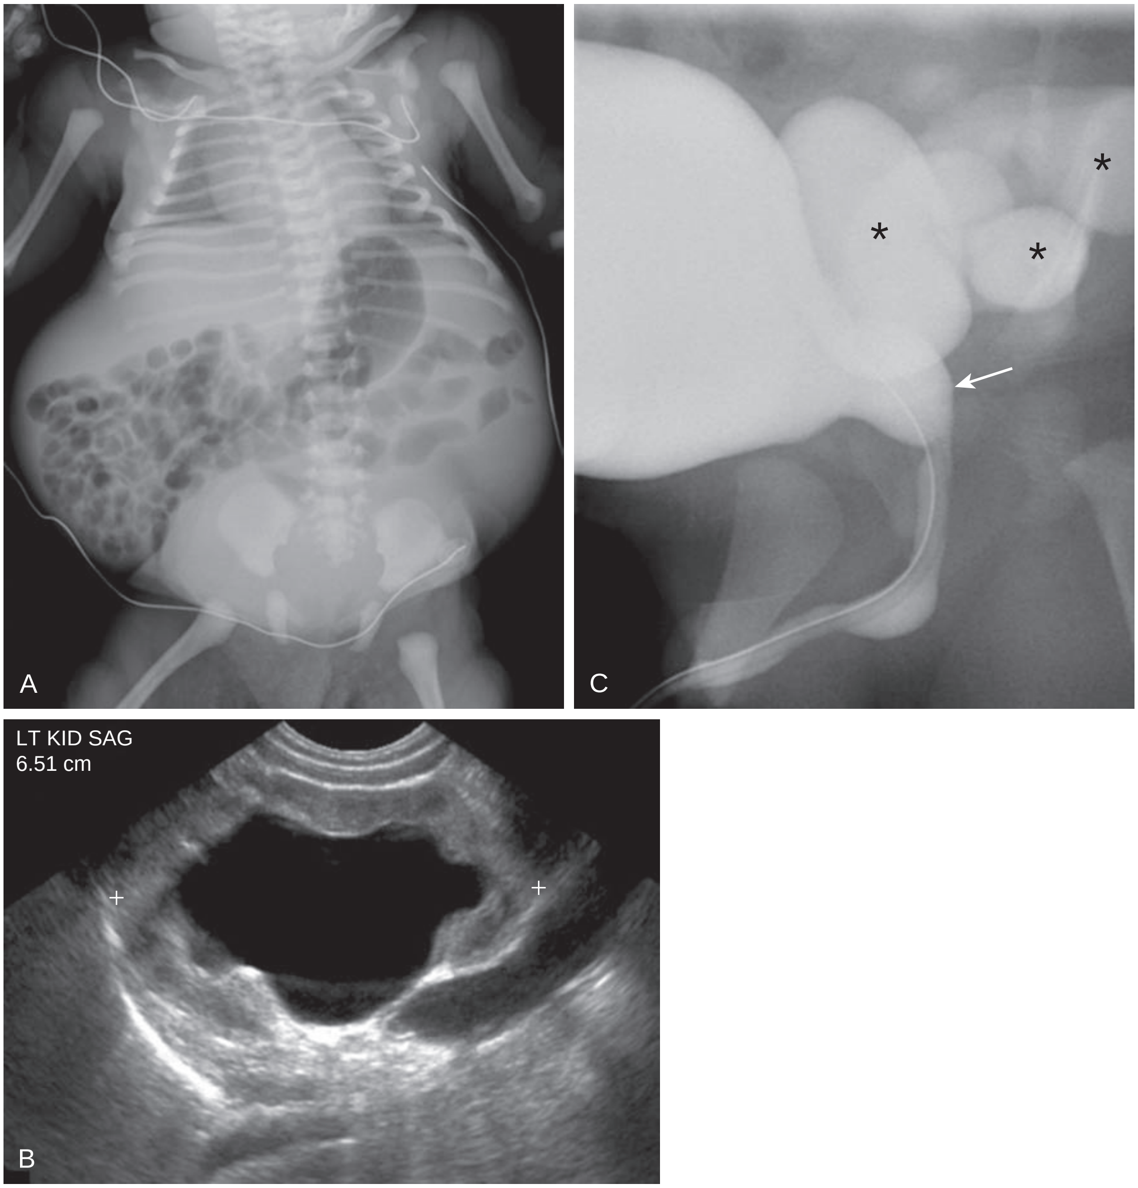

**Figure 113.31. A neonatal boy with prune-belly syndrome.** (A) Abdominal radiograph shows laxity of the anterior abdominal wall and bulging flanks. (B) Longitudinal ultrasound image of the left kidney shows dilatation of the collecting system and proximal ureter. The kidney demonstrates abnormally increased parenchymal echogenicity and contains a few subcortical cysts (not shown), suggestive of renal dysplasia. (C) Voiding cystourethrogram demonstrates dilatation of the posterior urethra *(arrow)* and high-grade vesicoureteric reflux *(asterisks)*.

***Imaging.*** Radiographs show abnormal pubic symphyseal widening (Fig. 113.35).[96,99] The hips may be dislocated. Renal imaging is most commonly normal at birth.[96] Recently, MRI has been used to assess pelvic floor anatomy after bladder exstrophy repair.[100]

***Treatment.*** The prognosis for bladder exstrophy is generally good. Although certain patients may be amenable to complete primary closure,[101] others may require multiple surgeries involving the genitourinary and skeletal systems early in life. An increased incidence of adenocarcinoma of the bladder later in life is found compared with age-matched control subjects.[1,102]

## CLOACAL EXSTROPHY

***Overview, Etiology, and Clinical Presentation.*** Cloacal exstrophy is a nonhereditary constellation of congenital anomalies that involves the anterior abdominal wall and multiple organ systems, and it is a result of maldevelopment of the cloacal membrane during organogenesis. The infraumbilical cloacal membrane persists, which interferes with normal infraumbilical anterior abdominal wall closure and leads to failure of urogenital septum separation from the rectum. Two hemibladders are separated by ileocecal bowel mucosa.[103] The terminal ileum prolapses through the exposed cecum (“elephant trunk” deformity).[103] Associated anomalies include omphalocele, abnormal genitalia, two-vessel umbilical cord, closed spinal defects, renal abnormalities, and Müllerian anomalies in girls.[104]

***Imaging.*** Radiographs may demonstrate a variety of abnormalities, including abnormal widening of the pubic symphysis, lumbosacral spine anomalies, dislocated hips, and clubfoot. Imaging of the kidneys may reveal agenesis or ectopia, and various Müllerian anomalies may be detected in girls (Fig. 113.36). Ultrasound and

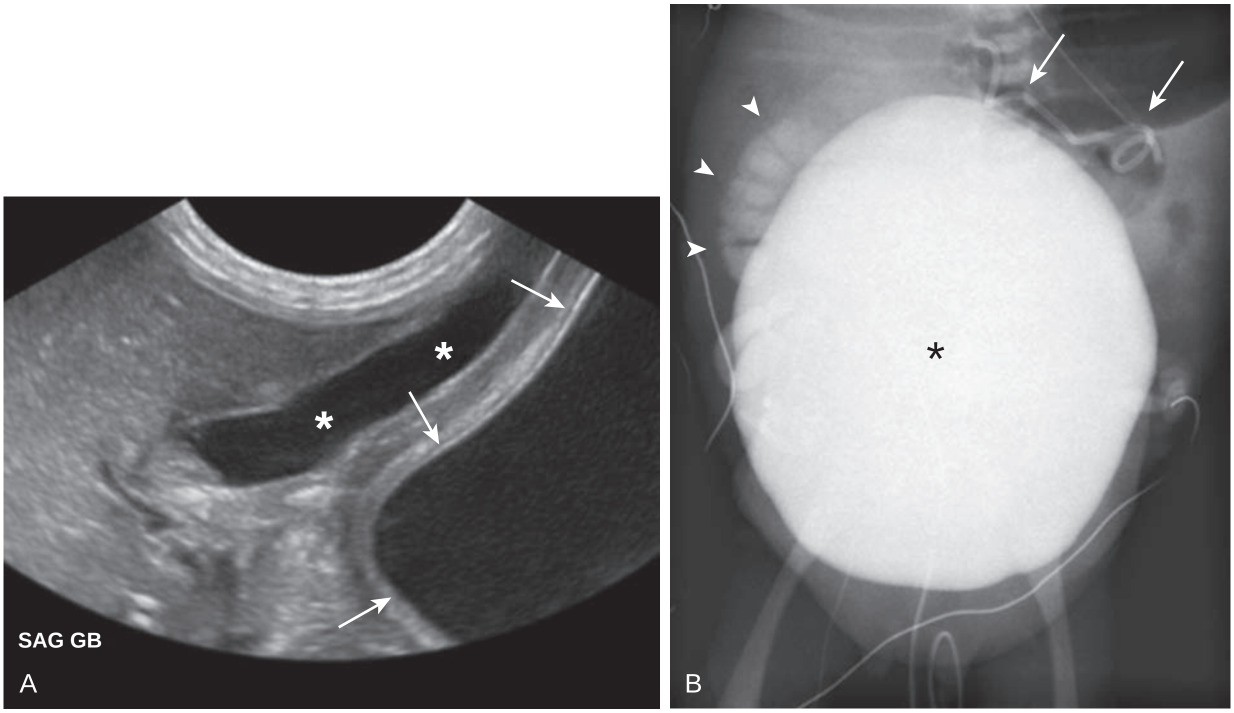

**Figure 113.33. Newborn boy with megacystis-microcolon-intestinal hypoperistalsis syndrome (Berdon syndrome).** (A) Longitudinal ultrasound image demonstrates a markedly dilated urinary bladder *(arrows)*, which extends into the upper abdomen and abuts the gallbladder *(asterisks)*. (B) Voiding cystourethrogram image shows the urinary bladder *(asterisk)* occupying most of the abdomen and pelvis. High-grade right vesicoureteral reflux is present *(arrowheads)*, and a retained vesicoamniotic shunt *(arrows)* projects over the left upper quadrant of the abdomen.

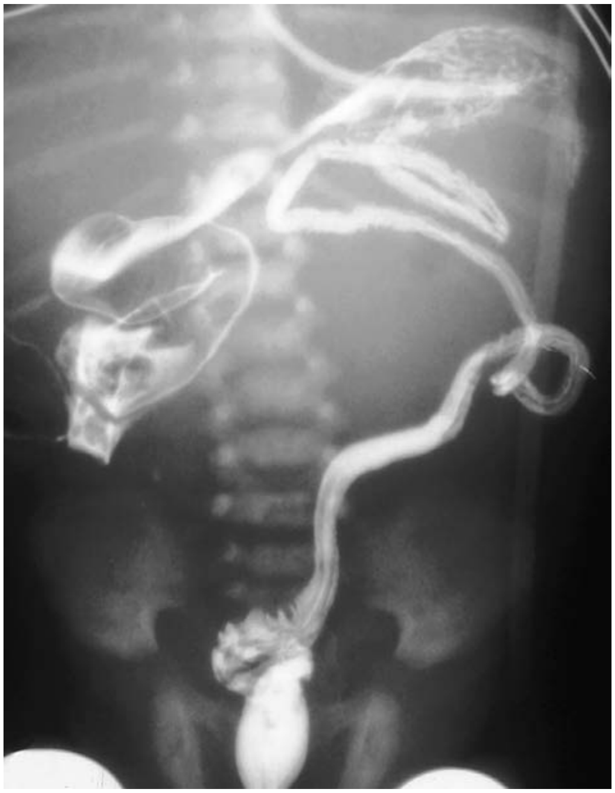

**Figure 113.34. Megacystis-microcolon-intestinal hypoperistalsis syndrome (Berdon syndrome).** The anterior view from a contrast enema reveals a severe microcolon. Contrast material in the upper GI tract shows abnormal duodenal course, consistent with malrotation.

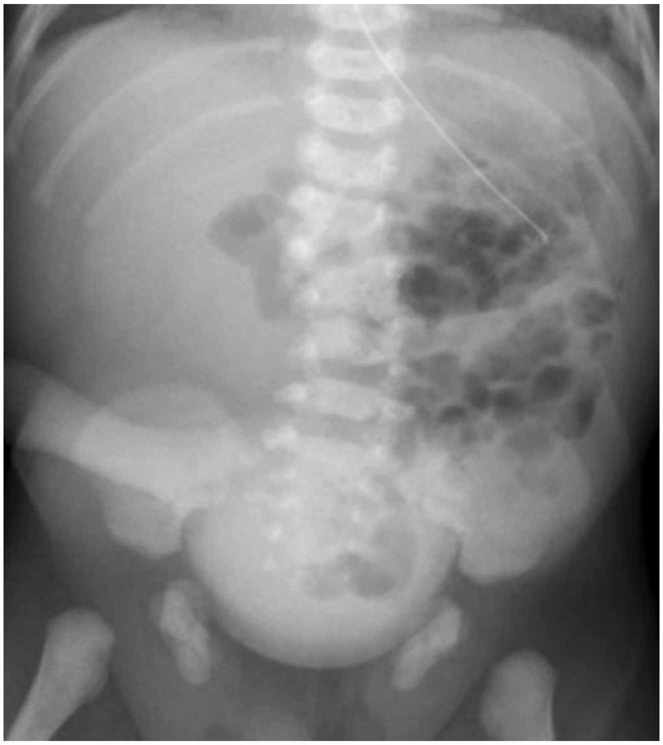

**Figure 113.35. Neonate with bladder exstrophy and a bifid scrotum.** Abdominal radiograph shows diastasis of the pubic symphysis, consistent with bladder exstrophy. A round, masslike opacity projecting over the pelvis is due to a large umbilical hernia. Incidental note is made of multiple lumbar vertebral anomalies.

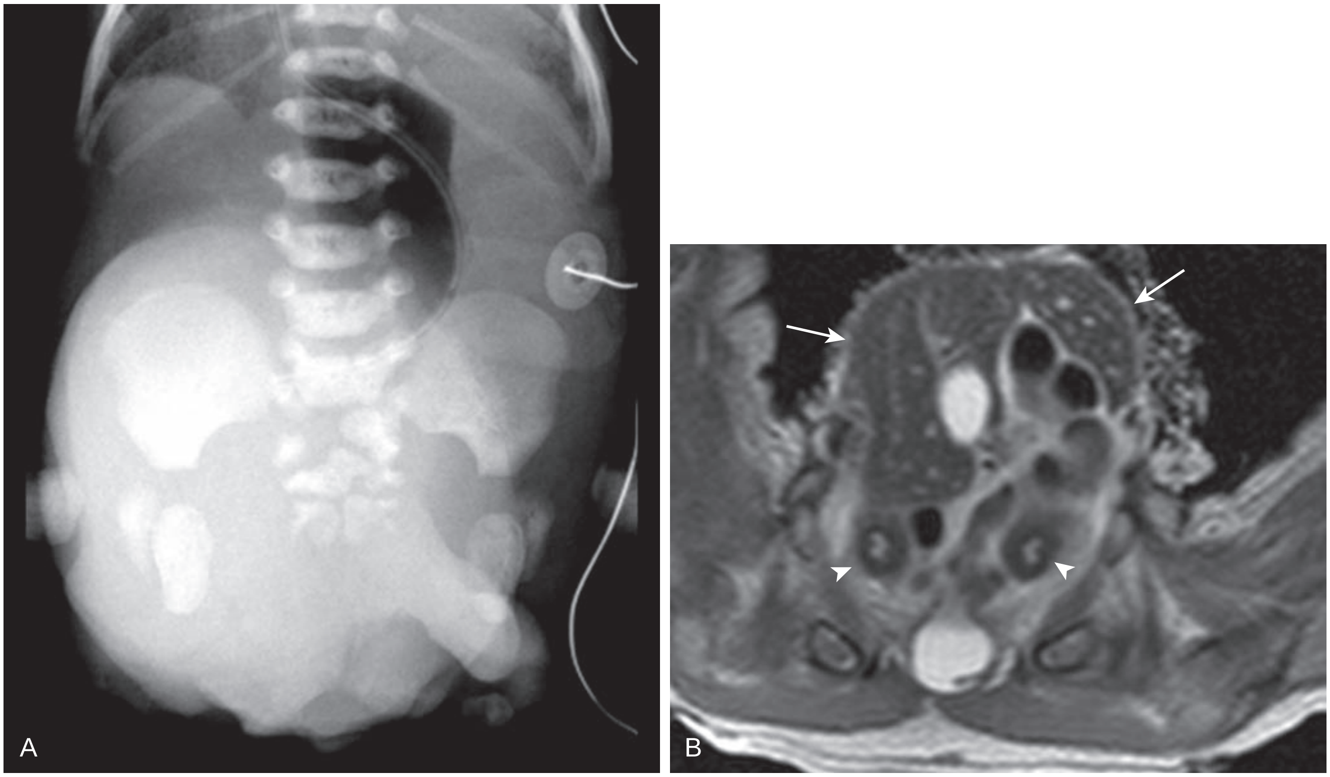

**Figure 113.36. A neonate with cloacal exstrophy.** (A) Abdominal radiograph shows multiple sacral anomalies and abnormal widening of the pubic symphysis. A masslike opacity projecting over the lower abdomen and pelvis was due to a large omphalocele. (B) Axial T2-weighted MR image shows a large liver-containing omphalocele at the level of the pelvis *(arrows)*. Two separate uterine horns *(arrowheads)* can be seen, consistent with uterus didelphys.

MRI imaging of the spine commonly reveal spinal dysraphism and spinal cord tethering (e-Fig. 113.37). Upper GI series evaluation should be performed because midgut malrotation may be present in up to 30% of affected children.[103]

***Treatment.*** This condition commonly requires a multistage approach to surgical reconstruction, with closure of spinal detects and management of gastrointestinal tract anomalies taking preference to urinary bladder and genital recontruction.[105] Advances in surgical technique and supportive care have improved survival and functional outcomes.

## CLOACAL MALFORMATION

***Overview, Etiology, and Clinical Presentation.*** Cloacal malformation is diagnosed when the urinary, genital, and gastrointestinal tracts all come together to form a single outflow channel of variable length.[76,106] On physical examination, the perineum has a single opening that eliminates urine, feces, and genital tract secretions.[106] Unlike with cloacal exstrophy, the anterior abdominal wall is intact.[76] Although the etiology of this congenital anomaly is not entirely understood, it is thought to be due to failure of urorectal septum to join the cloacal membrane in utero.[76] This condition only affects 1:40,000 to 1:50,000 phenotypic newborn girls.[106]

***Imaging.*** Contrast injection through a catheter placed within the single perineal orifice under fluoroscopic observation can be used to confirm the diagnosis and definitely characterize perineal anatomy.[76,106] Jaramillo et al[106] divided these malformations into urethral and vaginal subtypes based on the appearance of the common channel. Numerous genitourinary tract abnormalities may be seen in the setting of cloacal malformation, including VUR, ureteral ectopia, urinary bladder duplication, urethral duplication, urachal anomalies, and a variety of uterine and vaginal anomalies.[106] Renal abnormalities may include agenesis, horseshoe kidney, and obstruction, whereas osseous abnormalities may include widening of the pubic symphysis and partial sacral agenesis. Abnormalities of the spinal cord may be present and are best characterized by ultrasound or MRI. Contrast material injection through the distal limb of a diverting colostomy also can further assess perineal anatomy (Fig. 113.38).[76,106,107] Authors have described a combined fluoroscopic-MRI approach for anatomic assessment of infants with cloacal malformations allowing evaluation of the urinary, genital, and gastrointestinal tracts as well as the spine, kidneys, and Müllerian structures.[108,109]

***Treatment.*** The goals of surgery are to achieve urinary and fecal continence and to preserve future sexual function. A diverting colostomy is often performed soon after birth as a temporizing measure. Hematocolpos/hydrocolpos due to vaginal obstruction should be drained. Posterior sagittal anorectovaginourethroplasty is commonly performed to definitely repair the entire malformation with good results, although laparotomy also may be required.[110,111]

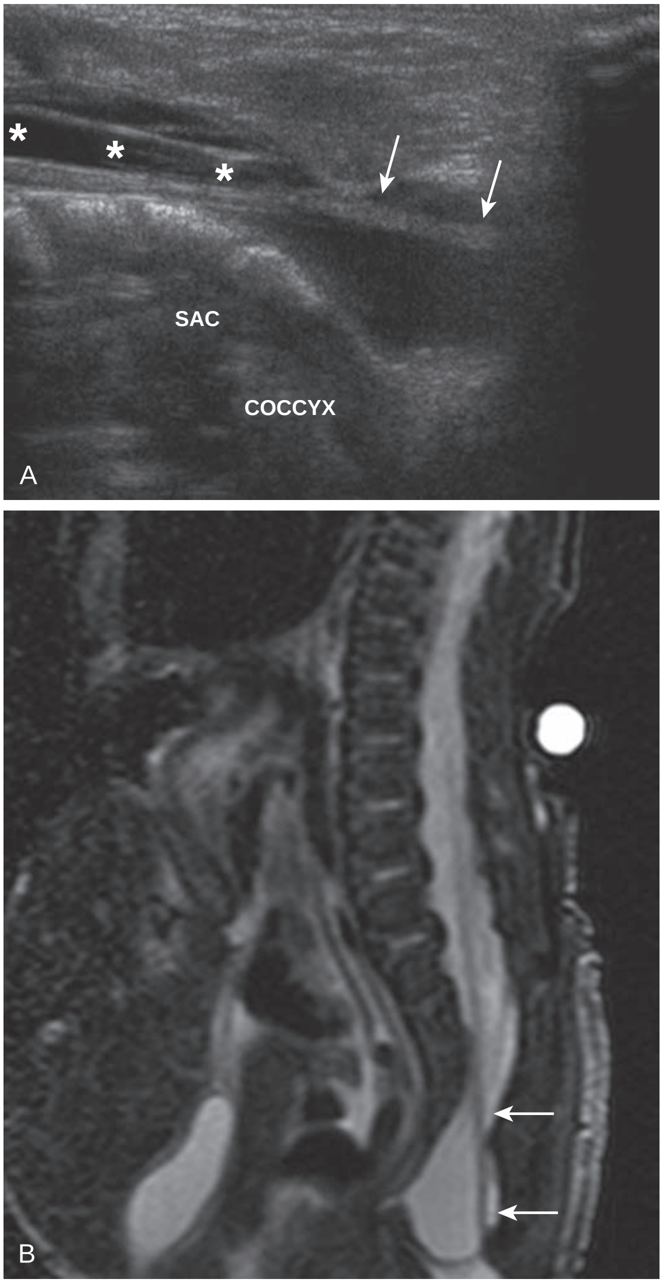
### Acknowledgment

The editors acknowledge the contributions of D. Gregory Bates to this chapter from the previous edition.

KEY POINTS

- MCDK usually involutes over time, eventually resulting in remnant dysplastic renal tissue that may be difficult to visualize by ultrasound.
- Two types of ADPKD (a ciliopathy) exist, each with clearly defined chromosomal mutations and prognoses.

*Continued*



**e-Figure 113.37. Neonate with cloacal exstrophy and a tethered spinal cord.** (A) Longitudinal ultrasound image of the lumbosacral spinal canal demonstrates a low-lying, elongated conus medullaris *(asterisks)* with thickening of the filum terminale *(arrows)*. The sacral portion of the thecal sac is abnormally dilated. (B) Sagittal T2-weighted MR image of the lumbosacral spine reveals a thickened, tethered filum terminale *(arrows)*. *SAC,* sacrum.

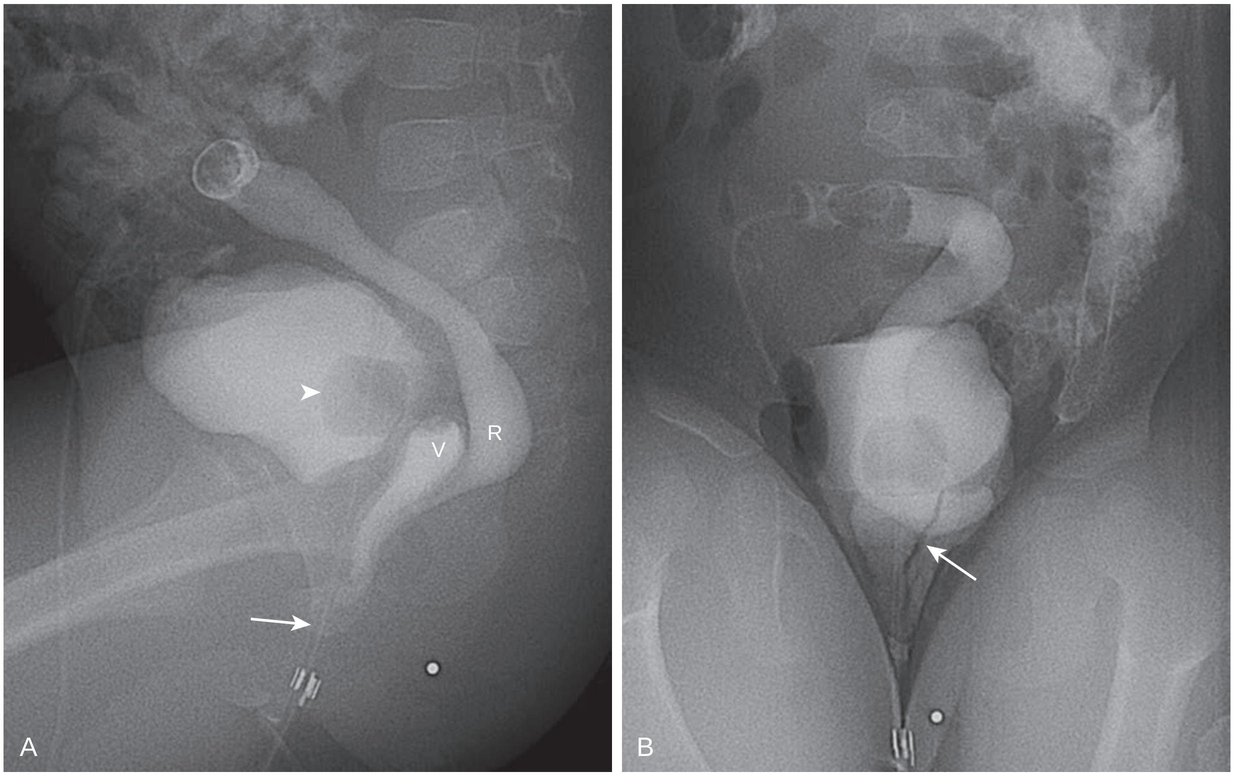


**Figure 113.38. Cloacal malformation in a 16-month-old girl.** (A) Sagittal fluoroscopic image obtained after injection of the contrast material into the child's mucous fistula and urinary bladder shows findings consistent with cloacal malformation. A catheter is present in the common channel *(arrow)*, and a metallic BB marker is on the skin surface at the expected location of the anus. *arrowhead*, Foley catheter balloon; *R*, rectum; *V*, vagina. (B) Frontal image shows two hemivaginas, separated by a thin septum *(arrow)*.

- ARPKD presenting early in life commonly requires renal replacement therapy; recent studies suggest that the severity renal and hepatic abnormalities are independent and not necessarily inversely proportional.
- About 30% of UPJ cases are bilateral, although the severity of obstruction and pelvicaliectasis may be asymmetric.
- The Weigert-Meyer rule, which applies only to complete duplications, states that the ureter that drains the upper moiety inserts inferior and medial to the lower moiety ureter. The upper moiety ectopic ureter is more likely to be obstructed (ectopic ureterocele or stenotic ectopic orifice), whereas the lower moiety ureter is more likely to reflux.
- Calyceal diverticula most commonly occur within the upper pole.
- Congenital megacalyces is a very rare nonobstructive anomaly of the renal collecting system that may be confused easily with obstructive hydronephrosis.
- Prune-belly syndrome, also known as *Eagle-Barrett* or *triad syndrome*, includes the constellation of bilateral cryptorchidism, anterior abdominal wall muscular deficiency, and a variety of urinary tract anomalies, including megacystis and hydroureteronephrosis.
- Megacystis-microcolon-intestinal hypoperistalsis-malrotation syndrome presents clinically with severe abdominal distention during the neonatal period as a result of functional bowel obstruction and severe urinary bladder distention.
- Cloacal malformation has a single perineal opening that eliminates urine, feces, and genital tract secretions. Unlike with cloacal exstrophy, the anterior abdominal wall is intact.

# 114 Acquired Abnormalities

Robert G. Wells

## RENAL INFECTION

### Acute Bacterial Pyelonephritis

***Overview.*** The term *pyelonephritis* encompasses infections of the renal parenchyma and pelvocaliceal system. Renal infections can be acute or chronic; unilateral or bilateral; and focal, multifocal, or diffuse. Potential complications include renal or perinephric abscess.[1]

***Pathophysiology and Clinical Presentation.*** The most common cause of acute bacterial pyelonephritis is ascending infection from the lower urinary tract. Parenchymal renal infection may also occur as a result of hematogenous inoculation; this mechanism is most common in infants. Risk factors for pyelonephritis include high-grade vesicoureteral reflux, urinary tract congenital anomalies, voiding dysfunction, intermittent catheterization, and urinary diversion. Potential clinical manifestations include flank pain, abdominal pain, fever, pyuria, nausea, and vomiting. Young infants with pyelonephritis often have nonspecific findings such as irritability, vomiting, and poor feeding; fever is sometimes lacking.[2–4]

***Imaging.*** Renal cortical scintigraphy with technetium-99m dimercaptosuccinic acid (DMSA) is highly sensitive (at least 90%) for the detection of acute bacterial pyelonephritis. Infected regions of the kidneys have diminished or absent radiotracer uptake, often with a spherical or flarelike pattern (Fig. 114.1). The scintigraphic defect of a renal abscess is usually indistinguishable from that of uncomplicated parenchymal infection.[5–7]

Contrast-enhanced computed tomography (CT) provides sensitivity similar to renal cortical scintigraphy for the diagnosis of acute bacterial pyelonephritis. CT findings include diminished nephrogram intensity; radially oriented linear streaks of diminished attenuation; round, masslike, or irregular hypoattenuating foci; wedge-shaped defects; and heterogeneous diminished enhancement throughout an enlarged kidney (Fig. 114.2). Delayed CT images of the infected kidney show retention of contrast material in obstructed tubules. A parenchymal or perinephric abscess appears as a hypoattenuating focus, sometimes with a prominently enhancing rim.[8]

Renal parenchymal edema resulting from infection leads to diminished signal intensity on T1-weighted magnetic resonance imaging (MRI) and increased signal intensity on T2-weighted images. Alternatively, the kidneys may show one or more focal areas of decreased T2-weighted signal intensity (Fig. 114.3). MRI findings can include nephromegaly, localized parenchymal expansion, diminished corticomedullary differentiation, parenchymal striation, perinephric edema/fluid, urothelial thickening, and decreased contrast enhancement of infected parenchyma.[9–11]

Reported sensitivities of sonography for the detection of acute bacterial pyelonephritis range from 25% to 50%. Potential findings include nephromegaly, abnormal parenchymal echogenicity, deficient corticomedullary differentiation, renal sinus hyperechogenicity, and urothelial thickening. Color Doppler or power Doppler imaging demonstrates diminished perfusion of the infected regions of parenchyma, sometimes with a wedge shape (Fig. 114.4). A parenchymal abscess usually appears as a spherical avascular hypoechoic focus with acoustic enhancement. Occasionally, pus within the cavity results in an isoechoic or hyperechoic appearance. A perinephric abscess appears as a hypoechoic, sometimes complex fluid collection immediately peripheral to the renal capsule.[7,12–14]

***Treatment and Follow-up.*** The treatment of bacterial pyelonephritis is antibiotic therapy. Follow-up sonography or scintigraphy serves to detect progression to scarring. Defects on renal cortical scintigraphy can persist for a few months after clinical resolution of the infection; therefore scintigraphy for scar detection should be delayed for at least 3 to 6 months.[15,16]

### Pyonephrosis

***Overview.*** Pyonephrosis is a bacterial infection of the kidney in which purulent material fills a dilated collecting system. Most often, a preexisting chronic urinary tract obstruction is present, such as ureteropelvic junction obstruction. Acute obstruction because of a calculus is an occasional cause in children. The clinical presentation of pyonephrosis is similar to that of other bacterial urinary tract infections. Fever, flank pain, pyuria, and hematuria are common.[17]

***Imaging.*** Sonography shows echogenic material within a dilated pelvocaliceal system (e-Fig. 114.5). The purulent material often layers in the dependent portions of the collecting system and may shift with changes in patient position. Thickening of the wall of the dilated renal pelvis is usually present. Echogenic foci in the urinary tract due to gas-forming organisms is an uncommon finding.[18,19]

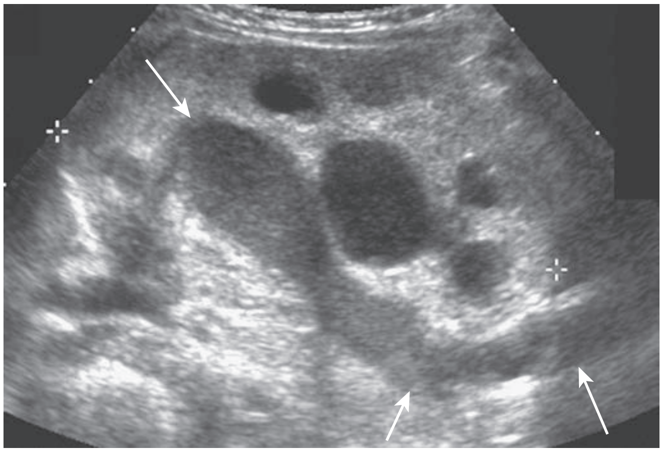
CT, MRI, or scintigraphy shows diminished function of the involved kidney. Contrast enhancement of the renal parenchyma is heterogeneous and delayed on CT. Excreted contrast material may outline filling defects in the dilated collecting system on delayed images. Debris usually is visible in the dilated renal collecting system on MRI. The renal parenchyma has abnormal heterogeneous signal intensity. The pus-filled collecting system is markedly hyperintense on diffusion-weighted images.[20,21]

***Treatment and Follow-up.*** The treatment of pyonephrosis includes prompt initiation of aggressive antimicrobial therapy. Drainage of the obstructed collecting system often is required, usually by percutaneous nephrostomy. Surgical correction of an underlying obstruction is delayed until resolution of the acute infection.

### Xanthogranulomatous Pyelonephritis

***Overview.*** Xanthogranulomatous pyelonephritis (XGP) is an uncommon form of severe chronic renal parenchymal infection that can sometimes mimic a renal tumor. The pathogenesis typically involves chronic infection of an obstructed kidney, often due to a large calculus. Diffuse involvement of the kidney is most common; segmental or focal forms also can occur, sometimes in association with obstruction of a duplicated collecting system or infundibulum. Clinical findings may be nonspecific and can include fever, flank pain, malaise, pyuria, weight loss, and anemia.[22–25]

***Imaging.*** In the early stages of XGP, the involved portion of the kidney typically has an irregular hyperechoic character on sonography. With the diffuse form, the kidney may be massively enlarged but usually maintains a reniform shape. Echogenic foci with shadowing indicate calcifications. With progression, necrotic



**e-Figure 114.5. Pyonephrosis.** Longitudinal sonogram shows a hydronephrotic duplex collecting system. There is echogenic debris within the upper pole collecting system and ureter *(arrows)*. Lesser debris is present within the lower pole collecting system.

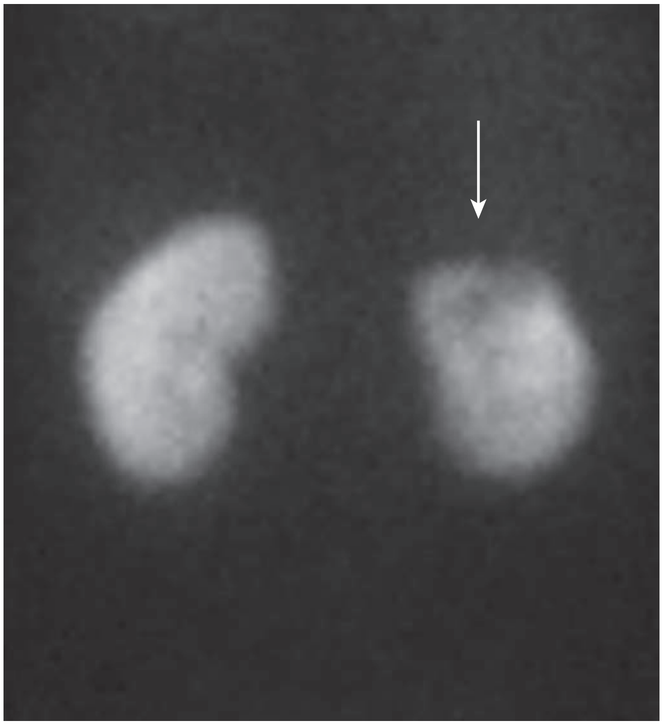


**Figure 114.1. Acute bacterial pyelonephritis.** Posterior technetium-99m DMSA image of a febrile 16-year-old shows absent uptake in the upper pole of the right kidney *(arrow)*.

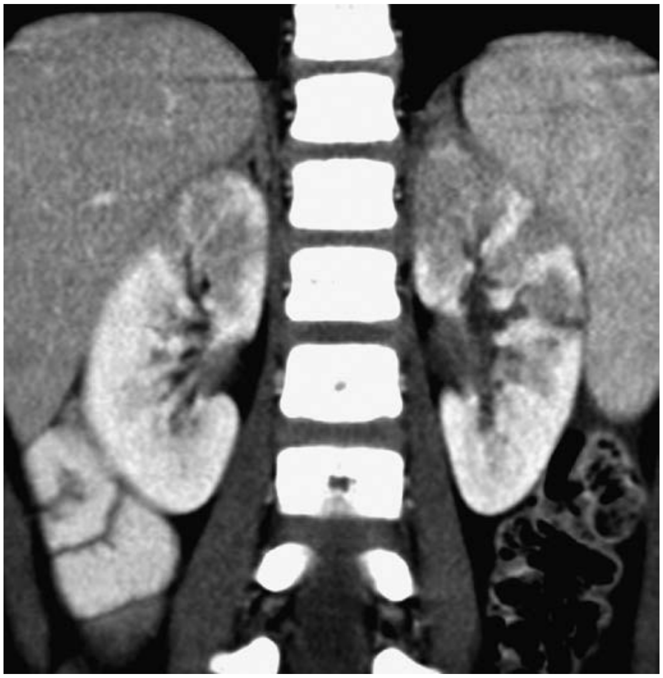

**Figure 114.2. Multifocal bacterial pyelonephritis.** Multiple areas of decreased contrast enhancement of the kidneys are present on this coronal CT image of a 6-year-old girl.

tissue and fluid are usually hypoechoic. Echogenic debris is sometimes visible within abscesses or the dilated collecting system.[26]

CT of diffuse XGP typically demonstrates an enlarged nonfunctioning kidney that has multiple low-attenuation parenchymal foci (Fig. 114.6). Most patients have a staghorn calculus in a contracted renal pelvis. Perinephric fat stranding is common. Perinephric abscesses are moderately hypoattenuating with peripheral enhancement. The pus-filled collecting system is hypoattenuating. Little or no contrast excretion occurs on delayed imaging. Regional retroperitoneal lymphadenopathy is common. With the focal form of XGP, CT typically demonstrates an expansile renal "mass". Peripheral granulation tissue or compressed renal parenchyma may result in an enhancing peripheral rim. The involved renal parenchyma typically has low or intermediate signal intensity on T1-weighted MRI and high intensity on T2-weighted images.[27]

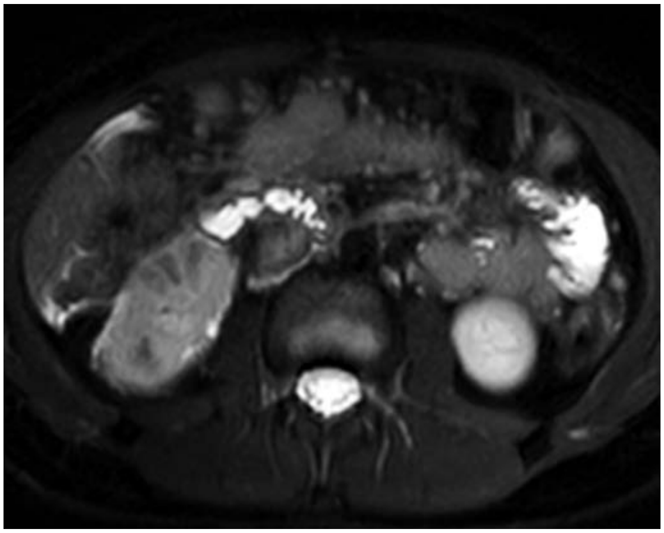

**Figure 114.3. Acute bacterial pyelonephritis.** Axial T2-weighted fat-saturated magnetic resonance (MR) image shows multiple areas of right kidney focal signal hypointensity and perinephric fluid in a 10-year-old girl with clinically suspected acute appendicitis and history of multiple urinary tract infections.

***Treatment and Follow-up.*** The usual treatment for XGP is antibiotic therapy followed by nephrectomy or heminephrectomy. A percutaneous biopsy occasionally is useful to allow differentiation from a neoplasm and to provide material for culture. With acute disease, percutaneous abscess drainage can serve as a temporizing measure.

## Candidiasis

***Overview.*** Candidiasis, typically due to *Candida albicans*, accounts for about 80% of renal fungal infections. Premature neonates are particularly susceptible. The clinical presentation in neonates usually is nonspecific: hypertension, oliguria, or anuria. Older children with renal candidiasis usually have immunocompromise. The clinical findings typically are indistinguishable from those of a bacterial infection: fever, chills, dysuria, and flank pain.[28]

***Imaging.*** Potential sonographic findings of renal candidiasis include parenchymal hyperechogenicity, nephromegaly, one or more small abscesses, and debris within the collecting system. A fungus ball (mycetoma) in the pelvocalyceal system appears as an echogenic object, with or without acoustic shadowing (Fig. 114.7). Dilation of the collecting system proximal to a fungus ball is common.

Findings on contrast-enhanced CT include nephromegaly, diffuse or multifocal edema, renal abscess, and hydronephrosis. Infected parenchyma lacks normal contrast enhancement. Disseminated candidiasis sometimes results in numerous tiny bilateral hypoattenuating renal lesions, often associated with splenic and hepatic disease. CT may demonstrate organ enlargement and a heterogeneous (salt and pepper) pattern of contrast enhancement.[29,30]

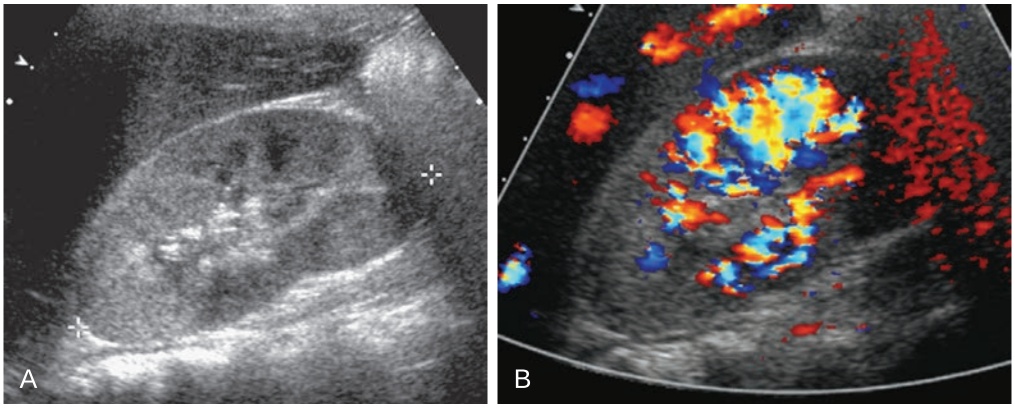

**Figure 114.4. Acute bacterial pyelonephritis.** (A) Gray-scale sonogram shows increased echogenicity and deficient corticomedullary differentiation in the upper pole. (B) There is diminished perfusion in the edematous infected upper pole upon color Doppler assessment.

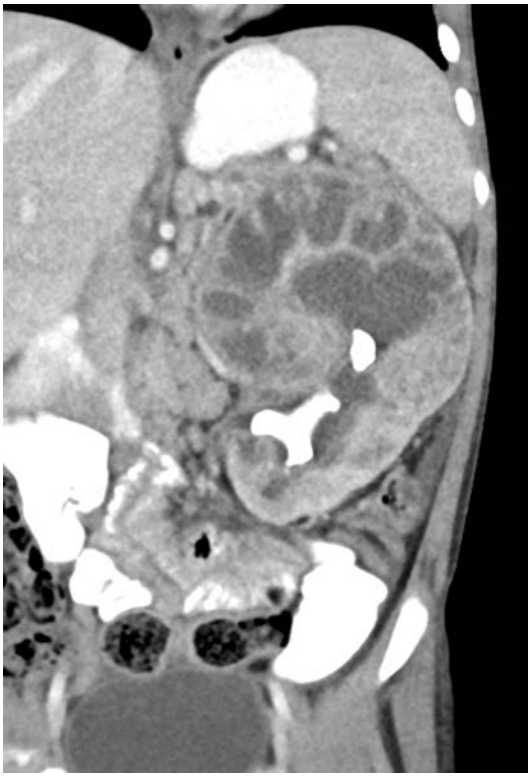

**Figure 114.6. Xanthogranulomatous pyelonephritis.** Coronal contrast-enhanced CT shows an enlarged left kidney that contains large calculi. There is no excretion of contrast into the dilated collecting system. There are multiple peripheral low attenuation areas in the upper pole due to parenchymal necrosis. *(Courtesy of Dr. Michael Mullin, DO, Milwaukee, WI.)*

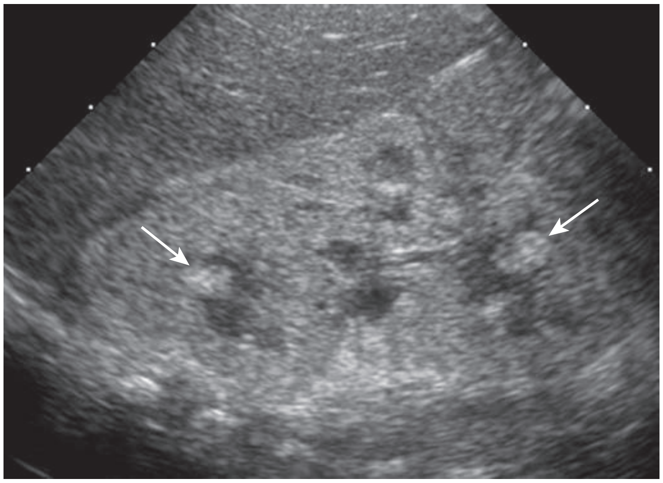

**Figure 114.7. Candidiasis.** Longitudinal renal sonogram of a premature infant with urinary candidiasis shows an echogenic right kidney with poor corticomedullary differentiation and echogenic fungus balls in the collecting system *(arrows)*.

***Treatment and Follow-up.*** The typical treatment is systemic antifungal medication. Percutaneous nephrostomy is an option for children with an obstructing fungus ball. This treatment allows decompression of the collecting system and provides a pathway for installation of antifungal or fibrinolytic medication.[31]

## Tuberculosis

***Overview.*** The urinary system is the most common site of extrapulmonary tuberculosis. Initial infection of the kidney consists of small caseous foci in the renal parenchyma that release the organism into the collecting tubules. Eventually, a larger mass may develop in the renal cortex, resulting in additional discharge of mycobacteria. Antegrade seeding frequently allows spread of infection to the ureters, prostate, or epididymis. Involvement of the collecting system can progress to fibrosis and calcification, sometimes leading to obstruction. Potential symptoms of urinary tuberculosis include dysuria, flank pain, and gross hematuria.[32]

***Imaging.*** In the acute phase of tuberculous infection, imaging of the renal parenchyma may be normal or show manifestations of edema and vasoconstriction. Involved areas lack normal contrast enhancement on CT and MRI, and sometimes have altered echogenicity on sonography. Inflamed urothelium may appear thickened and show prominent contrast enhancement. Parenchymal edema and large tubercles may cause distortion of the calyceal system. Excreted contrast sometimes pools within parenchymal cavitations. Multiple small filling defects may be present in the collecting system or ureter. Fibrotic strictures of the collecting system that are common late in the course of the disease result in focal dilation or hydronephrosis. Dystrophic calcifications can develop in necrotic parenchyma.[33–35]

***Treatment and Follow-up.*** The mainstay treatment is systemic antituberculous medication. Imaging studies serve to monitor treatment effectiveness and to detect complications. Apparent obstructive strictures of the ureter sometimes are due to edema that can regress during treatment. A persistent stricture may require surgical intervention.

## STONE DISEASE

### Overview

Urinary system calcifications can occur within the kidneys, ureters, bladder, or urethra. *Urolithiasis* refers to intraluminal stones. The term *nephrolithiasis* indicates calculi within the pelvicalyceal system. *Nephrocalcinosis* refers to intraparenchymal renal calcifications, either medullary or cortical. *Dystrophic* calcification of abnormal tissue, such as the wall of a renal cyst, inflammatory tissue, or a neoplasm, is a potential source of calcifications throughout the urinary system.

### Nephrocalcinosis

#### Medullary Nephrocalcinosis

***Overview.*** In more than 90% of children with nephrocalcinosis, the calcification predominantly is in the medullary region. The most common causes of pediatric medullary renal calcification are metabolic conditions that produce hypercalcemia and hypercalciuria (Box 114.1).[36–38]

***Etiologies, Pathophysiology, and Clinical Presentation.*** Type 1 (distal) renal tubular acidosis (RTA) is the most common metabolic condition associated with nephrocalcinosis in children. Nephrocalcinosis occurs in about three-quarters of patients with type 1 RTA. Progression to urolithiasis can occur.

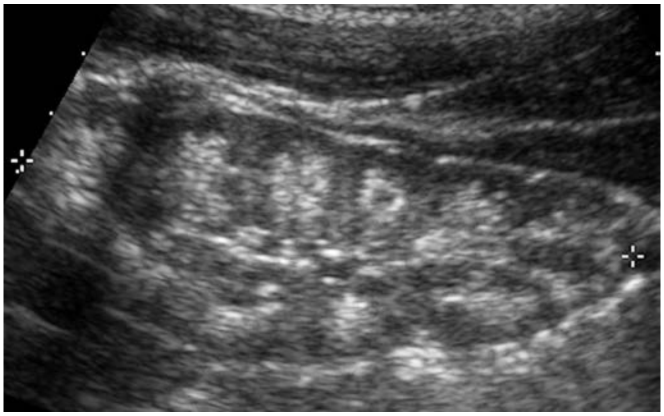

**Figure 114.8. Medullary nephrocalcinosis.** Longitudinal sonogram shows multiple punctate echogenicities involving the renal pyramids.

The administration of loop diuretics, such as furosemide, is an important cause of nephrocalcinosis in neonates. The typical time course to the earliest manifestations of stone formation is approximately 30 days after the start of diuretic therapy. Spontaneous resolution occurs in most, but not all, of these infants within several months.

In patients with primary hyperoxaluria, deposition of insoluble calcium oxalate monohydrate crystals in renal tubules leads to medullary nephrocalcinosis, interstitial fibrosis, and progressive renal functional impairment. Renal cortical calcification and urolithiasis can also occur.[39] Medullary sponge kidney is another cause of medullary nephrocalcinosis.

***Imaging.*** The major sonographic feature of medullary nephrocalcinosis is hyperechogenicity of one or more renal pyramids (Fig. 114.8). With macroscopic calcification, acoustic shadowing and color Doppler twinkling artifact may be present. The earliest sonographic sign of medullary nephrocalcinosis is loss of normal papillary hypoechogenicity. In some instances, hyperechogenicity occurs only at the tips or periphery of the pyramids.[40,41]

With extensive nephrocalcinosis, medullary calcifications are visible on standard radiographs. Most common are diffuse or uniform calcifications within the medullary pyramids, resulting in a triangular pattern. Renal calcification in patients with type 1 RTA typically is quite dense and involves all the medullary pyramids in a uniform fashion. Calcifications associated with medullary sponge kidney tend to be asymmetric.[42,43]

CT allows definitive localization of calcifications to the medullary or cortical regions (Fig. 114.9). With medullary sponge kidney, medullary calculi typically occur in clusters within the renal pyramids. Stagnation of contrast material is evident within the dilated collecting tubules on enhanced CT. With mild disease, stagnation of contrast material appears as linear papillary opacities; small cystic components may be visible with more advanced disease. The excreted contrast surrounds any calculi that are within the collecting tubules.[44,45]

The Anderson-Carr-Randall progression theory of urolithiasis suggests that microscopic calcifications within a renal pyramid can coalesce to form a plaque that migrates toward the calyx and thereby form a stone nidus. High-resolution ultrasonography of young children may reveal papillary hyperechogenicity caused by these microscopic calcifications, despite normal findings on other imaging studies. Hyperechoic pyramids are present in about 50% of children with diseases that predispose to nephrocalcinosis. Subepithelial calcium phosphate plaques sometimes are visible on radiographs or CT as slivers of calcification adjacent to the papillary tip.[46]

***Treatment and Follow-up.*** Adequate hydration is an important preventive measure in patients with known nephrocalcinosis or a

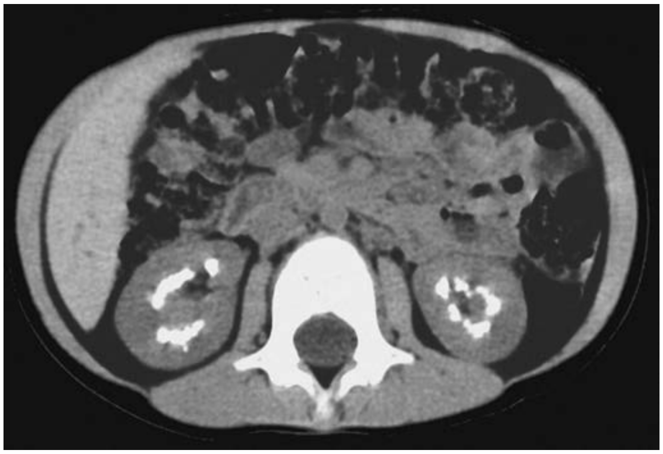

**Figure 114.9. Medullary nephrocalcinosis.** Unenhanced CT image shows dense renal pyramid calcifications in a child with type 1 renal tubular acidosis.

**BOX 114.2** Causes of Cortical Nephrocalcinosis

- Renal cortical necrosis
- Chronic glomerulonephritis
- Renal transplant rejection
- Alport syndrome
- Ethylene glycol poisoning
- Hyperoxaluria
- Acquired immunodeficiency syndrome–associated infections

**TABLE 114.1** Causes of Urolithiasis and the Most Commonly Associated Types of Stones

| Underlying Condition | Associated Stones |
|---|---|
| Idiopathic | Calcium |
| Urinary stasis | Calcium |
| Congenital obstruction | |
| Neurogenic bladder | |
| Pyelocalyceal diverticulum | |
| Surgical urinary diversions | |
| Urinary tract infection | Struvite, triple phosphate |
| Hypercalciuria | Calcium |
| Idiopathic hypercalciuria | |
| Idiopathic infantile hypercalcemia | |
| Hyperparathyroidism | |
| Sarcoidosis | |
| Type 1 renal tubular acidosis | |
| Immobilization | |
| Long-term diuretic use | |
| Hypervitaminosis D | |
| Hyperthyroidism | |
| Bone metastasis | |
| Prolonged corticosteroid therapy | |
| Fanconi syndrome | |
| Hyperoxaluria | Calcium oxalate |
| Primary oxaluria | |
| Small bowel disease | |
| Hyperuricosuria | Uric acid |
| Lymphoproliferative and myeloproliferative disorders | |
| Tumor lysis | |
| Lesch-Nyhan syndrome | |
| Cystinuria | Cystine |
| Hereditary cystinuria | |
| Xanthinuria | Xanthine |
| Hereditary xanthinuria | |
| Allopurinol therapy | |

metabolic condition that can cause nephrocalcinosis. Various medical therapies serve to reduce renal calcium excretion and increase the solubility of urinary calcium. These techniques occasionally lessen the severity of nephrocalcinosis over time. However, nephrocalcinosis is irreversible for most patients. Imaging studies provide early detection of renal calcifications, monitor response to therapy, and detect complications such as obstructive urolithiasis.

### Cortical Nephrocalcinosis

***Overview and Imaging.*** Cortical nephrocalcinosis involves the periphery of the kidney and the central septa of Bertin. In the pure forms of cortical nephrocalcinosis, the medullary pyramids are spared. The most common causes of cortical nephrocalcinosis are chronic glomerulonephritis, acute cortical necrosis, and oxalosis (Box 114.2).

Standard abdominal radiographs may show thin linear peripheral calcifications, diffuse homogeneous renal calcification, or diffuse punctate calcifications. On sonography, the involved cortex is echogenic, but acoustic shadowing does not occur unless conglomerate calcifications are present. CT accurately demonstrates the cortical location of calcification.[37,47,48]

Cortical hyperechogenicity in patients with acute renal cortical necrosis may be visible on sonography within a few weeks of the injury. Calcifications become more obvious sonographically and radiographically over time. Progressive renal atrophy also occurs. Various patterns of nephrocalcinosis can occur: (1) punctate;[49] (2) bandlike peripheral calcification with perpendicular extensions into the columns of Bertin; or (3) thin, parallel curvilinear calcifications at the interface between the necrotic cortex and the viable subcapsular cortex (i.e., the "tram-track" pattern).

## Urolithiasis

***Overview.*** The prevalence of urolithiasis varies according to geographic area, age, gender, and race. In the United States, urolithiasis affects approximately 1 in 1,000 children. Urolithiasis is slightly more common in Europe than in North America and is considerably more common in Asia. In American children, the prevalence of urolithiasis is greatest in southern California and the southeastern states. Urolithiasis is more common in white persons than in African Americans.[38,50–52]

***Pathophysiology.*** About 70% of patients with urolithiasis have a known predisposing condition, such as hypercalciuria, urinary stasis, or chronic infection (Table 114.1). A genitourinary anomaly is present in at least one-third of children with nephrocalcinosis and in nearly all patients with renal calculi related to infection. Urolithiasis is common in patients with urinary tract infections caused by a urea-splitting gram-negative enteric organism. These "infection stones" usually are a mixture of magnesium ammonium phosphate (struvite) and calcium phosphate (apatite), that is, a "triple phosphate stone." Struvite is the predominant composition of most staghorn calculi. Nonstruvite stones that occur in association with urinary tract infections are termed "infection-associated stones." Patients with neurogenic bladder, congenital urinary tract obstruction, surgical urinary diversion, or other types of urinary stasis have a propensity for calcium stones and infection stones.[53–55]

Hypercalciuria and hyperoxaluria are common causes of calcium stones. Uric acid stones due to hyperuricosuria account for only 5% of stones in North American children, but they are common in some areas of the world. Cystinuria and xanthinuria are rare causes of urolithiasis. Matrix stones are rare stones that consist of nonradiopaque inspissated mucoproteins, usually in conjunction

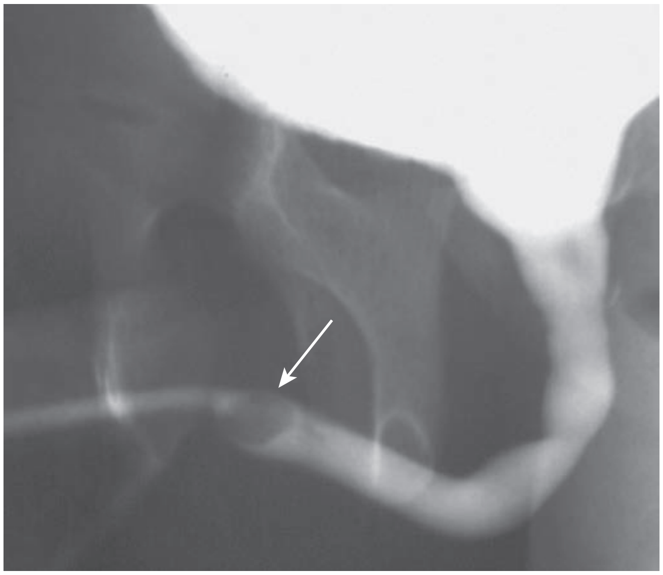

**Figure 114.11. Urethral calculus.** Urethrogram shows a partially obstructing urethral calculus as a filling defect *(arrow)* in the contrast column.

**TABLE 114.2** Radiopacity of Urinary Stones and Relative Frequency in North American Children

| Stone | Opacity | % of Stones |
|---|---|---|
| Calcium stones | +++ | 75–80 |
| Struvite | – | 10–15 |
| Triple phosphate | ++ | 5–15 |
| Cystine | + | Rare |
| Uric acid | – | 5 |
| Xanthine | – | Rare |
| Matrix | – | Rare |

with laminated or scattered calcific components. About 30% of pediatric urolithiasis is idiopathic. The typical composition of idiopathic stones is calcium phosphate or calcium oxalate. Idiopathic calcium stones sometimes have a nucleus of urate.[56]

Bladder stones can either originate from the upper urinary tract or develop within the bladder (e-Fig. 114.10). Bladder stones often are laminated and sometimes reach a very large size. Bladder stones also can form in a bladder diverticulum, surgical pouch/reservoir, or urachal remnant.

Urethral calculi are rare and only occur in males (Fig. 114.11). They can originate from a more proximal portion of the urinary tract or arise locally. Primary urethral calculi sometimes develop in association with prolonged obstruction or within a urethral diverticulum or prostatic utricle.

***Clinical Presentation.*** Pain is present in 50% to 75% of children with urolithiasis at the time of diagnosis. Pain can localize to the abdomen or flank, and may or may not radiate. Additional potential clinical manifestations include hematuria (common), urgency, dysuria, frequency, fever, pyuria, and bacteriuria. Urinary retention can occur in patients with stones of the bladder or urethra.

***Imaging.*** From 60% to 90% of urinary tract calculi are sufficiently radiopaque for visualization on standard radiographs (Table 114.2). Classification of a stone as radiopaque versus nonopaque is based on its appearance on standard radiographs (e-Fig. 114.12). In general, calcium stones are radiopaque. Stones composed of pure uric acid, xanthine, or struvite usually are nonopaque. Cystine stones are moderately radiopaque.[57,58]

The European Society of Pediatric Radiology recommends ultrasound as the initial cross-sectional imaging study for children with suspected nephrolithiasis, with reservation of CT for instances of complicated or equivocal urolithiasis.[59–61] Both radiopaque and nonopaque urinary tract stones appear echogenic on sonography and produce acoustic shadowing (Fig. 114.13). Twinkling artifact refers to a discrete focus of alternating colors that can occur at or deep to the site of a calculus on color Doppler images.[62] This is sometimes accompanied by a color comet-tail artifact distal to the stone (Fig. 114.14).[62] Secondary signs of an obstructing ureteral calculus include ureteropelvocalyectasis, nephromegaly, parenchymal hyperechogenicity, and elevated renal arterial resistive index. The sonographic appearance of acoustic shadowing aids in the differentiation of a bladder calculus from blood clot, debris, or tumor.

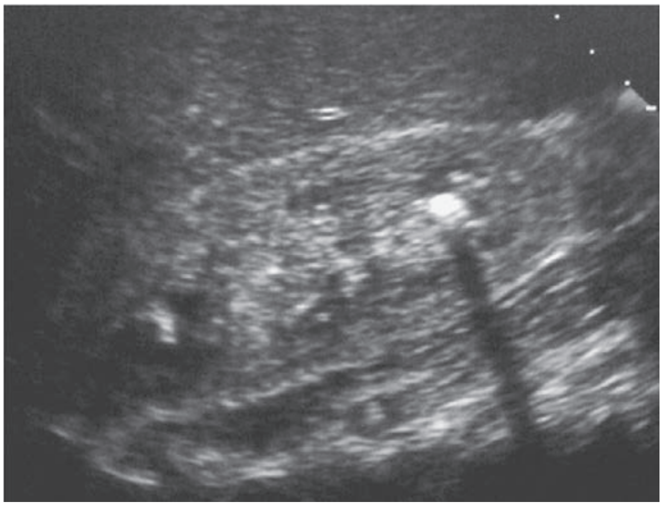

**Figure 114.13. Nephrolithiasis.** Longitudinal sonographic image of an infant with hypercalcemia and Williams syndrome reveals an echogenic, shadowing calculus in a right lower pole calyx.

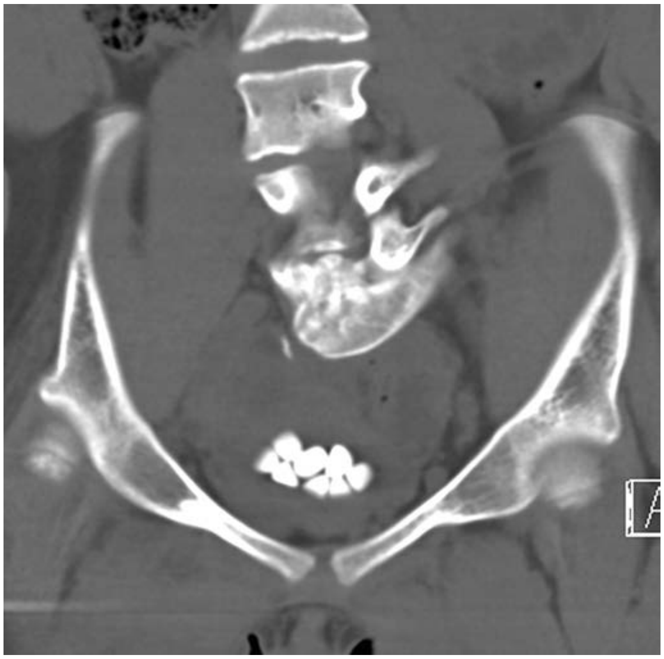
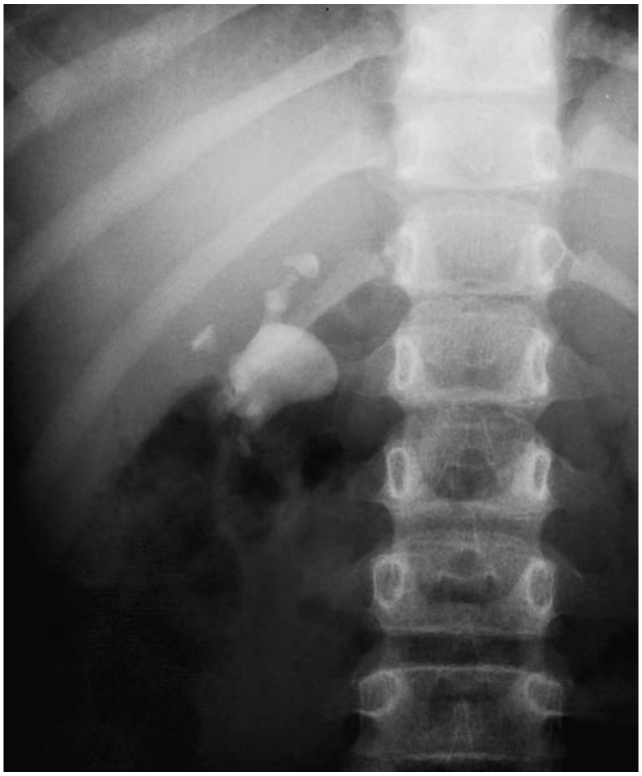
CT is the most sensitive imaging technique for the detection of urolithiasis (Fig. 114.15). Regardless of composition, most urinary tract stones are hyperattenuating on CT. Calcium oxalate stones generally have attenuation values between 800 and 1,000 Hounsfield unit (HU) range, infection stones between 300 to 900 HU, and uric acid stones between 150 and 500 HU. Secondary CT signs of an obstructing urinary tract stone include hydronephrosis, hydroureter, nephromegaly, delayed nephrogram, periureteral edema, and perinephric stranding or fluid. Usually, the portion of the ureteral wall that surrounds a calculus thickens (the "rim sign"); this sign typically is lacking with a phlebolith or other mimicking calcification. A linear soft tissue density (the involved pelvic vein) often extends from a phlebolith; this feature is the "comet tail sign."[58,63,64]

## KEY POINTS

- Renal cortical scintigraphy, contrast-enhanced CT, and MRI are highly sensitive for the detection of parenchymal renal infections.
- Pyelonephritis in children can occur without pyuria or vesicoureteral reflux.
- Pediatric renal candidiasis usually is associated with prematurity or immunocompromise.
- Most children with nephrocalcinosis have hypercalcemia and/or hypercalciuria.
- Most children with urolithiasis have a known predisposing condition such as hypercalciuria, urinary stasis, or chronic infection.



**e-Figure 114.10. Bladder calculi.** Coronal unenhanced CT image shows multiple stones in the urinary bladder of this child with spina bifida.



**e-Figure 114.12. Staghorn calculus.** Large opaque triple phosphate infection stone occupies the renal pelvis and extends into the calyces.

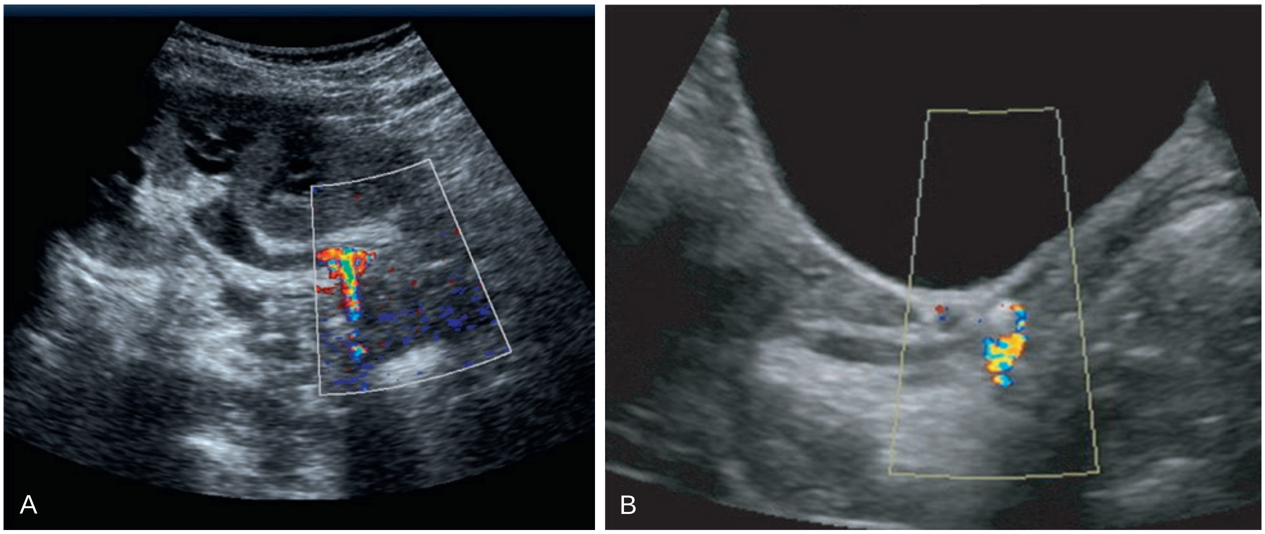


**Figure 114.14. Ureteral calculi showing twinkling artifact.** (A) Longitudinal color Doppler image shows twinkling and associated comet tail artifacts due to a calculus in the proximal aspect of the ureter. (B) Longitudinal color Doppler image shows twinkling and associated comet tail artifacts due to an echogenic calculus in the distal aspect of the ureter.

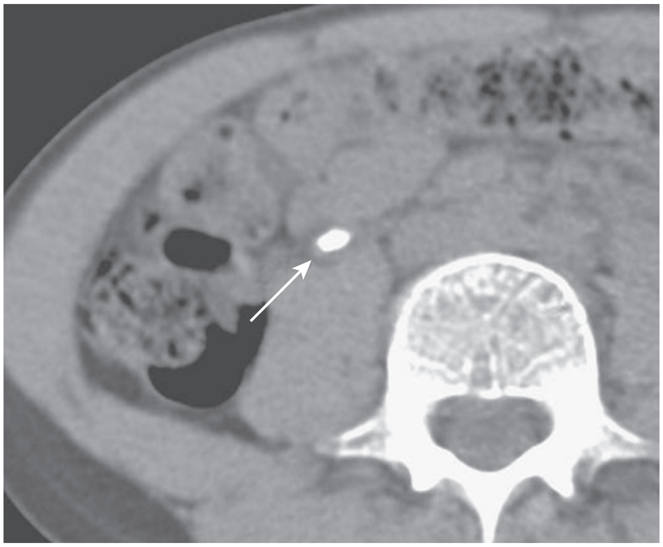

**Figure 114.15. Ureteral calculus.** Unenhanced CT image shows a right ureteral calculus with a surrounding thickened ureteral wall *(arrow)*.

# 115 Renal Neoplasms

Ethan A. Smith and D. Gregory Bates

## NEPHROGENIC RESTS AND NEPHROBLASTOMATOSIS

***Overview and Pathophysiology.*** Embryologic development of the kidneys is completed by the 36th gestational week. Residual embryonic fetal tissue (metanephric blastema) that persists beyond 36 weeks' gestation is called a *nephrogenic rest*. Multifocal or diffuse nephrogenic rests are termed *nephroblastomatosis*. Nephrogenic rests are identified in about 1% of neonatal autopsies. The vast majority of nephrogenic rests resolve spontaneously by 4 months of age. However, approximately 1% of nephrogenic rests will undergo malignant transformation into Wilms tumor (previously known as *nephroblastoma*).[1–3]

Nephrogenic rests can occur anywhere in the kidney and are usually found either within a renal lobule (intralobar) or peripherally within the cortex (perilobar). Intralobar nephrogenic rests develop earlier in nephrogenesis and are more likely to undergo malignant transformation into Wilms tumor. Nephrogenic rests also are classified according to histologic features of development; hyperplastic and neoplastic rests are thought to be active and to have higher malignant potential, whereas dormant or sclerosing nephrogenic rests are considered inactive.[1–4]

Intralobar nephrogenic rests are less common than perilobar nephrogenic rests. Intralobar nephrogenic rests tend to be few and are located randomly in the renal lobe. Intralobar rests are associated with sporadic aniridia, Drash syndrome (male pseudohermaphrodism and nephritis), and WAGR syndrome (Wilms tumor, aniridia, genital anomalies, and mental retardation). Patients with sporadic aniridia have a 30% to 40% risk of Wilms tumor, which represents the greatest likelihood of all of the genetic and syndromic abnormalities associated with nephroblastomatosis.[1–4]

Perilobar nephrogenic rests are often multiple and are located at the corticomedullary junction or in the cortex. Diffuse perilobar nephrogenic rests or diffuse perilobar nephroblastomatosis describes the presence of multiple perilobar rests involving the periphery of the renal cortex. Perilobar nephrogenic rests are associated with hemihypertrophy syndromes, Beckwith-Wiedemann syndrome (macroglossia, macrosomia, and omphalocele), Perlman syndrome (fetal gigantism and multiple congenital anomalies), and trisomy 18. Patients with hemihypertrophy and Beckwith-Wiedemann syndrome have about a 5% risk of developing a Wilms tumor.[1,3–5]

***Imaging.*** Some nephrogenic rests are microscopic and cannot be identified by imaging. Larger nephrogenic rests can be evaluated with ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI). In diffuse perilobar nephrogenic rests, the affected kidney may be enlarged. On sonography, corticomedullary differentiation is absent. Nephrogenic rests and areas of diffuse nephroblastomatosis may be hypoechoic or isoechoic with respect to normal renal cortex. Multifocal nephroblastomatosis is more difficult to identify on sonography due to the diffuse nature of the disease.[2,3,6]

CT is more sensitive than ultrasound for the evaluation of nephrogenic rests and nephroblastomatosis. On contrast-enhanced CT, nephrogenic rests appear as low attenuation lesions that enhance less than normal renal cortex (Figs. 115.1 and 115.2). Bulky masses may distort the pelvicalyceal system. Bilateral involvement may be symmetric or asymmetric. Lenticular or plaquelike lesions may be more difficult to identify on CT than round masses.[2,3,6] In diffuse perilobar nephrogenic rests, a thick rind of low attenuation tissue encases normally enhancing but architecturally distorted parenchyma (e-Fig. 115.3).

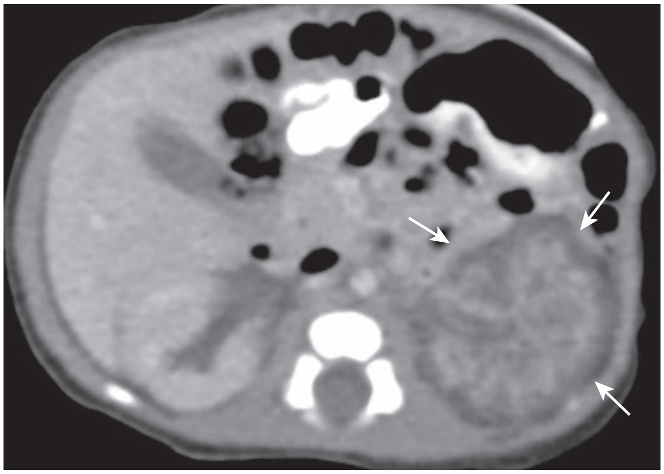
On MRI, nephrogenic rests are isointense to normal renal parenchyma on T1-weighted sequences and isointense to hyperintense on T2-weighted sequences. Similar to CT, nephrogenic rests enhance less than normal renal parenchyma after intravenous gadolinium chelate administration and hence appear as hypointense to enhancing renal parenchyma on T1-weighted postcontrast images. In general, the signal intensity and enhancement of nephroblastomatosis is homogeneous, whereas foci of Wilms tumor tend to be more heterogeneous.[2,3,6–8]

***Treatment and Follow-up.*** Presently, no specific treatment is advocated for nephrogenic rests/nephroblastomatosis unless Wilms tumor develops. Close radiologic follow-up is recommended for children with genetic abnormalities or syndromes associated with nephroblastomatosis. Children with hemihypertrophy or Beckwith-Wiedemann syndrome are at risk for the development of other embryonal tumors, such as hepatoblastoma. No large studies have been performed to establish the optimal screening interval for Wilms tumor surveillance. A baseline CT of patients with nephroblastomatosis-related genetic abnormalities or syndromes at 6 months of age (or at diagnosis if the patient is older than 6 months), followed by surveillance ultrasound examinations every 3 to 4 months until the child is at least 8 years of age, is recommended on the basis of results from the National Wilms Tumor Studies.[2,3,9–13]

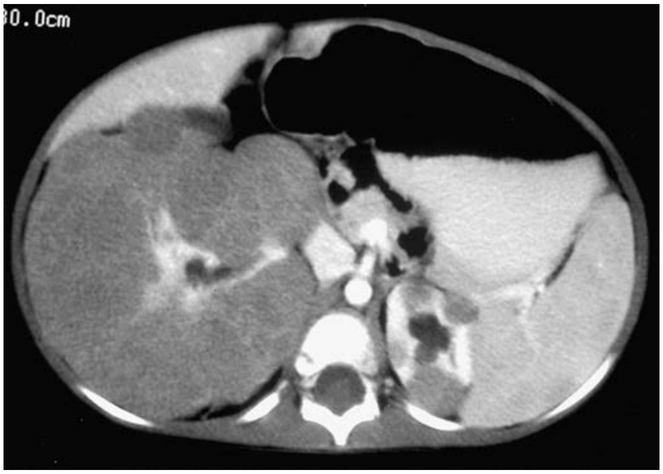
## WILMS TUMOR

***Overview, Pathophysiology, and Staging.*** Wilms tumor is one of the most common abdominal malignancies of childhood, and it accounts for approximately 90% of pediatric renal masses. Its peak incidence is at 3 to 4 years of age (80% occur in children <5 years old), but it has been described in the fetus, neonate, teenager, and adult. Clinical presentation includes a palpable mass, abdominal pain, hematuria, and occasionally hypertension (from tumor renin production). As discussed, certain syndromes and genetic abnormalities predispose to development of a Wilms tumor (e-Fig. 115.4). Two loci on chromosome 11 have been implicated in the genesis of Wilms tumors: 11p13 (*WT1* gene —WAGR or Drash syndrome) and 11p15 (*WT2* gene — Beckwith-Wiedemann syndrome or hemihypertrophy). Approximately 5% of children have bilateral Wilms tumor, and up to 7% have multicentric disease. Most Wilms tumors arise from the renal parenchyma; however, extrarenal Wilms tumors rarely may develop in the abdomen or at distant sites.[1,14–18]

In the United States, tumor stage (Box 115.1) is determined by a combination of preoperative imaging, intraoperative findings, and pathology, while the grade is established on histopathologic examination. Metastatic disease is present in 15% to 20% of patients at presentation and is most commonly seen in the lungs, followed by the liver.[17] The classic triphasic Wilms tumor arises from mesodermal precursors of the renal parenchyma (metanephros) and contains blastemal, stromal, and epithelial elements. The prognosis for tumors with a favorable histology is excellent, even for those at higher stages. Approximately 7% of tumors contain anaplastic elements and have a worse prognosis.[18] In Europe, the staging system is based completely on radiologic findings. Tumors



**e-Figure 115.3. Asymmetric diffuse perilobar nephroblastomatosis.** Axial contrast-enhanced CT image in a neonate shows a rind of hypoenhancing tissue involving the periphery of the left kidney *(arrows)*. The right kidney is normal.



**e-Figure 115.4. Diffuse perilobar nephroblastomatosis and right Wilms tumor.** Axial contrast-enhanced CT image demonstrates round, peripheral masses that enhance to a lesser extent than normal renal parenchyma in the upper pole of the left kidney. The right kidney has a thick rind of lobulated, hypoattenuating tissue without a discrete mass. A biopsy showed Wilms tumor on the right, and a nephrectomy was performed.

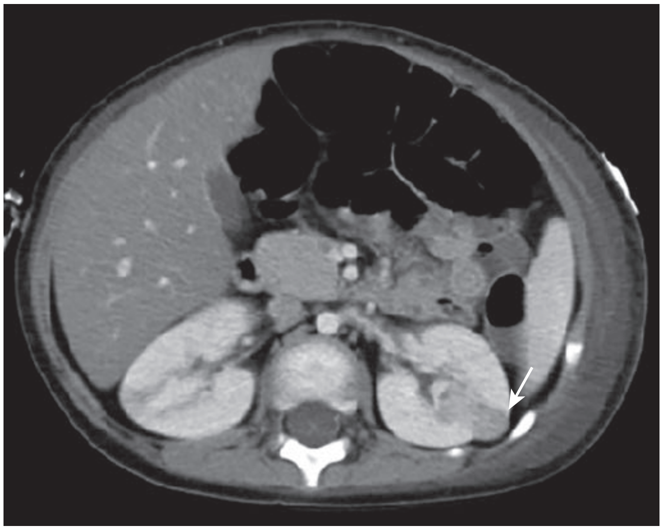


**Figure 115.1. Solitary nephrogenic rest.** Axial contrast-enhanced CT image shows a small, well-circumscribed hypoenhancing mass *(arrow)* in the left kidney.

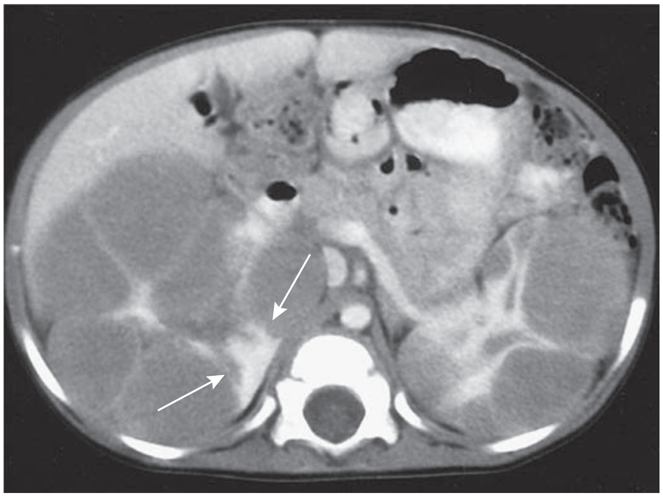

**Figure 115.2. Diffuse perilobar nephroblastomatosis with symmetric involvement.** Axial contrast-enhanced CT image shows enlarged kidneys with multiple, round, peripheral low attenuation masses. Only small areas of normally enhancing kidney tissue *(arrows)* are present.

**BOX 115.1** Children's Oncology Group (COG) Staging of Wilms Tumor

**STAGE I**

- A completely resected tumor limited to the kidney with an intact capsule
- No biopsy or rupture of tumor before removal
- No involvement of vessels or renal sinuses
- No tumor at or beyond the margins of resection
- Regional lymph nodes are negative for tumor

**STAGE II**

- A completely resected tumor
- No tumor at or beyond the margins of resection
- Regional lymph nodes are negative for tumor
- One or more of the following findings:
  - Penetration of the renal capsule
  - Invasion of vasculature extending beyond the renal parenchyma

**STAGE III**

- Residual tumor is present after surgery, confined to the abdomen, with one or more of the following attributes present:
  - One or more regional lymph nodes are positive for tumor
  - The tumor is implanted on or penetrating through the peritoneum
  - The presence of gross unresected tumor or tumor at the margin of resection
  - Any tumor spillage occurring before or during surgery, including biopsy
  - The tumor was removed in more than one piece

**STAGE IV**

- The presence of hematogenous metastasis (e.g., lung, liver, bone, or brain)
- The presence of lymph node metastasis outside the abdomen and pelvis

**STAGE V**

- Wilms tumor in both kidneys

*From Gratias EJ, Dome JS. Current and emerging chemotherapy treatment strategies for Wilms tumor in North America.* Paediatr Drugs. *2008;10(2):115–124.*

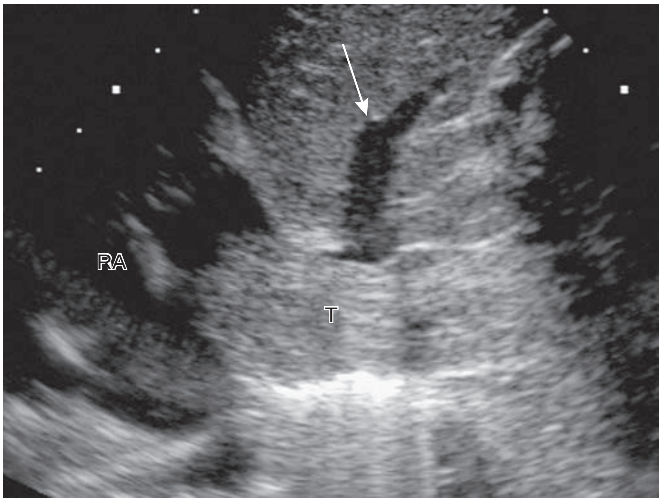
are classified on the basis of their imaging appearance, and chemotherapy is usually given before definitive surgery is performed. In the United States, neoadjuvant chemotherapy is reserved for tumors that are considered unresectable at presentation due to vascular invasion or other features.[1,2,18]

***Imaging.*** Radiologic evaluation of Wilms tumor is focused on identifying the site(s) of involvement, defining local extent of disease to assist in surgical planning, and evaluating for metastases. Preoperative imaging may include conventional radiography, abdominal sonography, and thoracic, abdominal, and pelvic CT, and/or MRI. The role of $F^{18}$-fluorodeoxyglucose positron emission tomography (FDG-PET) fused with CT (PET-CT) at diagnosis is less clear. PET-CT is often reserved for evaluating for residual disease or recurrence after therapy.[1,2,19,20]

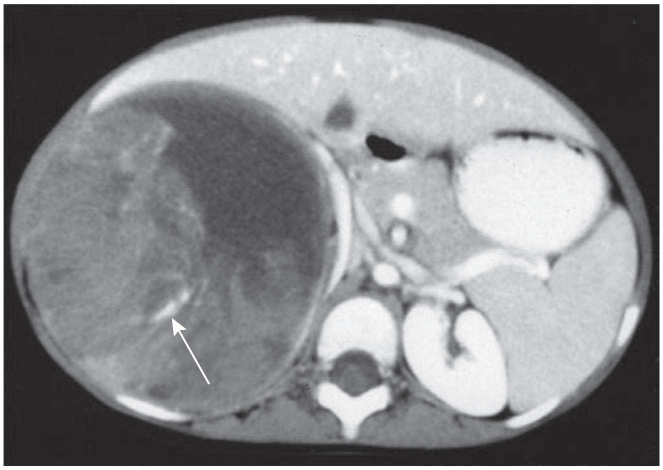
On sonography, Wilms tumor typically appears as a large, heterogeneous intrarenal mass. Some Wilms tumors may contain cystic components, portions of obstructed and entrapped pelvicalyceal systems, or hemorrhagic and necrotic tumor. Identification of vascular invasion with extension into the renal vein, inferior vena cava, or right atrium is important for surgical planning and can be assessed with ultrasound (e-Fig. 115.5), CT (Fig. 115.6), or MRI. The tumor may invade the renal capsule, seed the peritoneal space, or grow directly into the mesentery and omentum. Hepatic metastases, if present, appear as rounded, hypoechoic liver lesions. The contralateral kidney should be carefully evaluated for synchronous Wilms tumor, nephrogenic rests, or nephroblastomatosis.[1,2,6]

On CT, Wilms tumor typically appears as a large, heterogeneous mass arising from the kidney (Fig. 115.7). The tumor enhances to a lesser extent than does normal renal parenchyma. There is characteristically a rim of enhancing renal tissue surrounding at least a portion of the mass (the so-called "claw sign"), confirming the mass to be of renal origin. Calcifications are uncommon, being present in only about 9% of Wilms tumors (e-Fig. 115.8). CT of the chest is used to identify pulmonary metastases.[1,2,6,21,22]

On MRI, a Wilms tumor is isointense with respect to normal renal parenchyma on T1-weighted sequences and heterogeneously hyperintense with respect to normal renal parenchyma on T2-weighted sequences. After administration of intravenous contrast material, a Wilms tumor is typically hypoenhancing relative



**e-Figure 115.5. Wilms tumor extending into the inferior vena cava and the right atrium *(RA)*.** Longitudinal gray-scale ultrasound image demonstrates tumor thrombus *(T)* expanding the inferior vena cava and extending into the right atrium. The tumor partially occludes drainage from one of the hepatic veins *(arrow)*.



**e-Figure 115.8. Wilms tumor containing calcification.** Coronal contrast-enhanced CT image shows a large, heterogeneous renal mass with linear calcification present posteriorly *(arrow)*. Calcification may be dystrophic or indicate teratoid differentiation.

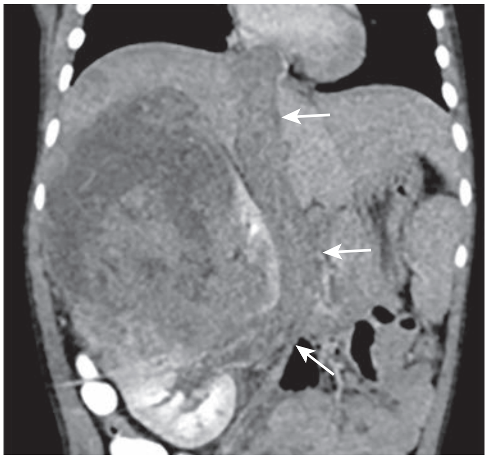


**Figure 115.6. Wilms tumor extending into the inferior vena cava and right atrium.** Coronal contrast-enhanced CT image demonstrates a large right Wilms tumor with heterogeneous soft tissue *(arrows)* filling the right renal vein and IVC, extending to the lower right atrium, consistent with extensive tumor thrombus.

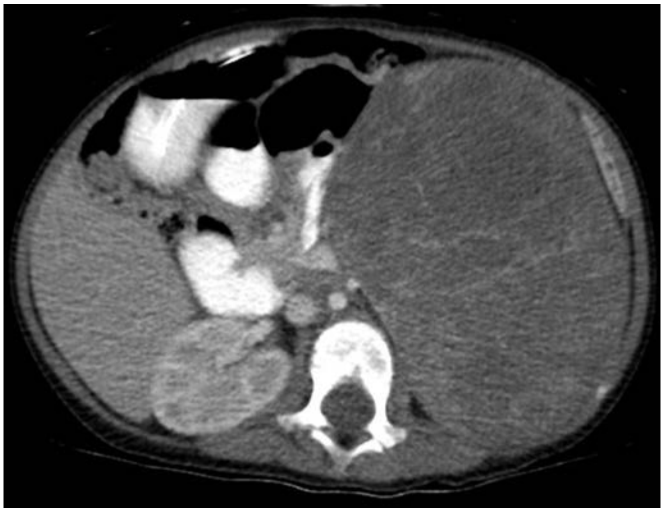

**Figure 115.7. Wilms tumor.** Axial contrast-enhanced CT in a 2-year-old girl shows a large, heterogeneous predominantly low attenuation left renal mass, consistent with Wilms tumor.

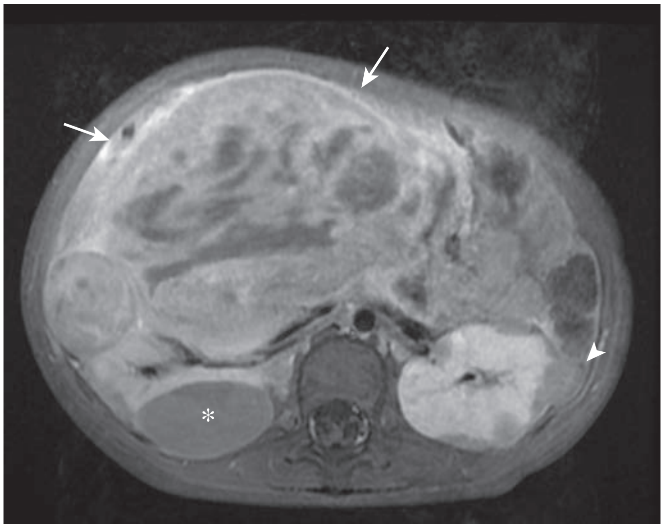

**Figure 115.9. Bilateral Wilms tumor.** Axial T1-weighted postcontrast magnetic resonance (MR) image in a 2-year-old boy shows a large, heterogeneous mass arising from the right kidney *(arrows)*. There is an additional mass in the right kidney *(asterisk)* as well as multiple smaller left renal masses *(arrowhead)*, proven to be multifocal bilateral Wilms tumors.

to normal renal parenchyma (Fig. 115.9). On diffusion-weighted imaging, the tumor typically has heterogeneous signal with areas of impeded diffusion reflecting the high cellularity of the viable tumor. T2-weighted sequences and diffusion-weighted imaging also readily depict liver metastases and enlarged retroperitoneal lymph nodes. Vascular invasion can be assessed on T2-weighted spin-echo images, seen as filling defects instead of the expected vascular flow voids, or as filling defects on T1-weighted postcontrast images.[1,2,7,8,23]

Wilms tumors are typically FDG-avid, but the role of FDG-PET in Wilms evaluation is as yet unclear. FDG-PET can help with a targeted biopsy of a viable Wilms tumor and biologically aggressive elements (e.g., anaplastic Wilms). Currently, FDG-PET is primarily used for evaluating for residual tumor after treatment or confirming local/regional recurrence.[2,19]

***Treatment.*** In the United States, therapy for Wilms tumor depends on the stage and primary resectability of the tumor. Up front *en bloc* resection of the mass and the entire affected kidney is performed if possible, followed by adjuvant chemotherapy. If needed based on disease stage (stage III or IV disease), radiation therapy to the flank, entire abdomen, and/or lungs is considered. If the primary tumor is not initially resectable, or if there is bilateral disease, neoadjuvant chemotherapy is given before resection. In bilateral disease, resection often involves partial nephrectomy as opposed to total nephrectomy to spare as much renal tissue as possible. In Europe, up-front chemotherapy is given before surgery based on data showing possible reduced rates of tumor rupture (stage III disease) when neoadjuvant chemotherapy is given. Ongoing clinical trials are focused on limiting surgical morbidity and therapy-related toxicity, especially with regard to limiting abdominal and pulmonary radiation therapy to only certain subsets of patients. Advancements in therapy over recent decades has resulted in a greater than 90% long-term survival for localized disease and greater than 70% survival for metastatic disease.[1,2,17,18,24–30]

## CLEAR CELL SARCOMA OF THE KIDNEY

***Overview.*** Clear cell sarcoma of the kidney accounts for approximately 5% of primary renal tumors in childhood. Clear cell sarcoma occurs in an age group similar to that affected by Wilms tumor (1–4 years of age) and has a male predominance. No familial or syndromic association has been identified. Immunohistochemical staining has shown no characteristic marker pattern, but negativity to the *WT1* gene is important.

***Imaging.*** Imaging features of the primary tumor are similar to those of Wilms tumor, typically a large, heterogeneous renal mass (Fig. 115.10). Distinct from Wilms tumor, clear cell sarcoma has a predilection for bone metastases (even being formerly known as "the bone-metastasizing renal tumor of childhood"). A pathologic diagnosis of clear cell sarcoma necessitates an evaluation of the skeletal system. Bone scintigraphy or a conventional radiographic skeletal survey may be used. However, metastases to lymph nodes, lung, and liver still are seen more frequently than bone metastases.

***Treatment.*** Due to the aggressive behavior of clear cell sarcoma, it is associated with a higher rate or relapse and mortality than Wilms tumor, with a reported long-term survival of 60% to 70%. Treatment consists of nephrectomy and aggressive chemotherapy.[1,31–38]

## RHABDOID TUMOR OF THE KIDNEY

***Overview.*** Rhabdoid tumor of the kidney accounts for 2% of pediatric renal malignancies. The name is derived from its monomorphous histologic appearance resembling that of skeletal muscle, although a myogenic origin has not been proved. Rhabdoid tumors occur in a younger age group than do Wilms tumors (80% occur in children younger than 2 years of age). The most common clinical presentation is hematuria secondary to invasion of the renal pelvis.

***Imaging.*** Rhabdoid tumors of the kidney also have imaging characteristics similar to those of Wilms tumors. Imaging features that may suggest the diagnosis include subcapsular fluid collections, medial location within the kidney, and tumor lobules separated by low-density hemorrhage or necrosis with peripheral calcifications. These tumors are highly aggressive, metastasize early, and often present with advanced disease. A distinct association with synchronous or metachronous primary or metastatic central nervous system lesions is seen, often in the posterior fossa. Primitive neuroectodermal tumors, medulloblastomas, ependymomas, and cerebellar and brainstem astrocytomas all have been reported. After tissue diagnosis of rhabdoid tumor of the kidney, MRI of the brain is often recommended.

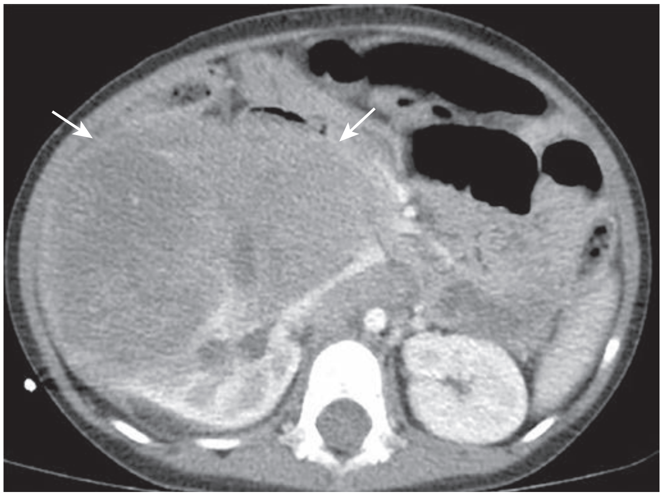

**Figure 115.10. Clear cell sarcoma of the kidney.** Axial contrast-enhanced CT image in an 18-month-old girl shows a large heterogeneous mass in the right kidney *(arrows)* found to be clear cell sarcoma of the kidney at pathology. This mass is indistinguishable from Wilms tumor.

***Treatment.*** Rhabdoid tumors have a poor prognosis, with an 18-month survival of only 20%. Treatment includes nephrectomy, radiation therapy to the tumor bed, and aggressive chemotherapy.[1,39–46]

## CONGENITAL MESOBLASTIC NEPHROMA

***Overview.*** Congenital mesoblastic nephroma (CMN) is the most common solid renal tumor in infants under 6 months of age and is typically identified within the first 3 months of life. Originally thought to represent a congenital Wilms tumor, it is now recognized as a distinct neoplasm. Clinical presentation is that of a palpable abdominal mass and, less frequently, hematuria. Histologically, the tumor is composed of monomorphic infiltrating spindle-shaped mesenchymal cells and embryonal metaplasia of entrapped renal tissue. CMN is subtyped into classic, cellular, and mixed forms.

***Imaging.*** CMN tends to be a large heterogeneous mass, often with poorly defined margins and lacking a capsule. At ultrasound, CMN is a predominantly solid intrarenal mass but may contain cystic components. The mass may distort and displace the pelvicalyceal system. On CT, CMN may show homogeneous or heterogeneous enhancement, is unilateral and unifocal, displaces adjacent vasculature without invasion, and typically does not have calcifications (Fig. 115.11). Low attenuation foci representing necrosis, fluid-filled cysts, or hemorrhage may be seen. On MRI, the tumor typically has a low signal on T1-weighted images (although foci of hemorrhage may be hyperintense) and has a variable signal on T2-weighted sequences. After intravenous contrast administration, the mass is typically heterogeneously enhancing but may also demonstrate homogeneous enhancement.

***Treatment.*** Complete surgical excision is the treatment of choice. CMN is associated with a favorable outcome after complete surgical resection. However, the cellular variant (resembling congenital infantile fibrosarcoma and often sharing a common chromosomal translocation) is associated with local recurrences (10%) and metastases. Adjuvant chemotherapy is not recommended

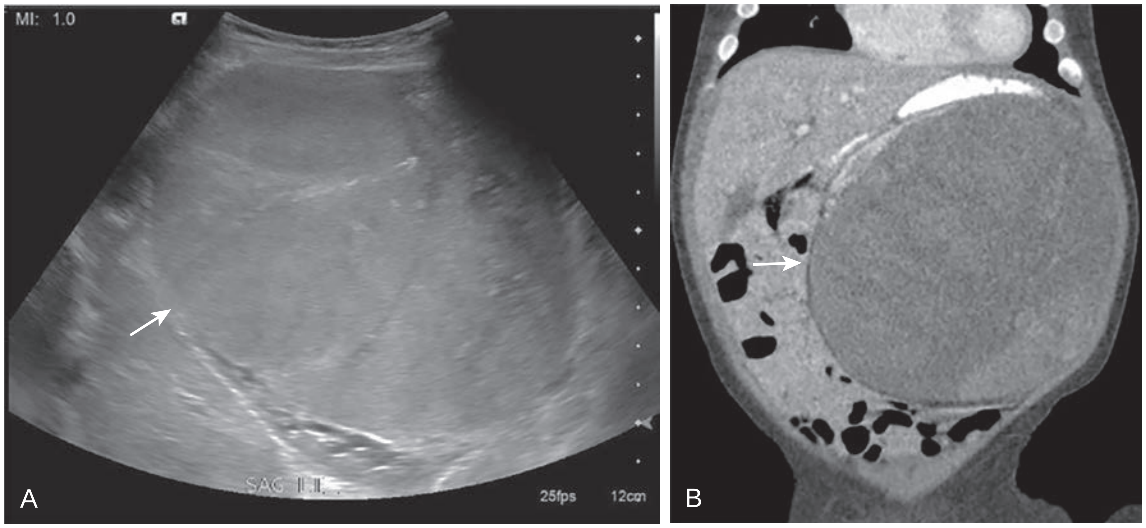

**Figure 115.11. Congenital mesoblastic nephroma.** (A) Longitudinal gray-scale ultrasound image shows a large, solid mass *(arrow)* arising from the left kidney in a 3-month-old boy. (B) Coronal contrast-enhanced CT image in the same child shows the mass *(arrow)* to be heterogeneously hypoenhancing. The “claw sign” is present.

if complete resection is feasible in either classic or cellular variants of CMN.[1,47–53]

## MULTILOCULAR CYSTIC RENAL TUMOR

***Overview and Pathophysiology.*** Multilocular cystic renal tumor occurs predominantly in boys during infancy and early childhood (3 months to 4 years) and in women during their seventh and eighth decades.[54] Multilocular cystic tumors with fibrous septa that contain mature tubules are called *cystic nephroma*. When the cystic mass has blastemal elements within its septa, it is called a *cystic partially differentiated nephroblastoma*. While multilocular cystic tumors can be sporadic, an association with the *DICER1* mutations is becoming more frequently recognized. *DICER1* mutations are also associated with pleuropulmonary blastoma, multinodular goiter and thyroid cancer, and sex cord-stromal tumors of the gonads.[55]

***Imaging.*** Partially differentiated cystic nephroblastomas and cystic nephromas cannot be distinguished from one another on the basis of imaging features. The multilocular cystic renal tumor may involve the entire kidney or only a small portion of it. Ultrasound is more sensitive than CT for identification of septa (Fig. 115.12). The lesions are typically well-circumscribed masses of multiple anechoic cysts varying in size from a few millimeters to several centimeters. Unilocular tumors are less common but do occur. One characteristic imaging feature is extension of the mass toward the renal pelvis. In a recent series of 44 cystic nephromas, all lesions abutted the renal pelvis and 42% had visible herniation into the renal pelvis on imaging.[55] On contrast-enhanced CT and MRI, the septa enhance but the locules do not enhance, and contrast material does not accumulate within individual locules (Figs. 115.12 and 115.13). Small curvilinear calcifications may rarely be present.[55]

***Treatment.*** Surgical excision generally is curative, and the prognosis is excellent. Local recurrence may occur if the tumor is incompletely excised. Metastases have not been reported. In the setting of *DICER1* mutation, additional imaging to investigate for other phenotypical features, such as pleuropulmonary blastoma, should be considered.[1,54–66]

## RENAL CELL CARCINOMA

***Overview.*** Renal cell carcinoma (RCC) is rare in the first two decades of life and accounts for approximately 5% of all pediatric renal tumors. Increasing evidence indicates that RCC in children differs from adult RCC in biology and behavior. Translocation RCC accounts for most instances of childhood RCC and generally involves the *TFE3* gene on chromosome Xp11.2 and less commonly the *TEFB* gene on chromosome 6p21. Prior chemotherapy currently is the only known risk factor for the development of Xp11 translocation RCC. Children with tuberous sclerosis complex,

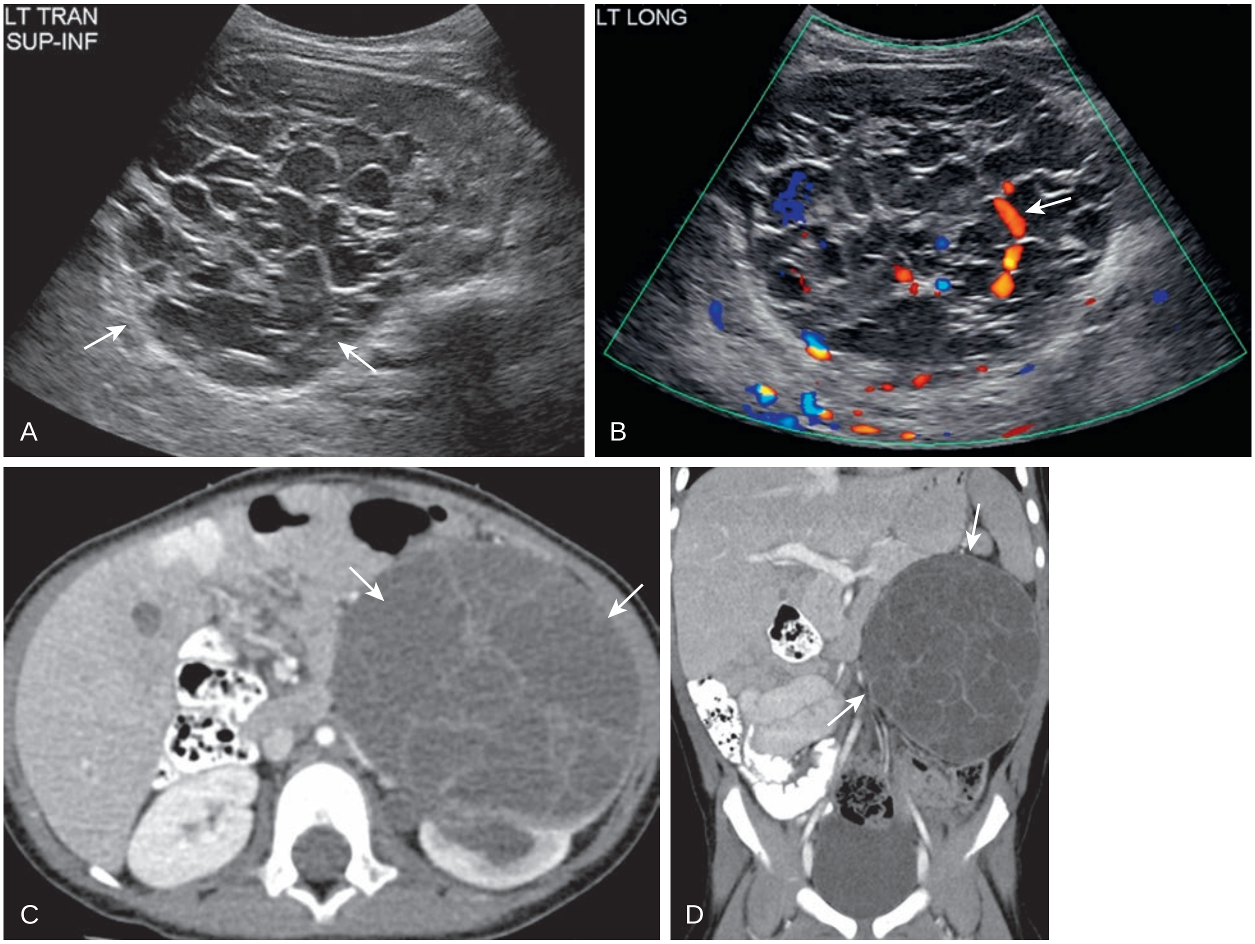

**Figure 115.12. Cystic nephroma.** (A) Transverse gray-scale ultrasound image of the left kidney shows a cystic mass *(arrows)* that contains many septa and locules of varying sizes. (B) Longitudinal color Doppler ultrasound image shows blood flow within the septations *(arrow)*. (C) Axial and (D) coronal contrast-enhanced CT images demonstrate a large hypoattenuating mass *(arrows)* arising from the left kidney with multiple thin septa. There is mild left pelvicaliectasis due to mass effect.

von Hippel-Lindau syndrome, and neuroblastoma appear to be at increased risk for the development of RCC. Wilms tumors outnumber RCCs in the first decade of life by a ratio of 30:1. During the second decade of life, a solid renal mass is equally likely to be an RCC or a Wilms tumor. Clinical presentation includes gross hematuria, flank pain, and a palpable abdominal mass. Fever, hypercalcemia, polycythemia, and hypertension are uncommon.

***Imaging.*** Although an RCC tends to be smaller than a Wilms tumor, its morphology can be similar, and the two can be indistinguishable preoperatively. Ultrasound, CT, and MRI will all show a solid, heterogeneous mass with variable necrosis, hemorrhage, calcification, and cystic degeneration (Fig. 115.14).[67] The tumor invades locally and spreads to retroperitoneal nodes. Vascular invasion into the renal vein and inferior vena cava (IVC) is also possible. Metastases to the lungs, bones, liver, or brain are found in 20% of patients at diagnosis.

***Treatment.*** Staging of RCC uses the Tumor, Node, Metastasis (TNM) system. The standard therapy for RCC in children and adolescents remains radical nephrectomy. RCC is often relatively resistant to systemic chemotherapy or radiotherapy. Nephron-sparing surgery currently is recommended only in adults, although it may be considered in children with predisposing conditions, such as von Hippel-Lindau syndrome. Retroperitoneal lymph node dissection remains controversial in children. Overall survival rates are approximately 50% to 60%, with the best prognosis for localized disease confined to the kidney. Xp11 translocation RCC has the potential to metastasize late, as many as 20 or 30 years after diagnosis.[1,68–79]

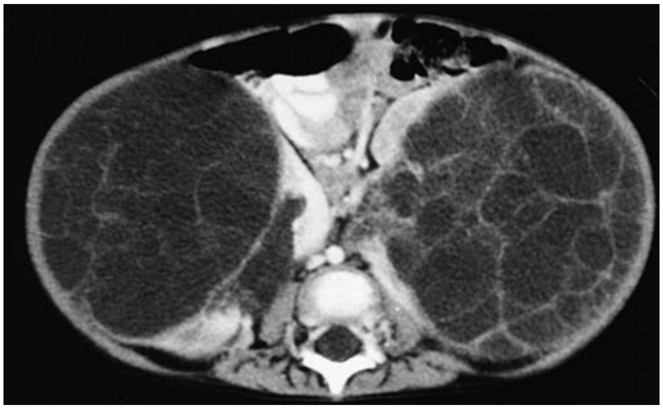

**Figure 115.13. Bilateral, partially differentiated cystic nephroblastoma.** Axial contrast-enhanced CT image shows multiple thin septa coursing through the bilateral renal low-attenuation masses. Both masses bulge into the renal hilar region.

## MEDULLARY CARCINOMA OF THE KIDNEY

***Overview.*** Medullary carcinoma of the kidney was described as a distinct entity in 1995. It is a highly aggressive malignant tumor of epithelial origin that appears almost exclusively in patients with the sickle cell trait or hemoglobin SC disease. The tissue of origin appears to be within the calyceal epithelium, a common region of papillary necrosis in the hemoglobin SC population. The mean age at presentation is 20 years (range, 10–39 years). A male-to-female ratio of 3:1 is seen in patients younger than 25 years. Presenting symptoms include gross hematuria, abdominal or flank pain, a palpable mass, and weight loss. Medullary carcinoma spreads aggressively with metastatic disease to regional lymph nodes and the lungs.

***Imaging.*** Medullary carcinomas develop in the renal medulla, infiltrate the cortex, encase the renal pelvis, invade the lymphatics and vasculature, and have a predilection for the right kidney. Ultrasound, CT, and MRI will all show a centrally located, infiltrative lesion with peripheral caliectasis, reniform enlargement, and peripheral satellite nodules (Fig. 115.15). The tumor has a heterogeneous echotexture on ultrasound and shows heterogeneous enhancement on CT and MRI secondary to intratumoral hemorrhage and extensive necrosis. CT and MRI also excellently depict collecting system involvement and metastatic disease to the regional lymph nodes.

***Treatment.*** Treatment includes a combination of surgery, aggressive chemotherapy, and radiation. The tumor generally responds poorly to therapy, with a mean survival of 15 weeks from diagnosis.[1,80–83]

## RENAL ANGIOMYOLIPOMA

***Overview.*** Angiomyolipomas are lesions consisting of a disordered arrangement of vascular, smooth muscle, and fatty elements. Histologic composition suggests a hamartoma, but currently angiomyolipomas are thought to represent a true neoplasm. In children, angiomyolipomas are rare in the absence of tuberous sclerosis. Angiomyolipomas also are associated with neurofibromatosis and von Hippel-Lindau syndrome. These lesions are usually asymptomatic; however, larger lesions (over 4 cm) are susceptible to spontaneous hemorrhage, resulting in flank or abdominal pain, hematuria, and severe retroperitoneal hemorrhage.

***Imaging.*** The imaging appearance of angiomyolipomas is variable depending on the histologic contents. CT and MRI are diagnostic when macroscopic fat is identified within the lesion,

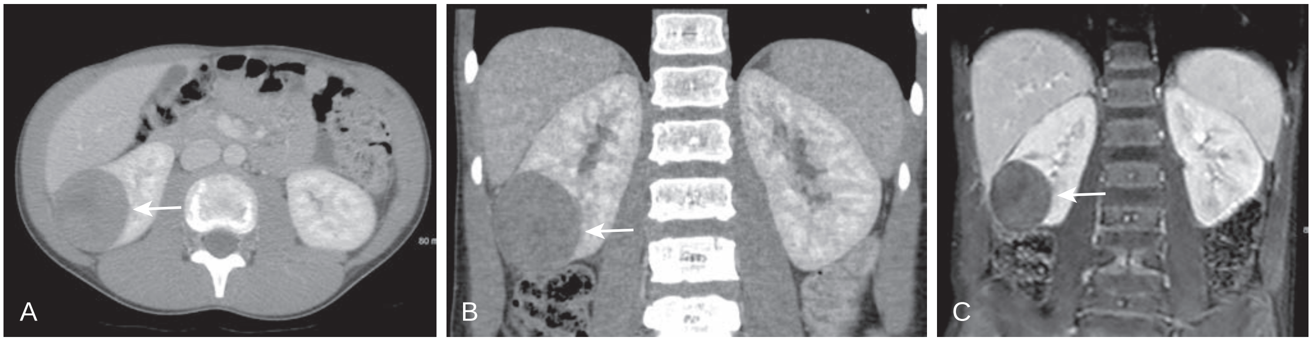

**Figure 115.14. Renal cell carcinoma.** (A) Axial and (B) coronal contrast-enhanced CT images in a 12-year-old boy show a well-circumscribed, mildly heterogeneous mass arising from the lower pole of the right kidney *(arrow)* found to be renal cell carcinoma at histopathology. (C) Coronal T1-weighted postcontrast MR image in the same patient shows the mass *(arrow)* to be hypoenhancing compared with normal renal tissue.

remembering that fat may very rarely be seen in Wilms tumors and RCCs. In addition to traditional T1-weighted MRI and fat suppression techniques, Dixon techniques can be used to definitely show the presence of fat. Fat can also be identified as areas of hyperechogenicity at US. Sporadic lesions are rare and are usually unilateral, while bilateral lesions often are seen in persons with tuberous sclerosis (Fig. 115.16). Angiomyolipomas without visible fat are commonly hypointense on T2-weighted MRI sequences and may be indistinguishable from other solid renal masses at CT and MRI. On angiography, angiomyolipomas demonstrate characteristic tortuous, dilated vessels with aneurysm formation.

***Treatment.*** Lesions larger than 4 cm may be selectively embolized or surgically removed to prevent a life-threatening hemorrhage. Serial imaging to monitor angiomyolipoma size is recommended every 2 to 3 years before puberty and then annually after puberty.[1,84–93]

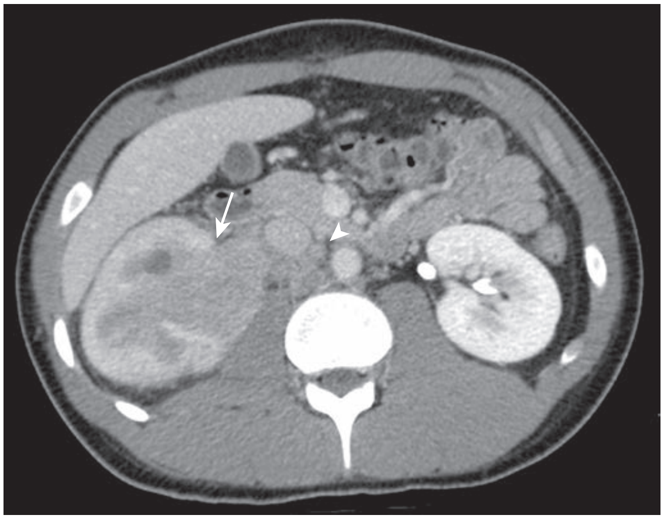

**Figure 115.15. Medullary carcinoma of the kidney.** Axial contrast-enhanced CT image in an 18-year-old young man with sickle cell trait demonstrates an infiltrative, enhancing mass involving the right renal hilum and central portion of the kidney *(arrow)*. There were multiple prominent and mildly enlarged retroperitoneal lymph nodes *(arrowhead)*, and tumor extended into the proximal right ureter.

## RENAL LYMPHOMA

***Overview.*** Lymphomatous involvement of the kidney is due to hematogenous spread or direct extension from retroperitoneal sites. The kidney normally does not contain lymphoid tissue, and for this reason, primary renal lymphoma is rare. In children, non-Hodgkin lymphoma (especially Burkitt lymphoma) is most common. Lymphomatous involvement of the kidney typically does not produce symptoms until late in its course. Flank pain, abdominal pain, hematuria, anemia, weight loss, and a palpable mass are most common.

***Imaging.*** The most common imaging pattern is multiple parenchymal masses distorting the collecting system; less common findings are a solitary renal mass, diffuse infiltration, and isolated perinephric disease. Both CT and MRI are better than sonography for locating renal lesions and identifying extension into adjacent structures. On CT and MRI, multiple round homogeneous and hypoenhancing masses are seen (Fig. 115.17). The findings of perinephric disease include thickening of Gerota fascia, soft tissue nodules, or soft tissue plaques that are typically hypoenhancing relative to normal enhancing renal parenchyma. On sonography, the lesions are typically hypoechoic, with frequent through transmission. Hypoechoic, isoechoic, and hyperechoic subcortical masses all have been described (e-Fig. 115.18). Lymphomatous lesions, however, may be occult or may present as diffuse nephromegaly because of tumor infiltration as the only finding.[1,94–100]

## OSSIFYING RENAL TUMOR OF INFANCY

***Overview.*** Ossifying renal tumor of infancy is an exceedingly rare benign renal mass. The age at presentation ranges from 6 days to 14 months. Hematuria is the presenting symptom. Histologically, the lesion consists of an osteoid core, osteoblasts, and spindle cells.

***Imaging.*** At imaging, ossifying renal tumor of infancy is a small renal mass (usually 2–3 cm) arising from the papillary region of the renal pyramid and extending into the collecting system, with or without evidence of obstruction. Calcifications are typically present, with hyperechogenicity and posterior acoustic shadowing on US, high attenuation on CT, and signal loss on MRI.

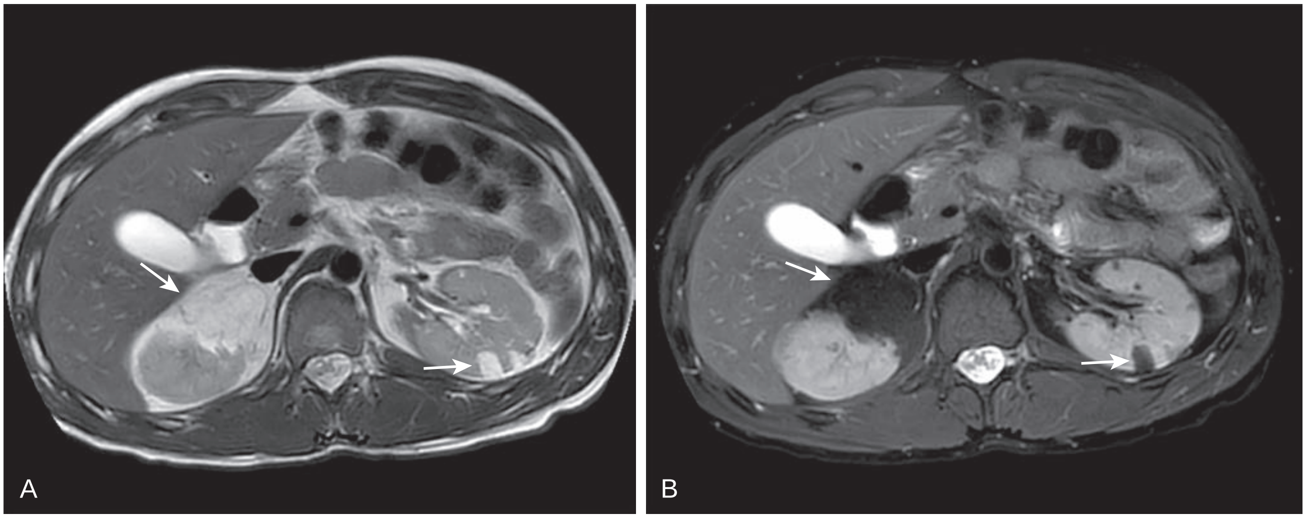

**Figure 115.16. Angiomyolipomas of the kidneys.** (A) Axial T2-weighted MR image without fat saturation in a teenage boy with tuberous sclerosis demonstrates multiple hyperintense masses *(arrows)* in both kidneys. (B) The same lesions all lose signal on a T2-weighted fat-saturated MR image at the same level, confirming the presence of macroscopic fat *(arrows)*.

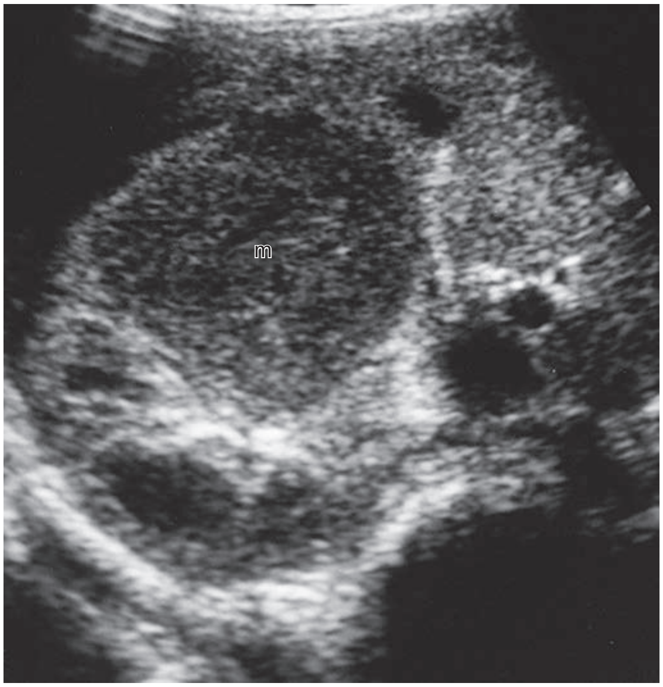

**e-Figure 115.18. Non-Hodgkin lymphoma of the kidney.** Transverse gray-scale ultrasound image of the right kidney demonstrates a hypoechoic mass *(m)* that is replacing the anteromedial portion of the kidney.

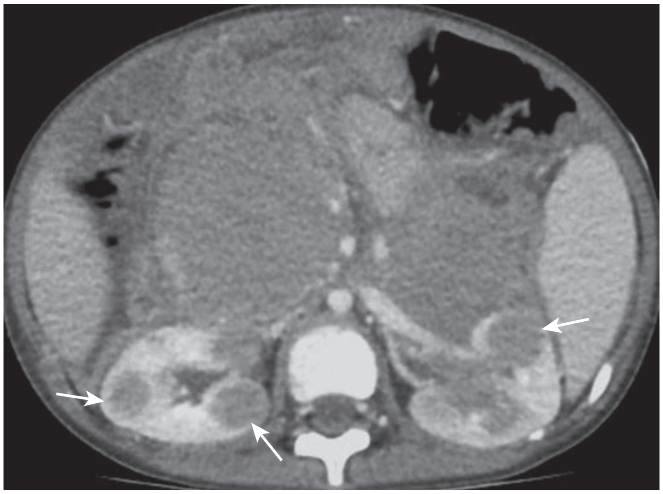

**Figure 115.17. Non-Hodgkin (Burkett) lymphoma of the kidneys.** Axial contrast-enhanced CT image in a 5-year-old boy with abdominal pain shows multiple, bilateral round hypoattenuating renal masses *(arrows)*. There is extensive lymphomatous involvement of the mesentery and omentum as well.

***Treatment.*** The treatment is resection; either complete or partial nephrectomy was performed in the reported cases. The biologic behavior appears to be benign, with no case of malignant spread or postsurgical disease at follow-up.[1,101–103]

## KEY POINTS

- Nephroblastomatosis commonly regresses and resolves spontaneously; however, it may degenerate into a Wilms tumor.
- Children with genetic and syndromic abnormalities associated with nephroblastomatosis should be screened for Wilms tumor by ultrasound.
- The imaging features of clear cell sarcoma of the kidney are similar to those of Wilms tumor, and it has a predilection for bone metastases.
- Rhabdoid tumor of the kidney has the worst prognosis of all of the childhood renal tumors and is associated with primary or metastatic central nervous system lesions.
- CMN is the most common primary renal mass in infants under 6 months of age.
- Multilocular cystic renal tumors occur in two distinct age and gender groups: young boys and adult women.
- RCC in children differs from adult RCC in biology and behavior.
- Life-threatening retroperitoneal hemorrhage is a complication of angiomyolipomas; the risk of hemorrhage increases in lesions that are larger than 4 cm.
- Medullary carcinoma of the kidney is a highly aggressive malignant tumor of epithelial origin that occurs almost exclusively in patients who have sickle cell trait or hemoglobin SC disease.

# 116 Vascular Conditions

Robert G. Wells

## RENOVASCULAR HYPERTENSION

***Overview.*** Approximately 5% to 10% of children and adolescents with severe hypertension have an underlying renal vascular lesion. In children younger than 5 years, up to 80% of clinically significant hypertension is due to renovascular disease. There are myriad developmental and acquired causes of renovascular hypertension (Box 116.1). A complication related to umbilical artery catheterization is the most common cause of renovascular hypertension in neonates. In older children, renal arterial dysplasia is the most common cause.[1–5]

***Imaging.*** Renal size asymmetry on sonography is an important sign of possible renovascular hypertension, as the affected kidney often is small. The examination should include assessment of the renal vessels and aorta with gray-scale and color Doppler images, as well as spectral Doppler of the renal arteries and suprarenal aorta. In children, the most specific diagnostic sonographic findings for renovascular hypertension are visualization of a stenosis on color Doppler images (with turbulent flow and aliasing) and a tardus-parvus spectral Doppler pattern distal to the stenosis (slow systolic acceleration and diminished peak systolic velocity, often associated with a decreased resistive index) (Fig. 116.1). Objective criteria for poststenotic blood flow alterations include acceleration index <300 cm/sec[2] and acceleration time >70 msec; there is commonly flattening of the systolic peak. Measurements at the stenotic segment show a renal artery-to-aorta peak systolic velocity ratio >3.5 and a peak systolic velocity of >200 cm/s.[6–11]

The most useful scintigraphic technique for detection of renovascular hypertension involves the evaluation of renal function without and with the use of an angiotensin-converting enzyme inhibitor, usually captopril or enalaprilat. Tc-99m mercaptoacetyltriglycine (MAG3) is the optimal imaging agent for this study. In the presence of renovascular disease, imaging in conjunction with angiotensin-converting enzyme inhibitor therapy typically shows diminished perfusion, diminished initial uptake, and poor parenchyma clearance of the affected kidney. Comparative imaging in the absence of the medication shows improved function (Fig. 116.2).[12] However, children often have segmental arterial or smaller disease, making perfusion changes difficult to detect, and thus scintigraphy has a limited role in children.

Computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) are noninvasive techniques for visualization of renal vascular anatomy. Upon administration of contrast material, global and regional alterations in kidney perfusion and function also can be assessed. Both of these modalities have limited sensitivity for detecting intrarenal stenoses.

Transcatheter angiography remains the gold standard technique for detection and characterization of renal arterial stenosis and should be considered when noninvasive tests are nondiagnostic, or when there is a clinical suspicion of small vessel disease. In general, >50% narrowing of the renal arterial diameter is hemodynamically significant. The presence of enlarged collateral pathways is an additional indicator of significant renal artery stenosis. Transcatheter renal vein renin sampling is useful in selected cases of suspected renal hypertension (e-Fig. 116.3).[13–15]

## RENAL ARTERY DYSPLASIA

***Overview.*** Renal artery dysplasia (commonly referred to as *fibromuscular dysplasia*, or FMD) is the most common cause of renal artery stenosis in children (Fig. 116.4). Hypertension is the typical presenting feature; other potential clinical findings include headaches and an abdominal bruit. Subcategorization of FMD is based on the layer of the arterial wall that is involved.[16–22]

### Primary Intimal Fibroplasia

Primary intimal fibroplasia is characterized by circumferential accumulation of collagen subintimally and within the internal elastic membrane. This form is the most common cause of renal artery stenosis in children. Imaging shows a smooth, bandlike, tubular, or funnel-shaped stenosis that usually involves the distal two-thirds of the renal artery or a branch vessel.

### Perimedial or Subadventitial Fibrodysplasia

Perimedial or subadventitial fibrodysplasia involves collagen deposition in the outer border of the media over a variable length of the renal artery. Angiography typically shows severe long-segment beaded narrowing of the renal artery. This disease occurs almost exclusively in girls older than 10 years of age. About 15% of patients have bilateral involvement.

### Fibromuscular Hyperplasia

Fibromuscular hyperplasia is an extremely rare vasculopathy. Concentric thickening of the renal arterial wall is due to proliferating smooth muscle and fibrous tissue. Angiographically, this lesion appears as a smooth stenosis of the renal artery or its branches. The appearance often is indistinguishable from that of intimal fibroplasia.

### Medial Fibroplasia

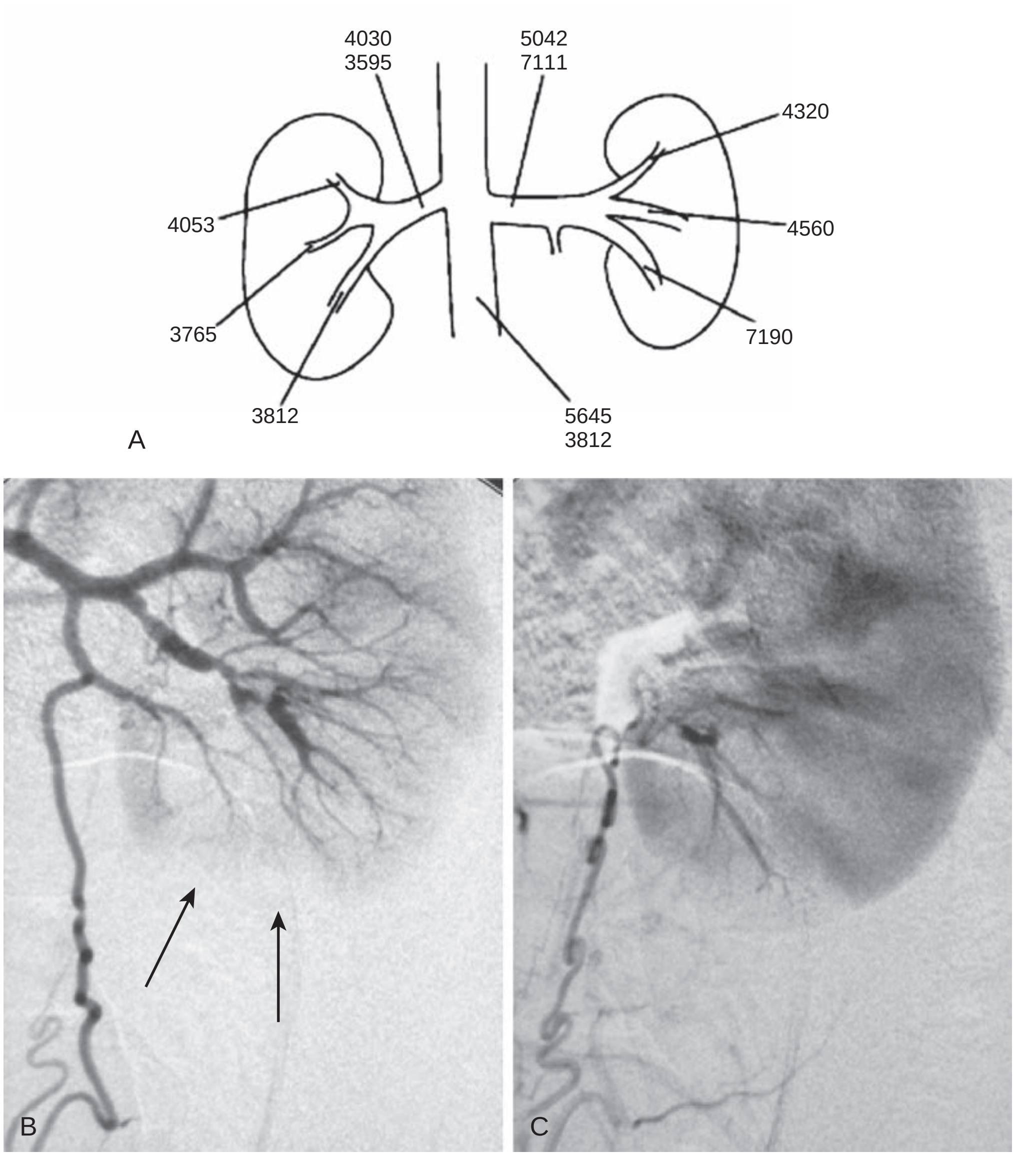
Medial fibroplasia is rare in children. Alternating areas of focal thinning of the internal elastic membrane and focal collagenous thickening of the medial muscular layer are present. Angiographically, there is a “string-of-beads” appearance, typically involving the distal two-thirds of the main renal artery and its branches. Areas of dilation between stenoses are usually greater in caliber than the normal renal artery.

## NEUROFIBROMATOSIS TYPE 1

The most common vascular pathology in patients with neurofibromatosis type 1 is stenosis of the aorta or a large branch vessel. Occasionally, an aneurysm occurs. In the kidney, a small-vessel mesodermal dysplasia also can occur. Arterial stenosis in these patients is often long and tapered.[22–24]

## TAKAYASU ARTERITIS

Takayasu arteritis is a rare idiopathic chronic inflammatory vasculitis. Hypertension due to stenosis of a renal artery or the suprarenal aorta is common. Computed tomography (CT) and magnetic resonance imaging (MRI) features of Takayasu arteritis include luminal narrowing, mural thickening, adherent thrombus, and mural calcification of the aorta, pulmonary arteries, and major aortic branch vessels. With active disease, the thickened vascular wall has prominent contrast enhancement at CT and MRI, and



**e-Figure 116.3. Hypertension in an 11-year-old girl.** (A) Map of renal vein renin activity shows that the hypertension is driven by a focus in the left lower pole. (B) Arterial phase angiography shows complex segmental stenoses, an area of delayed perfusion owing to a "missing vessel" *(arrows)*, and a prominent collateral ureteric artery. (C) Capillary phase angiography shows that the ureteric artery collateral reconstitutes the "missing vessel," completing the nephrogram. *(From Roebuck DJ. Paediatric interventional radiology.* Imaging*. 2001;13:302–320.)*

### BOX 116.1 Causes of Renovascular Hypertension in Children

**Renal Artery (Fibromuscular) Dysplasia**

**Inflammatory Disease**

- Vasculitis (e.g., Takayasu arteritis)
- Moyamoya disease
- Irradiation

**Genetic Disorders**

- Williams syndrome
- Neurofibromatosis type 1
- Feuerstein-Mims syndrome (Schimmelpenning syndrome)
- Degos disease
- Marfan syndrome

**Atherosclerosis**

- Hyperlipidemias

**Vascular Anomaly**

may appear T2 hyperintense; periarterial inflammation may also be seen (Fig. 116.5).[25–27]

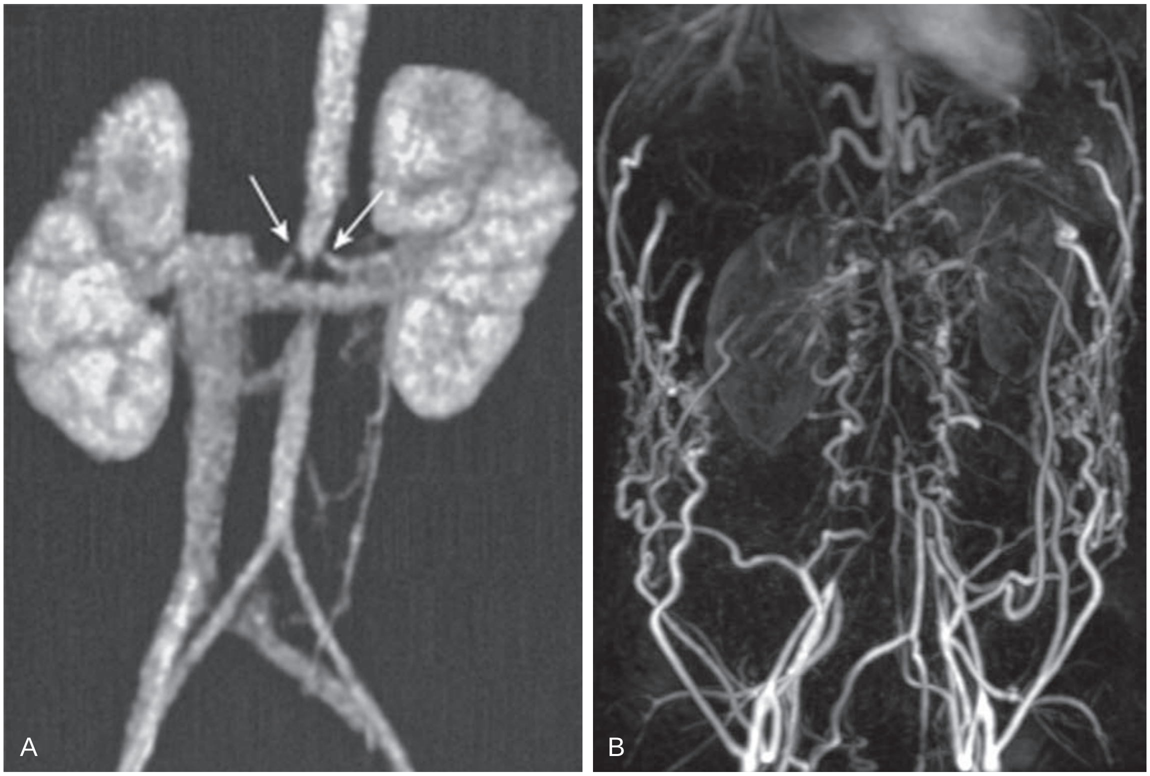
## MIDDLE AORTIC SYNDROME

Middle aortic (or midaortic) syndrome is an often progressive vascular disorder that involves the midthoracic through abdominal segments of the aorta. Most affected individuals also have narrowing of major visceral branches, including the renal arteries. Imaging shows diffuse narrowing or even absence of the thoracoabdominal segment of the aorta and the major branch vessels (e-Fig. 116.6 and Fig. 116.7). If renal artery narrowing is severe, collateral flow to the kidneys usually occurs via ureteral, adrenal, and gonadal arteries that fill from lower intercostal vessels.[28,29] Middle aortic syndrome appearance may be caused by a congenital malformation, developmental arterial dysplasia, neurofibromatosis type 1, vasculitis (including radiation-induced), and rarely Williams syndrome.

## RENOVASCULAR TRAUMA

***Overview.*** Potential renal arterial injuries include intimal disruption, main renal artery avulsion, branch vessel transection, false aneurysm, and arteriovenous fistula. Most renal injuries in children result from blunt trauma; penetrating injuries are uncommon. The intimal layer is most susceptible to a stretching injury because it is less elastic than the media and adventitia. An intimal tear can precipitate dissection, luminal occlusion, or thrombosis. Stretching injury also can cause spasm of the renal artery without a tear. With severe, rapid motion of the kidney, vascular avulsion can occur. Penetrating injuries and iatrogenic mechanisms such as a needle biopsy can lead to an intrarenal arteriovenous fistula or pseudoaneurysm.[30]

***Imaging.*** Globally deficient parenchymal contrast enhancement is an important CT indicator of possible disruption, thrombosis, or spasm of the main renal artery. Contrast enhancement in the



**e-Figure 116.6. Middle aortic syndrome and hypertension.** (A) Volume-rendered CTA image of a child with middle aortic syndrome reveals severe narrowing of the renal artery origins *(arrows)* and infrarenal portion of the abdominal aorta. (B) Maximum intensity projection MRA image from another child demonstrates nonvisualization of the entire abdominal aorta with reconstitution of lower extremity blood flow from extensive paraspinous and body wall collateral vessels.

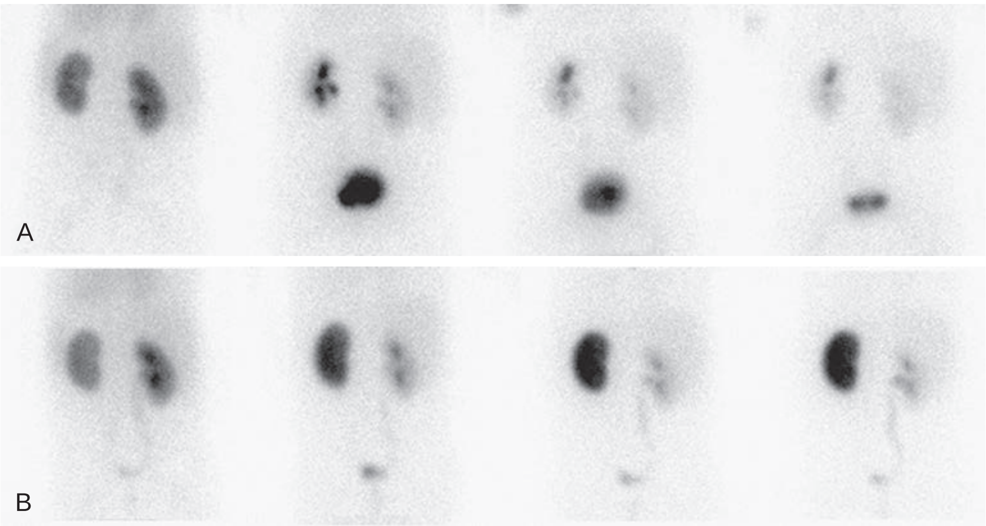


**Figure 116.2. Renovascular hypertension and angiotensin-converting enzyme (ACE) inhibition scintigraphy.** (A) Renogram shows normal uptake and excretion from both kidneys. (B) Renogram after administration of an ACE inhibitor shows marked radiopharmaceutical retention in the left kidney, indicating renal artery stenosis. *(Courtesy Douglas F. Eggli, MD, Hershey, PA.)*

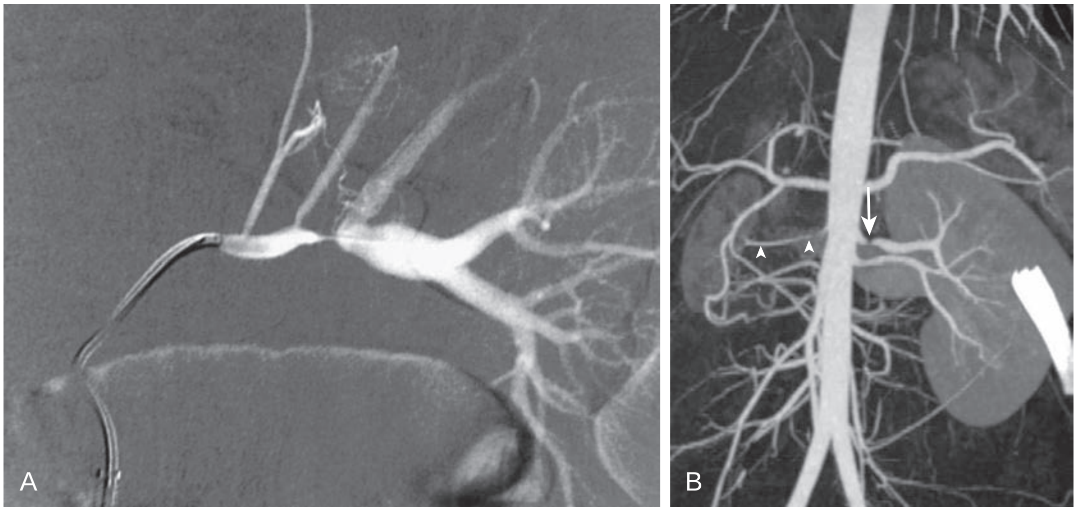

**Figure 116.4. Renal artery stenosis.** (A) Selective renal arteriogram of a 12-year-old girl with hypertension due to primary intimal fibroplasia shows severe stenosis and poststenotic dilatation of the left main renal artery. (B) Contrast-enhanced CT coronal maximum intensity projection image shows two left renal arteries; the superior artery has a severe focal stenosis proximally *(arrow)*. The right main renal artery is diffusely narrowed *(arrowheads)*, and the right kidney is atrophic.

periphery of an ischemic kidney (the "cortical rim sign") is an indicator of acute renal arterial occlusion, although this does not occur until at least several hours after the event. A localized renal infarction due to traumatic occlusion of an intrarenal vessel or embolic phenomenon results in a wedge-shaped or rounded area of absent enhancement, often with sharp margins. With partial main renal artery occlusion, the nephrogram intensity is diminished. Arterial phase CT is useful to detect occlusion, pseudoaneurysm, or active extravasation of the renal artery.[31–33]

## ANEURYSM

***Overview.*** Renal artery aneurysms are rare in childhood. Classifying features include location (extraparenchymal vs. intraparenchymal) and morphology (saccular, fusiform, dissecting, or false). Some pediatric renal artery aneurysms are idiopathic; others are due to infection (e.g., mycotic aneurysms), renal artery stenosis (often related to neurofibromatosis type 1 or FMD), or autoimmune vasculitis (e.g., polyarteritis nodosa). Aneurysms of the renal artery also can occur in patients with Kawasaki disease and Ehlers-Danlos syndrome. The most common clinical manifestations of a renal artery aneurysm are hematuria and flank pain.[34,35]

***Imaging.*** Renal artery aneurysms can be single or multiple. Most are saccular. Thrombus or calcification occasionally is present within the aneurysm (Fig. 116.8). Most are detectable with sonography, CTA, or MRA. Conventional angiography sometimes is required for the detection and characterization of small lesions, such as in patients with polyarteritis nodosa.[11,36]

## ARTERIOVENOUS MALFORMATION AND FISTULA

About three-quarters of renal arteriovenous fistulas are iatrogenic or related to trauma. Congenital arteriovenous malformations of the kidney are rare. Hematuria and a bruit are common clinical

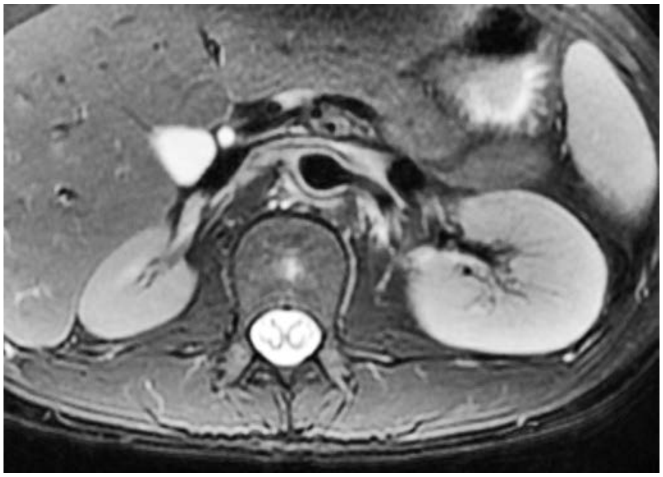

**Figure 116.5. Takayasu arteritis.** Axial T2-weighted fat-saturated magnetic resonance (MR) image of a child with hypertension shows abnormally increased signal in the walls of the abdominal aorta and renal arteries due to active inflammation. The right renal artery is narrowed, and the right kidney is atrophic. Periarterial signal hyperintensity is also due to inflammation.

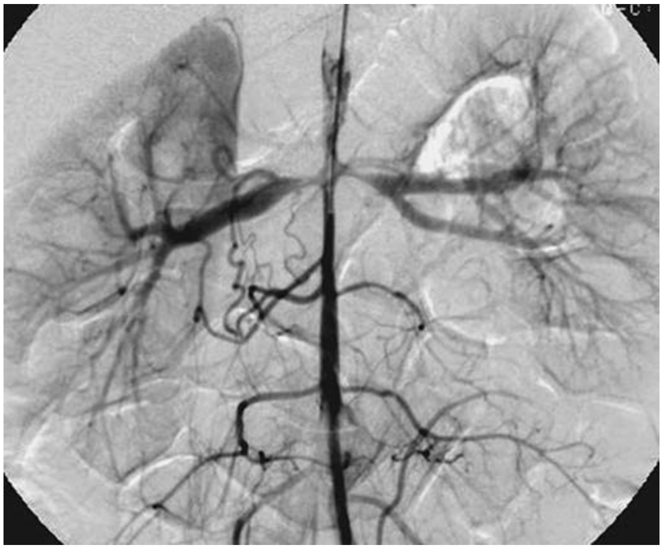

**Figure 116.7. Middle aortic syndrome.** Aortogram of a 3-month-old boy with severe hypertension reveals a hypoplastic abdominal aorta and bilateral proximal renal artery stenoses.

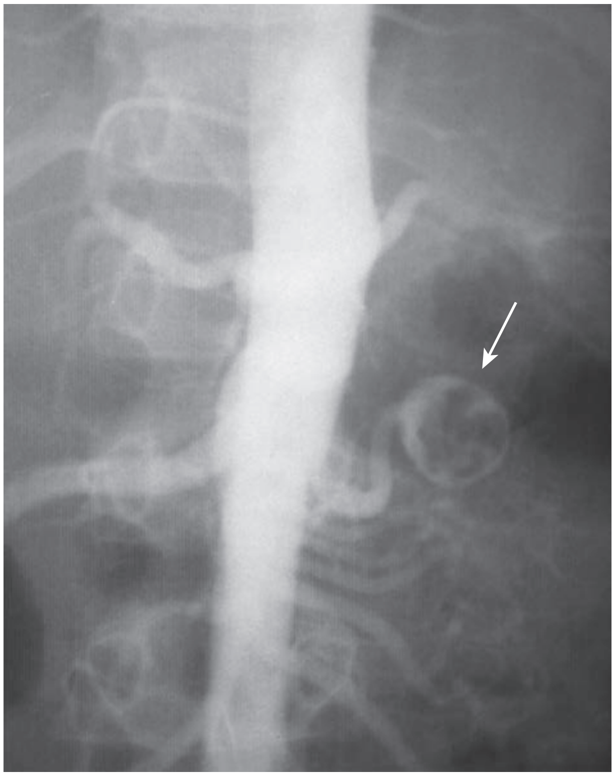

**Figure 116.8. Renal artery aneurysm.** Abdominal aortogram shows a partially thrombosed saccular aneurysm *(arrow)* of the left renal artery.

findings with both of these lesions. A large shunt can cause high-output heart failure. Imaging studies show a focal abnormal direct communication between an artery and a vein, whereas shunting in an arteriovenous malformation occurs through a nidus of abnormal vessels. Supplying and draining vessels are enlarged. Doppler analysis shows turbulent flow and arterial velocity in the draining veins. Angiography shows rapid flow through the lesion.[37–41]

## THROMBOSIS, EMBOLISM, AND INFARCTION

***Overview.*** Thromboembolic disease of the renal arteries is uncommon in children. Predisposing conditions include sepsis (endocarditis), prolonged hypotension, severe dehydration, congenital heart disease, trauma, and hypercoagulable disorders. In neonates, the most common cause is an umbilical arterial catheter. Infants of diabetic mothers are at increased risk for renal arterial thrombosis. In older children, acute occlusion of a major renal artery causes flank pain, nausea, vomiting, fever, and hematuria. Small emboli or minor thrombosis may be asymptomatic, although hypertension is a common complication.[42]

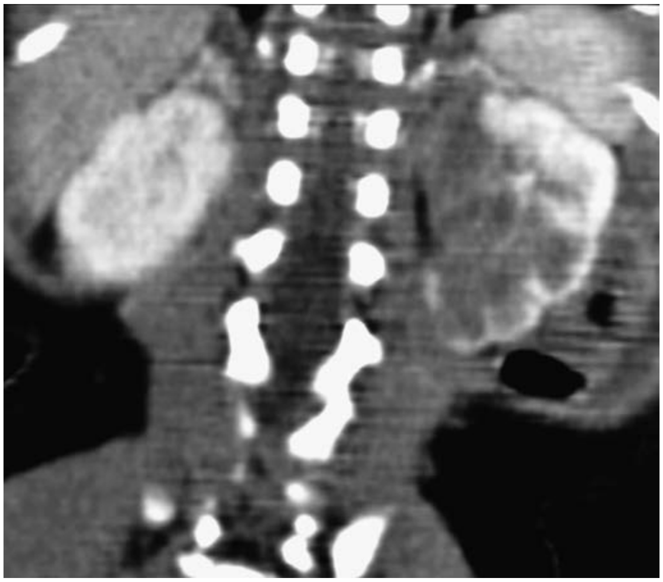
***Imaging.*** In the acute phase of renal artery thromboembolism, sonography is normal or shows nonspecific renal enlargement and cortical hyperechogenicity. Color or power Doppler evaluation sometimes reveals global, focal, or multifocal perfusion deficits. Blood flow within the capsule may be increased. Careful evaluation of the main renal artery sometimes demonstrates a clot, as well as abnormal arterial waveforms. If the main renal artery remains patent, the resistive index often is elevated.

CTA and MRA of patients with renal arterial thromboembolic disease may reveal filling defects or narrowing of the renal artery. With global renal infarction, renal parenchymal enhancement and contrast material excretion are mostly absent. One or more wedge-shaped enhancement defects may occur in the presence of segmental renal infarction. In about 50% of patients with renal infarction, a thin prominently enhancing rim is visible at the peripheral margin (e-Fig. 116.9).[11,33,40,43]

## DISEASES OF THE INTRARENAL ARTERIES

### Renal Vasculitis

The kidney is a relatively common site of involvement in various forms of vasculitis. The most widely used classification of vasculitis is based on the size of the predominantly involved vessels. Takayasu arteritis is an example of large vessel vasculitis. Polyarteritis nodosa and Kawasaki disease predominantly involve medium-sized vessels. The presence or absence of antineutrophil cytoplasmic antibodies (ANCAs) allows subcategorization of the small vessel vasculitides. Henoch-Schönlein purpura (HSP) is ANCA negative; ANCA-positive vasculitides that can affect the kidney include granulomatosis with polyangiitis (Wegener granulomatosis) and microscopic polyarteritis. Small-vessel vasculitis also can occur in



**e-Figure 116.9. Acute renal artery thrombosis in a neonate.** Coronal reformatted contrast-enhanced CT shows deficient enhancement in most of the left kidney. Note preserved enhancement of a thin peripheral rim of cortex.

association with various infectious diseases, such as Rocky Mountain spotted fever, human immunodeficiency virus, hepatitis B, and tuberculosis.[44–48]

## Polyarteritis Nodosa

Polyarteritis nodosa is a rare idiopathic focal segmental necrotizing vasculitis. Renal involvement occurs in about half of affected children. Clinical manifestations of kidney involvement include hematuria, proteinuria, and hypertension. Imaging studies of the kidneys may show manifestations of focal or multifocal renal ischemia. Intraparenchymal or perirenal hemorrhage can occur due to aneurysm rupture. Catheter arteriography reveals small (2–3 mm) aneurysms, typically located at the bifurcations of interlobular or arcuate arteries. Small intrarenal vessels are irregular and tortuous because of vascular and perivascular inflammation (Fig. 116.10).[49–51]

## Granulomatosis with Polyangiitis (Wegener Granulomatosis) and Microscopic Polyarteritis

Granulomatosis with polyangiitis (Wegener granulomatosis) is a rare necrotizing vasculitis that predominantly affects the respiratory tract. Up to 80% of patients have manifestations of renal involvement, such as hematuria, proteinuria, and diminished glomerular filtration rate. Similar clinical findings occur in patients with microscopic polyarteritis, although respiratory system involvement is lacking. Diagnostic imaging findings of kidney involvement with these two vasculitides are similar to those of polyarteritis nodosa. Foci of parenchymal scarring may occur as the result of ischemia. Rupture of a small-vessel aneurysm can lead to intrarenal or perirenal hemorrhage.[52–54]

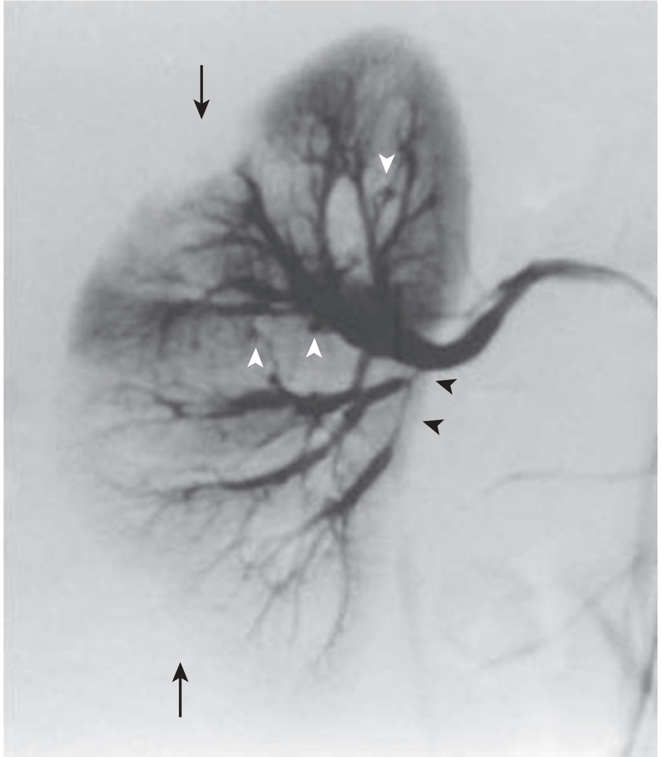


**Figure 116.10. Polyarteritis nodosa.** This patient had an established diagnosis of polyarteritis nodosa for 1 year and new-onset hypertension. Selective right renal angiogram shows segmental narrowing of the intrarenal branch to the lower pole *(black arrowheads)*, small saccular aneurysms at vessel branch points *(white arrowheads)*, and patchy perfusion deficits in the upper and lower poles *(arrows)*.

## Systemic Lupus Erythematosus

Up to 75% of children with systemic lupus erythematosus have clinical manifestations of renal involvement. The major pathologic manifestation is thickening of the basement membrane as a result of focal glomerulonephritis; inflammatory narrowing of interlobular arteries can also occur. In the absence of renal failure, the kidneys often appear normal on imaging studies. Mild nephromegaly is common. Diffuse or multifocal hyperechogenicity of the renal parenchyma may be present on sonography. Elevation of the resistive index on spectral Doppler evaluation may be predictive of worsening renal function.[55,56]

## Hemolytic-Uremic Syndrome

***Overview.*** Hemolytic-uremic syndrome is the most common cause of acute renal failure in early childhood. The pathogenesis involves bacterial infection (commonly *Escherichia coli*) and endothelial cell damage within glomeruli and renal arterioles. In most cases of hemolytic-uremic syndrome, anemia, fever, vomiting, bloody diarrhea, and abdominal discomfort develop in an otherwise healthy infant. Affected children beyond infancy are usually around 3 years of age. The child may become critically ill, with signs and symptoms that include pallor, irritability, seizures, heart failure, hypertension, gastrointestinal bleeding, and oliguria. Acute renal failure usually lasts for 1 to 4 weeks, with subsequent slow improvement[57]; a minority of patients develop end-stage renal disease.

***Imaging.*** Early in the disease, sonography is normal or shows minimal nephromegaly. Subsequent abnormally increased parenchymal echogenicity usually is most prominent in the glomerular and subcortical regions. The degree of cortical echogenicity correlates with the severity of the illness. Spectral Doppler shows diminished blood flow. In most patients, the kidney returns to a normal size as the disease resolves, but more severe injury can lead to atrophy and/or nephrocalcinosis.[58–60]

## Henoch-Schönlein Purpura

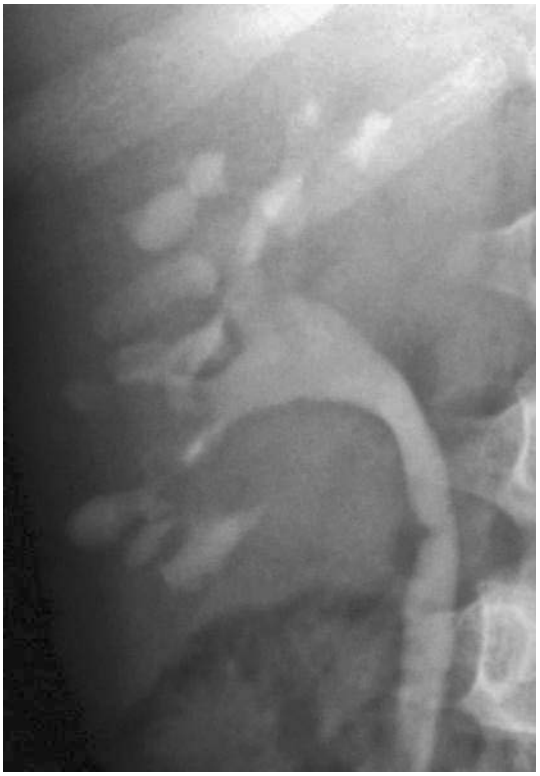
***Overview.*** HSP is a hypersensitivity vasculitis that affects small vessels and is an important cause of nephritis in children. The clinical tetrad includes a purpuric rash, arthralgias, abdominal pain, and glomerulonephritis. Between 20% to 30% of patients with HSP have hematuria, and 30% to 70% have proteinuria. Clinical signs of renal involvement may follow or coincide with the appearance of purpura, but they rarely antedate the skin findings.[61–64]

***Imaging.*** Sonography may show normal or bilaterally enlarged kidneys. Hyperechogenicity of the renal cortex is usually diffuse, and the medullary pyramids remain hypoechoic. Renal cortical hyperechogenicity diminishes as the acute disease regresses. Occasionally, cross-sectional imaging studies show an intramural hematoma of the bladder wall or ureter. Ureteral fibrosis is a rare complication. Imaging of the bowel may reveal mural thickening and small bowel intussusceptions.

## Sickle Cell Disease

***Overview.*** Stasis of red blood cells within the renal medulla is common in patients with sickle cell disease. Recurrent episodes of medullary ischemia lead to alterations in papillary morphology, sometimes with progression to papillary necrosis. Cortical hypertrophy can occur.[65,66]

***Imaging.*** Intravenous urography and CT may show calyceal blunting and prominent papillae with broad, deep calyces. The collecting system often is distorted (e-Fig. 116.11). In some patients, papillary necrosis is evident. Nephromegaly, usually bilateral, is common. Recurrent infarction and subsequent fibrosis eventually may lead to renal scarring and atrophy.[67,68]



**e-Figure 116.11. Sickle cell disease.** Intravenous urogram of a 13-year-old child with sickle cell disease shows calyceal dilation and collecting system distortion.

Renal sonography typically shows mild diffuse enlargement, hyperechogenicity, and loss of corticomedullary differentiation (Fig. 116.12). A perirenal hematoma can occur as a complication of renal infarction. Doppler sonography may detect renovascular disease. MRI shows decreased cortical signal intensity relative to the medulla on T1-weighted and T2-weighted images due to iron deposition in the renal cortex (Fig. 116.13).[69,70]

## RENAL VEIN THROMBOSIS

***Overview.*** Renal vein thrombosis (RVT) is the most common renal vascular abnormality of neonates. Most affected infants have a predisposing systemic abnormality, such as dehydration, sepsis, polycythemia, or maternal diabetes mellitus. Small intrarenal vessels are the initial or only site of thrombosis in many children with RVT. Propagation of a central venous catheter–related inferior vena cava clot is an additional potential mechanism. RVT in older patients can occur as a complication of nephrotic syndrome, glomerulonephritis, a hypercoagulable state, trauma, retroperitoneal tumor, or renal transplantation. Typical clinical manifestations of RVT include nephromegaly, signs of renal insufficiency, hematuria, and hypertension.[71]

***Imaging.*** The typical sonographic features of RVT are abnormal parenchymal echogenicity and loss of corticomedullary differentiation (Fig. 116.14). In some patients, interlobular echogenic streaks are present. Interstitial hemorrhage occasionally leads to parenchymal hyperechogenicity. Elevation of the arterial resistive index occurs as a result of venous outflow obstruction (Fig. 116.15). Narrowing of the systolic peak also is common. Careful sonographic evaluation of the renal veins sometimes reveals an echogenic clot; however, the absence of a clot within the major renal veins does

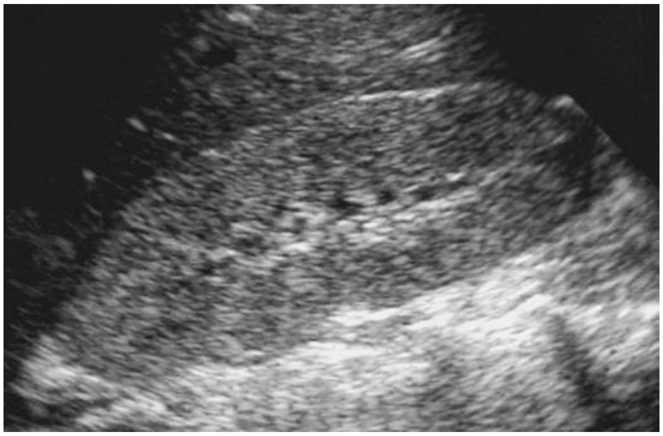


**Figure 116.12. Sickle cell disease.** Longitudinal sonogram of a 15-year-old boy with sickle cell disease shows hyperechogenicity of the kidney and absent corticomedullary differentiation.

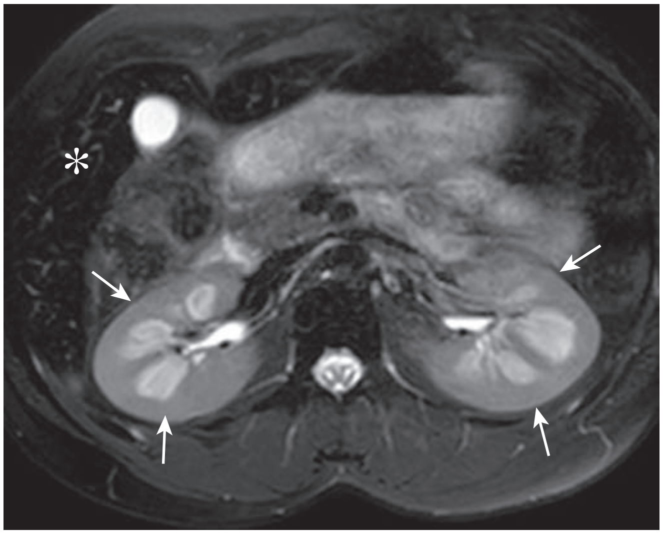

**Figure 116.13. Sickle cell disease.** Axial T2-weighted fat-saturated MR image shows abnormal signal hypointensity of the renal cortices *(arrows)* due to hemolysis and iron deposition. The liver is also markedly hypointense due to the presence of iron *(asterisk)*.

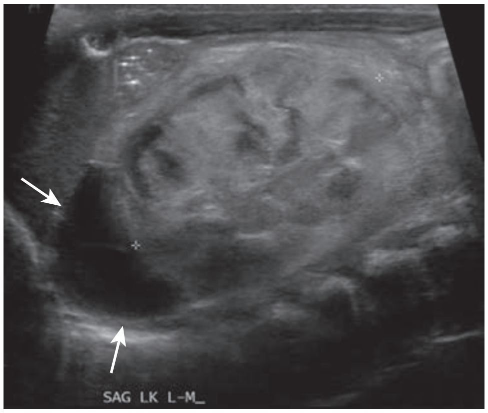

**Figure 116.14. Renal vein thrombosis.** Longitudinal sonogram from a neonate with renal vein thrombosis shows an enlarged, echogenic, heterogeneous left kidney with loss of corticomedullary differentiation. A hypoechoic collection superior to the kidney is due to concomitant adrenal hemorrhage *(arrows)*.

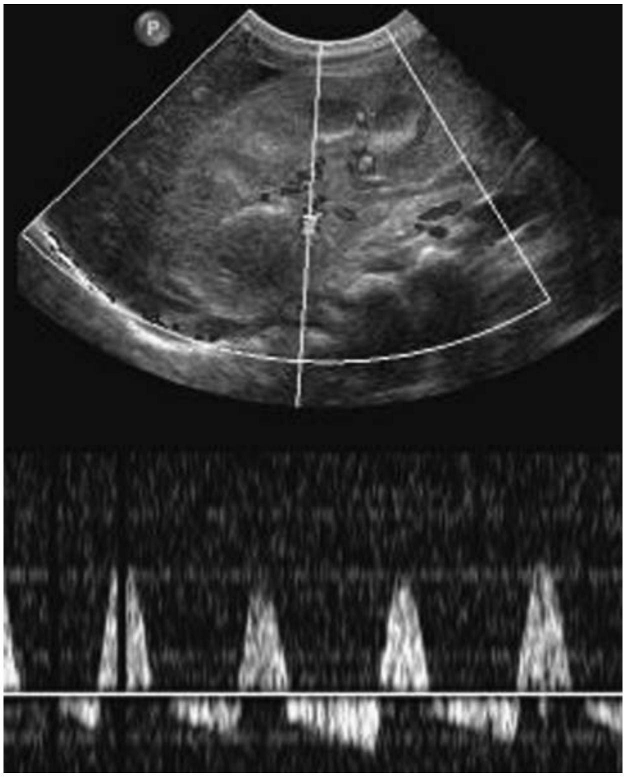

**Figure 116.15. Renal vein thrombosis.** Longitudinal sonogram of this 2-day-old infant shows an enlarged and echogenic kidney. A highly resistive pattern of intrarenal arterial flow is present with reversal of diastolic blood flow.

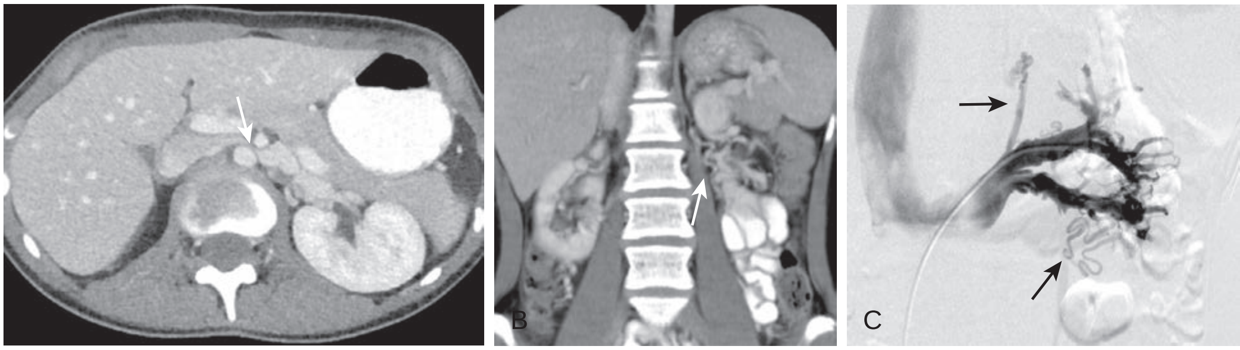

**Figure 116.17. Nutcracker syndrome.** (A) Axial contrast-enhanced CT image from a 17-year-old girl with hematuria and left flank pain shows narrowing of the left renal vein as it passes between the abdominal aorta and superior mesenteric artery *(arrow)*. (B) Coronal CT image shows multiple collateral veins in the left renal hilar region *(arrow)*. (C) Catheter venography shows enlargement of the left renal vein and multiple venous collateral vessels *(arrows)*.

not exclude the diagnosis of small-vessel RVT. Doppler evaluation of the main renal vein shows absent or monophasic flow.[72–74]

***Treatment and Follow-up.*** Therapy of RVT is supportive and directed toward treatment of the underlying cause. Renal scintigraphy during the acute phase provides prognostic information; mild compromise of uptake and excretion indicates a good prognosis (e-Fig. 116.16). Within a few weeks of onset of RVT, the affected kidney decreases in size. In some patients, progression to global atrophy occurs. Follow-up radiography or CT occasionally demonstrates a reticular pattern of calcification within the intrarenal veins; this finding is essentially pathognomonic of previous RVT.

## NUTCRACKER SYNDROME

***Overview.*** The nutcracker syndrome is clinically symptomatic venous hypertension of the left kidney due to compression of the left renal vein between the aorta and superior mesenteric artery (or narrowing of a retroaortic left renal vein). The most common clinical findings are hematuria and flank pain. Renal vein-to-gonadal vein reflux can lead to pelvic congestion syndrome in females and varicocele in males.

***Imaging.*** CT and MRI show abrupt narrowing of the aortomesenteric portion of the left renal vein and acute angulation of the superior mesenteric artery relative to the aorta (<35 degrees); prominent collateral veins may also be present (Fig. 116.17). Doppler shows elevated velocity of the narrowed segment (suggested criteria: peak systolic velocity >5 times that at the renal hilum). Clinically significant narrowing is suggested by sonographic demonstration of reduction of the AP diameter of the renal vein by ≥3 times that of the vein diameter at the renal hilum in the supine position or by >5 times after standing for ≥15 minutes.[11,75]

### KEY POINTS

- Sonography, including Doppler evaluation, is the most appropriate initial imaging technique for most children with suspected renovascular pathology.
- Renal arterial dysplasia is the most common cause of renal arterial stenosis in children. Renal artery thromboembolism in infants often is related to an umbilical artery catheter.
- Hemolytic-uremic syndrome is the most common cause of acute renal failure in childhood.
- RVT is the most common neonatal renovascular abnormality.

# 117 Renal Failure and Transplantation

Harriet J. Paltiel

## ACUTE RENAL INJURY

***Overview.*** Acute renal failure is defined as a sudden loss of renal function that may be due to inadequate renal perfusion, renal cell injury, or obstruction to urine flow. The term *acute kidney injury* (AKI) has been proposed to replace the term *acute renal failure* and is gaining wide acceptance.[1,2] AKI usually develops in hospitalized children as a result of systemic illness or its treatment and not from primary renal disease. The most common causes of AKI in children are renal ischemia, nephrotoxic drugs, and sepsis.[3,4] Other important causes are listed in Box 117.1. AKI from any cause can lead to chronic kidney disease.[5–9] Recovery of renal function, at least in part, depends on the underlying events leading to injury.

***Imaging.*** In general, sonography should be the first diagnostic imaging study in the workup of persons with AKI, and in most cases it is the only imaging required. The role of sonography is to determine renal size and to exclude anatomic abnormalities as the cause of AKI. The renal cortex, medulla, and collecting system have different acoustic properties, and pathologic changes are readily detected and correlate well with histologic findings. Doppler techniques provide information about renal perfusion and vascular abnormalities. Sonography also is used to localize the kidneys for percutaneous biopsy. More precise functional information may be obtained with nuclear medicine studies that can aid in differentiating between prerenal, intrinsic renal, and postrenal causes of AKI.

***Prerenal Injury.*** In persons with prerenal injury, the kidney is intrinsically normal, and renal function is diminished as a result of decreased renal perfusion (e.g., hypovolemia). Sonographic examination of the kidneys is normal. Restoration of renal perfusion results in a prompt return of renal function.

***Intrinsic Renal Disease.*** Renal ischemia due to a prolonged prerenal injury or a severe hypoxic/ischemic insult can lead to acute tubular necrosis. Imaging findings depend on the severity of parenchymal injury. A generalized increase in renal cortical echogenicity indicates intrinsic renal disease (Fig. 117.1). In mild cases, the kidneys may appear normal or may demonstrate slightly increased renal cortical echogenicity. Decreased corticomedullary differentiation may be noted. Doppler flow may be normal in mild disease, whereas poor peripheral perfusion and diminished arterial diastolic flow due to increased intrarenal vascular resistance occur in more severe cases.

Nephrotoxic drugs commonly associated with AKI include antibiotics, chemotherapeutic agents, nonsteroidal antiinflammatory medications, and iodinated contrast material.[10] Some agents such as aminoglycoside antibiotics cause tubular injury. Methicillin and other penicillin analogs, cimetidine, sulfonamides, rifampin, and nonsteroidal antiinflammatory drugs may cause acute interstitial nephritis, which is thought to be related to a hypersensitivity reaction with development of antitubular basement membrane antibodies in some cases. While iodinated contrast material has historically been considered a common cause of AKI in children and adults, recent adult studies suggest that the risk may be lower than previously thought.[11–13]

Children with acute lymphocytic leukemia and B-cell lymphoma are at risk for the development of uric acid nephropathy and tumor lysis syndrome. One mechanism of injury believed to be of importance in uric acid nephropathy is precipitation of uric acid crystals in the renal microvasculature leading to obstruction of renal blood flow, or precipitation in the renal tubules leading to obstruction of urine flow. Tumor lysis syndrome is a constellation of metabolic abnormalities resulting from spontaneous or treatment-related tumor necrosis. As tumor cells are lysed, rapid increases in serum potassium, uric acid, and phosphorus occur, with a decrease in serum calcium. Patients who are treated with allopurinol, a purine analog used to diminish the excretion of uric acid, instead excrete large quantities of the uric acid precursors xanthine and hypoxanthine. Precipitation of these compounds is thought to play a role in the development of AKI.

In patients who are in septic shock, AKI can develop from hypotension, leading to renal ischemia and acute tubular necrosis, or AKI can develop as a result of the use of nephrotoxic medications.

***Obstructive Uropathy and Lower Tract Lesions.*** Urinary tract obstruction can cause AKI if the obstruction affects a solitary kidney, both ureters, or the urethra. Congenital causes include ureteropelvic junction obstruction, ureterovesical junction obstruction, and posterior urethral valves. Acquired urinary tract obstruction can be caused by urinary tract stones or, rarely, tumors. Bladder rupture is another rare cause of AKI associated with ascites. Bladder rupture in children usually is due to trauma or as a complication of bladder augmentation. It can also occur rarely in patients with chronically unused bladders or conditions with outflow obstruction combined with a diseased bladder wall, such as posterior urethral valves or congenital bladder diverticula.[14–17]

## CHRONIC KIDNEY DISEASE

***Overview.*** The terms *chronic renal failure* and *chronic renal insufficiency* have been used historically to describe varying degrees of chronic renal dysfunction. Currently, the term *chronic kidney disease* (CKD) is used by both adult and pediatric nephrology communities throughout the world.[17] The classification of CKD published by the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative is based on the estimated glomerular filtration rate and is applicable to children older than 2 years and to adults.[18] The classification categorizes CKD into five different stages and is widely used in clinical practice (Table 117.1).

It has been recognized that most patients with CKD (estimated to be one in eight adults) never reach end-stage renal disease and the need for renal replacement therapy because they are at risk for accelerated cardiovascular disease and are more likely to die prematurely from cerebrovascular or cardiovascular disease.[19] Therefore clinical management requires measures to diminish cardiovascular risk factors in both adult and pediatric patients.

According to the North American Pediatric Renal Trials and Collaborative Studies 2008 report,[20] the most common causes of pediatric CKD in North America are congenital disorders, such as obstructive uropathy (20.7%); renal aplasia, hypoplasia, and dysplasia (17.3%); and reflux nephropathy (8.4%) (Fig. 117.2; Table 117.2). In contrast, in Japan, 34% of pediatric CKD is due to glomerulonephritis, primary focal segmental glomerulosclerosis, and immunoglobulin A nephropathy.[21] In Jordan[22] and Iran,[23] where consanguinity is more common, heritable disorders such as cystic kidney diseases, primary hyperoxaluria, cystinosis, Alport syndrome, and congenital nephrotic syndrome represent a greater proportion of cases of CKD. In the developing world, acquired causes of CKD predominate, particularly infection-related glomerulopathies.[24,25]

## Abstract:

Sonography is the initial imaging study performed when assessing patients with acute and chronic renal failure and may be the only imaging that is necessary. The role of sonography is to determine renal size and to exclude anatomical abnormalities as the cause of renal failure, and to monitor the effects of treatment. When functional information is required, nuclear medicine studies are done to help differentiate prerenal, renal and postrenal causes of acute and chronic renal failure. Sonography is the imaging study of choice in the evaluation of renal transplants and detection of complications. Imaging is focused on an assessment of graft perfusion and vascular anastomoses. Late complications include chronic rejection and PTLD. Chronic rejection will be manifest as a gradual reduction in graft size, increased parenchymal echogenicity and decreased perfusion. PTLD is the most common neoplastic disorder in pediatric transplant recipients and sonography is used to search for enlarged lymph nodes and solid masses in the abdomen and pelvis. Sonographic monitoring of the native kidneys in transplant recipients is required because of an increased risk of malignancy in this population.

### BOX 117.1 Common Causes of Acute Kidney Injury

**PRERENAL FAILURE**

- Decreased true intravascular volume
- Decreased effective intravascular volume

**INTRINSIC RENAL DISEASE**

- Acute tubular necrosis
- Hypoxic/ischemic insults
- Drug-induced
- Toxin-mediated
  Endogenous toxins—hemoglobin, myoglobin
  Exogenous toxins—ethylene glycol, methanol

**URIC ACID NEPHROPATHY AND TUMOR LYSIS SYNDROME**

**Interstitial Nephritis**

- Drug-induced
- Idiopathic

**Glomerulonephritis**

**Vascular Lesions**

- Renal artery thrombosis
- Renal vein thrombosis
- Cortical necrosis
- Hemolytic uremic syndrome

**Hypoplasia/Dysplasia with or Without Obstructive Uropathy**

- Idiopathic
- Exposure to nephrotoxic drugs in utero

**Hereditary Renal Disease**

- Autosomal-dominant polycystic kidney disease
- Autosomal-recessive polycystic kidney disease
- Alport syndrome
- Sickle cell nephropathy
- Juvenile nephronophthisis

**Obstructive Uropathy/Lower Tract Lesions**

- Obstruction in a solitary kidney
- Bilateral ureteral obstruction
- Urethral obstruction
- Bladder rupture

*From Andreoli SP. Clinical evaluation of acute kidney injury in children. In: Avner ED, ed.* Pediatric nephrology. *6th ed. Berlin: Springer-Verlag; 2009.*

The worldwide incidence and prevalence of CKD is greater for boys than for girls because of the higher incidence of congenital causes of CKD in boys.[20–27]

***Imaging.*** Imaging plays an essential role in diagnosis, assessment of function, and monitoring of the effects of treatment at all stages of CKD, from the antenatal period to pretransplantation evaluation. Many urinary tract abnormalities are discovered by prenatal sonography or magnetic resonance imaging (MRI). Postnatal imaging usually focuses on growth, function, and assessment of complications. A multimodality approach often is required, including radiography, sonography, fluoroscopy, nuclear medicine, and MRI.

As with AKI, sonography is the primary imaging modality used to investigate CKD and guide performance of a percutaneous biopsy. Assessment of renal and bladder morphology permits detection of congenital anomalies, such as ureteropelvic junction obstruction, posterior urethral valves, duplex collecting systems and ureters, and ectopic ureteral insertion. Determination of kidney size is critical for long-term follow-up. Enlarged kidneys may occur in the setting of obstruction, certain cystic diseases, and glomerulonephritis. Hypoplastic/dysplastic and scarred kidneys usually are small. A gradual reduction in kidney size usually occurs in persons with CKD. With progressive CKD, a concomitant loss of corticomedullary differentiation usually occurs, and most patients will have echogenic renal parenchyma.[28]

Dysplastic kidneys have disordered development that generally is manifested as a combination of echogenic parenchyma and cysts (Fig. 117.3). Dysplasia may be focal or diffuse and generally appears sonographically as echogenic tissue without recognizable

**TABLE 117.1** Kidney Disease Outcomes Quality Initiative Stages of Chronic Kidney Disease

| Stage | Description | GFR (mL/min/1.73 m$^2$) |
|---|---|---|
| 1 | Kidney damage with normal or increased GFR | ≥90 |
| 2 | Kidney damage with mild decrease in GFR | 60–89 |
| 3 | Moderate decrease in GFR | 30–59 |
| 4 | Severe decrease in GFR | 15–29 |
| 5 | Kidney failure | <15 (or dialysis) |

*From VanDeVoorde RG, Warady BA. Management of chronic kidney disease. In Avner ED, ed.* Pediatric nephrology. *6th ed. Berlin: Springer-Verlag; 2009.*

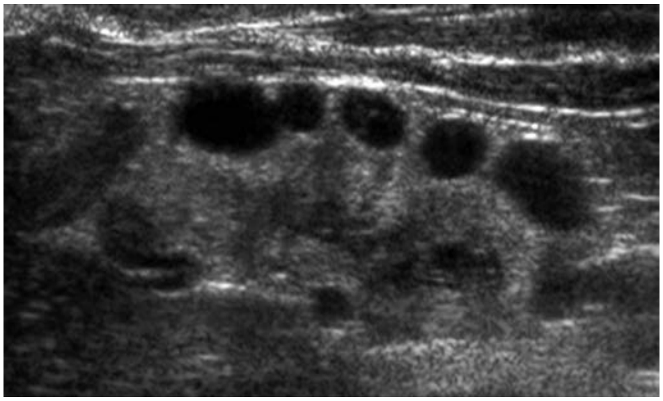

**Figure 117.3. Renal dysplasia.** Sagittal sonogram of the right kidney in a 7-week-old boy with renal failure shows a small kidney with echogenic parenchyma and multiple peripheral cysts. The left kidney had a similar appearance (not shown).

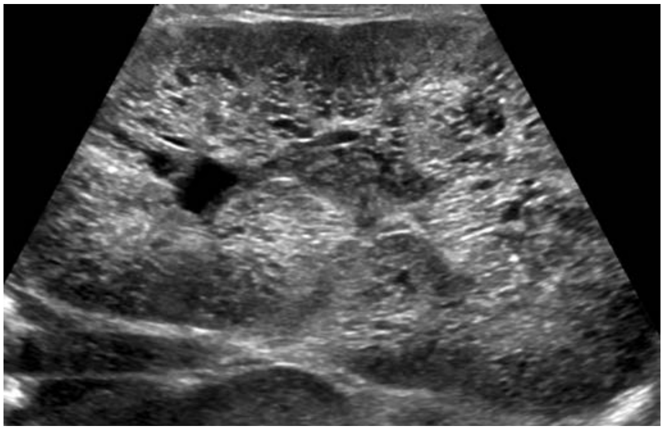

**Figure 117.4. Autosomal-recessive polycystic kidney disease.** Sagittal sonogram of the left kidney in a 3-day-old girl demonstrates nephromegaly, loss of normal corticomedullary differentiation, hypoechoic subcapsular cortex, and multiple cysts of varying size in the medullary region. The right kidney had a similar appearance (not shown).

corticomedullary differentiation. Severe bilateral renal dysplasia (i.e., bilateral multicystic dysplastic kidneys) is incompatible with life. Multicystic dysplastic kidney is the most common form of unilateral dysplasia and consists of multiple large, generally noncommunicating cysts of varying size and minimal intervening echogenic parenchyma. About half of these kidneys eventually will involute by ultrasound.[29] Monitoring of the contralateral functioning kidney is critical in these patients, because associated abnormalities are common.[30] Renal scarring may occur as a sequela of infection or vesicoureteral reflux. Sonography is relatively insensitive in the detection of scarring, and nuclear scintigraphy with dimercaptosuccinic acid or MRI may be required for more precise assessment of renal parenchymal integrity.[31,32]

Children with autosomal recessive polycystic kidney disease have large, echogenic kidneys with poor corticomedullary differentiation due to the presence of innumerable tiny (often microscopic) cysts. Visible cysts less than 1 cm in diameter are detected in about 50% of children (Fig. 117.4). Evaluation of the liver is necessary because of the high association of ductal plate malformations. Autosomal dominant polycystic kidney disease may manifest in childhood, although associated CKD is rare. The kidneys usually appear normal initially, with cystic changes developing later in life. Occasionally, cysts may be present at birth.[33–36]

Renal vascularity reflects functional status and will decrease in persons with CKD. Several recent publications suggest that the renal arterial resistive index may correlate with creatinine levels and may be an independent risk factor for the progression of CKD.[37,38]

## TRANSPLANTATION

***Overview.*** Renal transplantation is the treatment of choice in children with end-stage renal disease, with improved patient survival and quality of life compared with dialysis. However, renal transplantation in children is associated with a number of specific problems, including a higher incidence of graft failure and post-transplant malignancy than in adults, as well as growth retardation. Furthermore, it may be challenging technically to transplant a relatively large adult kidney into a small pediatric abdomen. Transplantation of kidneys from donors younger than 5 years usually is avoided because the risk of early graft failure is increased, mainly as a result of graft thrombosis.[39] Adult kidneys almost always are used. An allograft may be from a living, related donor; from a living, unrelated donor; or it may be cadaveric in origin. In the United States, more than 50% of transplanted kidneys in children are from living, adult donors.[40]

***Imaging.*** Assessment of the transplant kidney is similar to that of a native kidney, with an emphasis on graft perfusion and vascular anastomoses; sonography is the primary imaging technique. Familiarity with the surgical anatomy is essential to a complete evaluation of the vasculature. In small children, the kidney is often placed intraperitoneally with anastomosis of the donor renal artery and vein to the recipient distal aorta and inferior vena cava, respectively. In older children, the graft is placed in a retroperitoneal location within an iliac fossa. The donor renal artery is anastomosed either to the recipient external (more commonly) or internal iliac artery, and the donor vein is anastomosed to the recipient external iliac vein. The donor ureter is anastomosed to the recipient urinary bladder (ureteroneocystostomy).[41]

A normal kidney transplant allograft has a sonographic appearance similar to that of a normal native kidney. The close proximity of the graft to the body surface accentuates the distinction between the renal cortex, medullary pyramids, and central sinus. Doppler evaluation reveals continuous antegrade flow within the main renal artery throughout the cardiac cycle, with low-impedance arterial waveforms in the intrarenal vessels. The intrarenal arterial resistive indices range from 0.5 to 0.8.[42] Flow within the main renal vein and intrarenal veins is opposite in direction to that in the arteries and usually is mildly pulsatile, reflecting normal cardiac and respiratory motion.

In the immediate postoperative period, the most common complications are acute tubular necrosis, vascular narrowing or thrombosis, and rejection. These entities may be difficult to distinguish with imaging techniques. In all three entities, the graft will appear swollen, with loss of normal corticomedullary differentiation and abnormal (usually elevated) arterial resistive indices. Renal vein thrombosis usually occurs in the first postoperative week and manifests as decreased or absent flow within the main renal vein associated with elevated arterial resistive indices (including possible reversal of diastolic blood flow) (Fig. 117.5). Additional acute complications include urine leaks, other fluid collections (e.g., hematoma or abscess), urinary obstruction, and vesicoureteral reflux, all of which are readily demonstrated by imaging.[43–45] Lymphoceles are the most common fluid collections and are caused by lymphatic disruption. They usually develop weeks to months after transplantation (Fig. 117.6).[46]

Renal artery stenosis usually occurs within the first 3 years after transplantation.[47,48] Doppler sonography may demonstrate an elevated velocity within the main renal artery of greater than 200 cm/sec (Fig. 117.7), as well as a *pulsus parvus et tardus* waveform in the arteries distal to the stenotic site (including an abnormally low resistive index). Although Doppler sonography is the screening modality of choice, significant stenotic lesions can be missed. Computed tomographic angiography, magnetic resonance angiography, and catheter angiography are useful problem-solving techniques when sonography is inconclusive. Catheter angiography remains the definitive imaging technique for renal artery imaging.[48–50]

Important late complications include chronic rejection and posttransplant lymphoproliferative disorder (PTLD). Chronic rejection is manifested sonographically by a gradual reduction in graft size, increased parenchymal echogenicity, and decreased perfusion.[42,45] In the pediatric renal transplant population, two large series have reported an incidence of PTLD of 1.2%[51] and

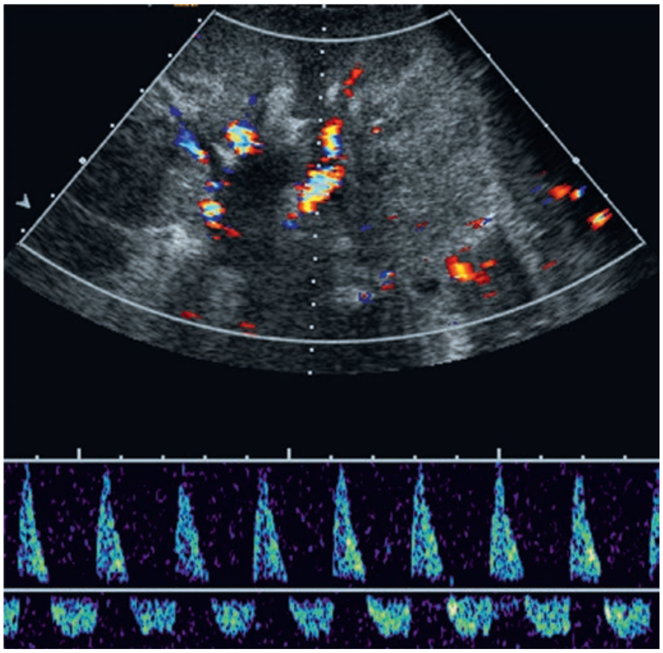

**Figure 117.5. Transplant renal vein thrombosis.** Longitudinal sonogram of a 20-month-old boy 1 day after living–related donor transplantation shows a swollen, echogenic kidney with diminished corticomedullary differentiation. Marked pulsatility of the main renal arterial waveform is noted with reversed diastolic flow, reflecting increased peripheral resistance.

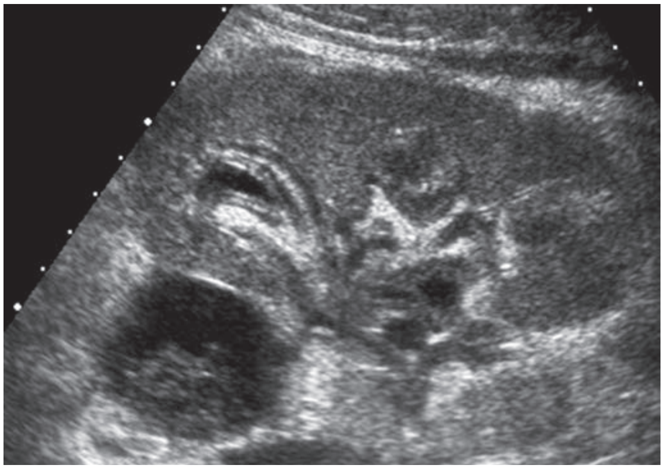

**Figure 117.6. Lymphocele.** Sagittal sonogram of a 16-year-old girl obtained 6 months after deceased donor renal transplantation depicts a small fluid collection with internal echogenic debris indenting the upper pole of the right-sided kidney.

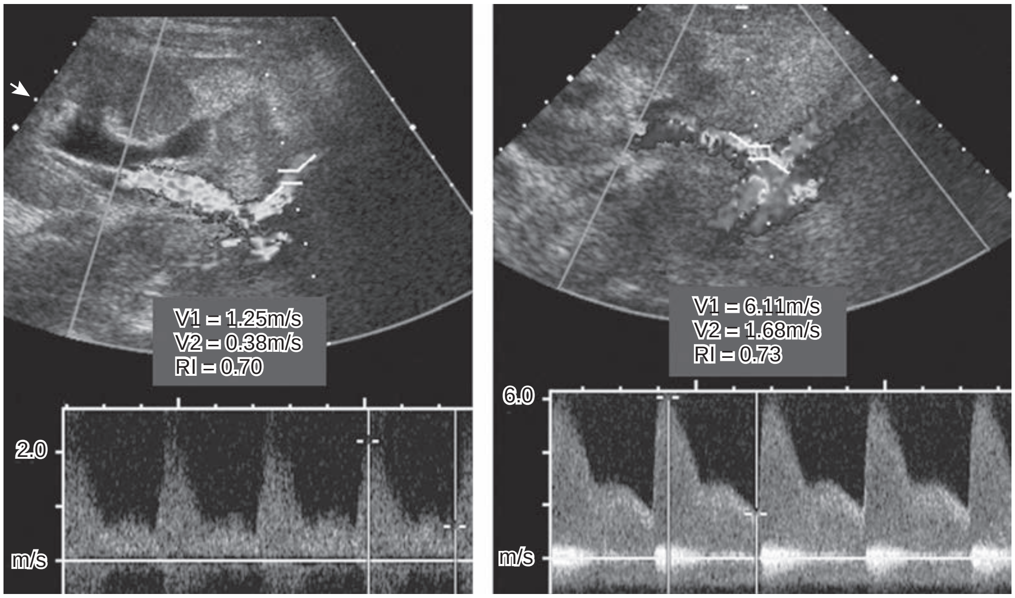

**Figure 117.7. Transplant renal arterial stenosis.** Spectral Doppler sonograms of a child with a rising serum creatinine level shows a nearly fivefold increase in renal arterial peak systolic velocity *(right image)* compared with the supplying external iliac artery *(left image)*, indicating hemodynamically significant stenosis.

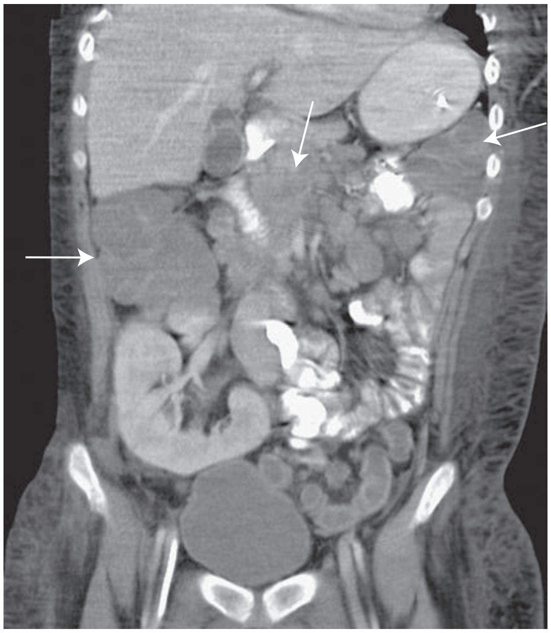

**Figure 117.8. Posttransplant lymphoproliferative disorder.** Coronal reformatted image from a contrast-enhanced CT in a 17-year-old boy shows a right lower quadrant renal transplant. Multiple low-density conglomerate masses within the abdomen represent lymphoproliferative tissue *(arrows)*.

4.5%, respectively.[52] PTLD is the most common neoplastic disorder in pediatric transplant recipients, accounting for 52% of all malignancies in this patient population[53] and is associated with Epstein-Barr virus (EBV) infection. In immune-suppressed persons with impaired T-cell immune surveillance, EBV infection can cause abnormal B-cell proliferation, especially in persons who were seronegative at the time of transplantation.[53,54] Patients at risk will have elevated EBV titers, and sonographic follow-up must include a search for lymph node enlargement and solid masses of the abdominal and pelvic viscera (Fig. 117.8).

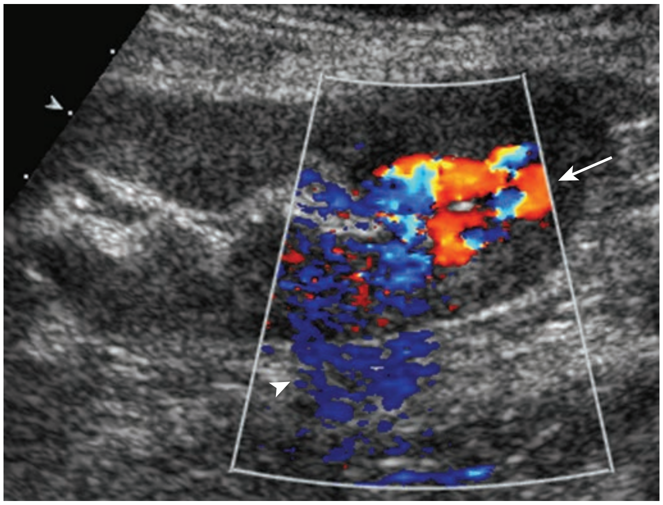

**Figure 117.9. Postbiopsy arteriovenous fistula.** Color Doppler sonogram shows enlarged vessels in the lower pole of a renal transplant *(arrow)* associated with soft tissue vibration artifact *(arrowhead)*.

Percutaneous renal biopsy may be indicated at any stage after transplantation and often is performed under sonographic guidance. Iatrogenic complications of biopsy include hemorrhage and arteriovenous fistula formation (Fig. 117.9). Sonographic monitoring of the native kidneys always should be performed because of an increased risk of malignancy.[55,56]

## KEY POINTS

- Sonography is the first imaging study performed for evaluation for AKI and CKD and often is the only imaging required.
- Nuclear medicine studies provide functional information that helps distinguish prerenal, renal, and postrenal causes of AKI and CKD.

*Continued*

- Sonography is the technique of choice for detecting complications of renal transplantation.
- PTLD is the most common neoplastic disorder in pediatric transplant recipients.
- Sonographic monitoring of native kidneys in transplant recipients is necessary because of an increased risk of malignancy.

# 118 The Ureter

*Andrew H. Schapiro and Jonathan R. Dillman*

## EMBRYOLOGY

During the fifth week of gestation, the urinary collecting system begins development as an outpouching from the mesonephric duct known as the ureteral bud. Contact between the bulbous portion of the ureteral bud and the metanephric blastema induces this portion of the bud to branch and develop into the renal pelvis, calyces, and collecting tubules. Meanwhile, the stalk of the ureteral bud develops into the ureter. The segment of distal mesonephric duct located between the ureteral bud and developing bladder, known as the common nephric duct, undergoes apoptosis, bringing the distal ureter into contact with the developing bladder. The ureteral orifice then migrates cranially and laterally as the bladder tissue surrounding the ureteral insertion expands and differentiates.[1–3]

## IMAGING

Ultrasound is the first-line imaging technique in pediatric uroradiology. Unfortunately, the ureter can generally only be visualized when it is sufficiently filled with urine, and even then only the proximal and distal aspects are typically seen. Using the kidney as an acoustic window from a posterior or lateral approach, the ureteropelvic junction (UPJ) can usually be identified in well-hydrated patients with a tapering of the pelvis toward the proximal ureter. To visualize the ureterovesical junction (UVJ) and distal ureter, sufficient fluid distension of the urinary bladder is mandatory so that it can serve as a window to the retrovesical space. Once the bladder is sufficiently filled, the normal ureter can be followed superiorly for several centimeters. Further visualization up to the iliac vessels or higher is only possible in cases with a significantly dilated ureter and sufficient sonographic access.

Sonographic evaluation of the urine inflow jet from the ureteral orifice into the urinary bladder can provide useful information about the patency and peristaltic activity of the ureter, as well as the position and function of the UVJ. This ureteral jet can sometimes be seen on gray-scale ultrasound as a rush of echoes from the ureteral ostium into the bladder lumen, but it is more easily seen with color Doppler sonography. Sonographic visualization of this jet can be limited with patient dehydration or when the specific gravity of ureteral urine and bladder urine are similar after recent voiding.[4–8]

Modern multidetector computed tomography (CT) can rapidly acquire high spatial resolution images of the entire ureter and surrounding structures. In pediatric uroradiology, CT can be useful for evaluation of severe trauma, urolithiasis and its complications, inflammatory disease, suspected obstructing crossing vessels, and tumors.[8–11] For evaluation of urolithiasis, noncontrast enhanced CT is typically performed, but for other indications, opacification of the ureteral lumen with contrast is often beneficial. This can be achieved either with delayed, excretory phase imaging after a single contrast material injection or with a split-bolus CT urography technique in which the renal parenchyma and ureter are opacified with contrast material simultaneously.[12] CT angiography can be used to assess vascular anatomy. Although a useful technique, CT does impart ionizing radiation and often requires iodinated contrast, which carries its own inherent risks. Thus CT should be used only when necessary, and protocols should be tailored to minimize radiation exposure.[8]

Diuretic renography is a well-established nuclear medicine technique for assessment of renal function and urinary tract drainage, where serial image acquisitions are obtained after intravenous injection of 99m-technetium-mercaptoacetyltriglycine ($^{99m}$Tc-MAG3) or $^{99m}$Tc-diethylene triamine pentaacetic acid ($^{99m}$Tc-DTPA) both before and after diuretic stimulation.[13,14] With this technique, ureteral drainage can be visualized and quantified in a standardized fashion providing excellent functional information. Limitations and drawbacks include patient exposure to ionizing radiation, limited assessment of urinary tract drainage in the setting of poor renal function, and poor anatomic resolution.[13,15]

Magnetic resonance urography (MRU) can provide excellent spatial resolution and functional information in a single study without the use of ionizing radiation or iodinated contrast material. In children, MRU can be particularly useful in the investigation of congenital genitourinary anomalies and hydronephrosis.[16–18] With MRU, anatomic assessment of the entire ureter can be obtained without the need for intravascular contrast material by using a variety of T2-weighted pulse sequences. Postdiuretic contrast-enhanced MRU (so-called functional MRU) allows for functional assessment by using fast T1-weighted gradient recalled echo pulse sequences to image at multiple time points after contrast material administration, allowing assessment of the arterial, corticomedullary, nephrographic, and excretory phases.[19–20] Downsides of this technique at present include availability, cost, inability to image patients with certain implantable devices, need for sedation or anesthesia for many pediatric patients, and risk of nephrogenic systemic fibrosis if a linear gadolinium contrast agent is administered to patients with severe kidney disease.[17,18] There is also growing concern about detectable deposition of gadolinium in body tissues, but at present long-term effects remain uncertain.[21]

## URETERAL OBSTRUCTION

There is a spectrum of ureteral obstruction ranging from partial obstruction without any clinical consequence to severe obstruction that can threaten renal function. Most ureteral obstructions occur at the UPJ or UVJ. However, obstructive lesions between these two points can occur as a result of congenital and acquired causes.

### Congenital Obstruction

***Ureteral Valve.*** Congenital ureteral valves are transverse folds of mucosa and variable smooth muscle that are typically cusp-shaped or diaphragm-like in configuration.[22–25] They are by definition associated with upstream obstructive uropathy and a normal downstream urinary tract, without evidence of other cause for obstruction.[23] They are often associated with other urinary tract anomalies (Fig. 118.1).[24,26] Neonates and infants may have physiologic ureteral folds that can mimic ureteral valves, but the former are not associated with obstruction and typically disappear during the first years of life (Fig. 118.2).[27] Imaging will demonstrate dilation of the upstream ureter and renal collecting system with abrupt transition at the level of obstruction. The fold may be visible

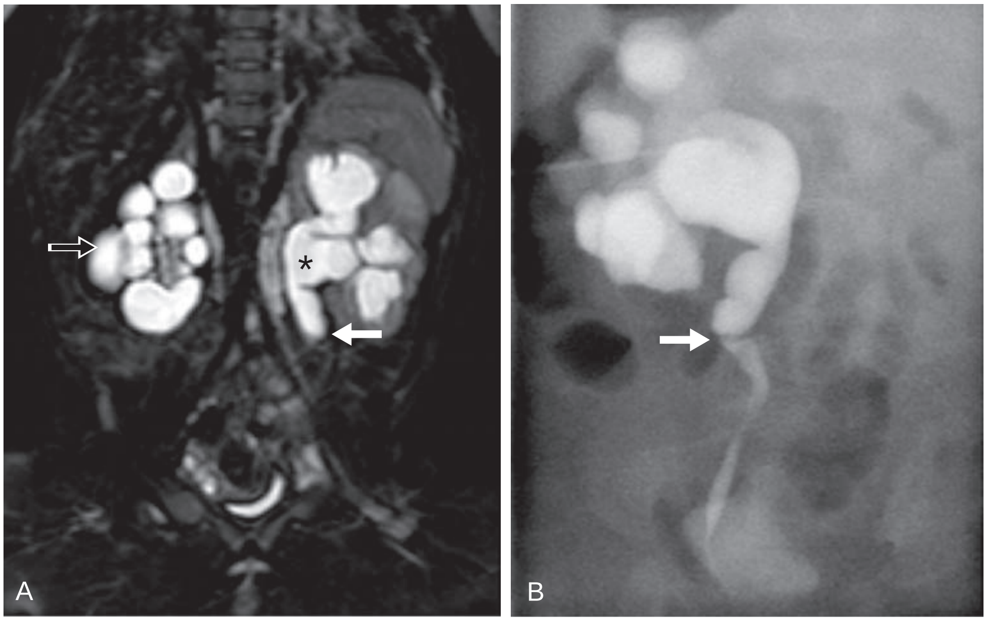

**Figure 118.1. Left ureteral valve in a 2-month-old girl.** (A) Coronal T2-weighted fat-saturated MRU image demonstrates dilation of the left pelvocalyceal system *(asterisk)* and proximal ureter with high-grade transition to a decompressed more distal ureter *(white arrow).* The right kidney consists of multiple cysts of variable size and a small amount of dysplastic parenchyma *(black arrow)*, compatible with multicystic dysplastic kidney (MCDK). (B) Percutaneous antegrade pyelogram of the same patient in the prone position demonstrates focal shelflike narrowing of the left ureter *(arrow)* at the level of transition seen on MRU.

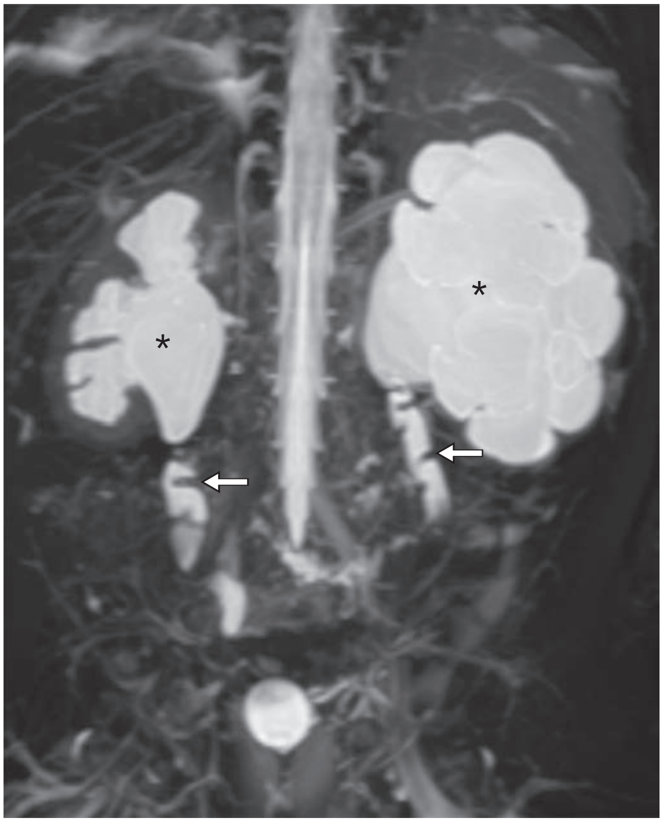

**Figure 118.2. Bilateral ureteral folds as well as bilateral UPJ obstructions in a neonate.** Coronal T2-weighted maximum intensity projection MRU image shows linear filling defects in both proximal ureters without associated ureteral caliber change at the level of the filling defects *(arrows)*, compatible with ureteral folds. Marked bilateral pelvocaliectasis *(asterisks)*, worse on the left, is due to superimposed bilateral UPJ obstructions.

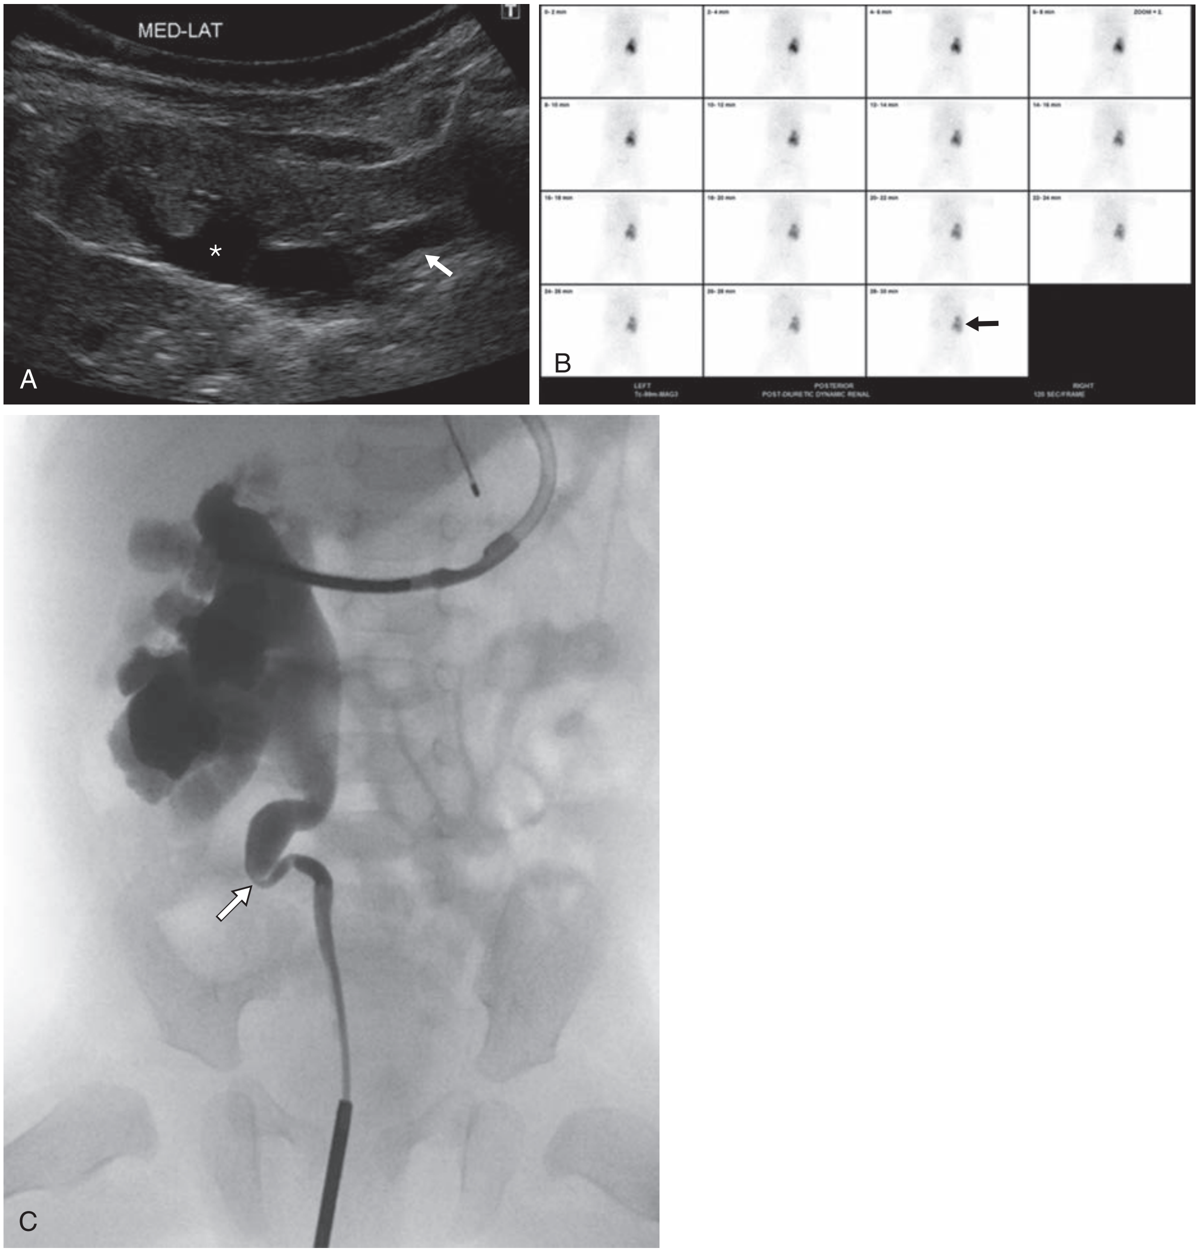
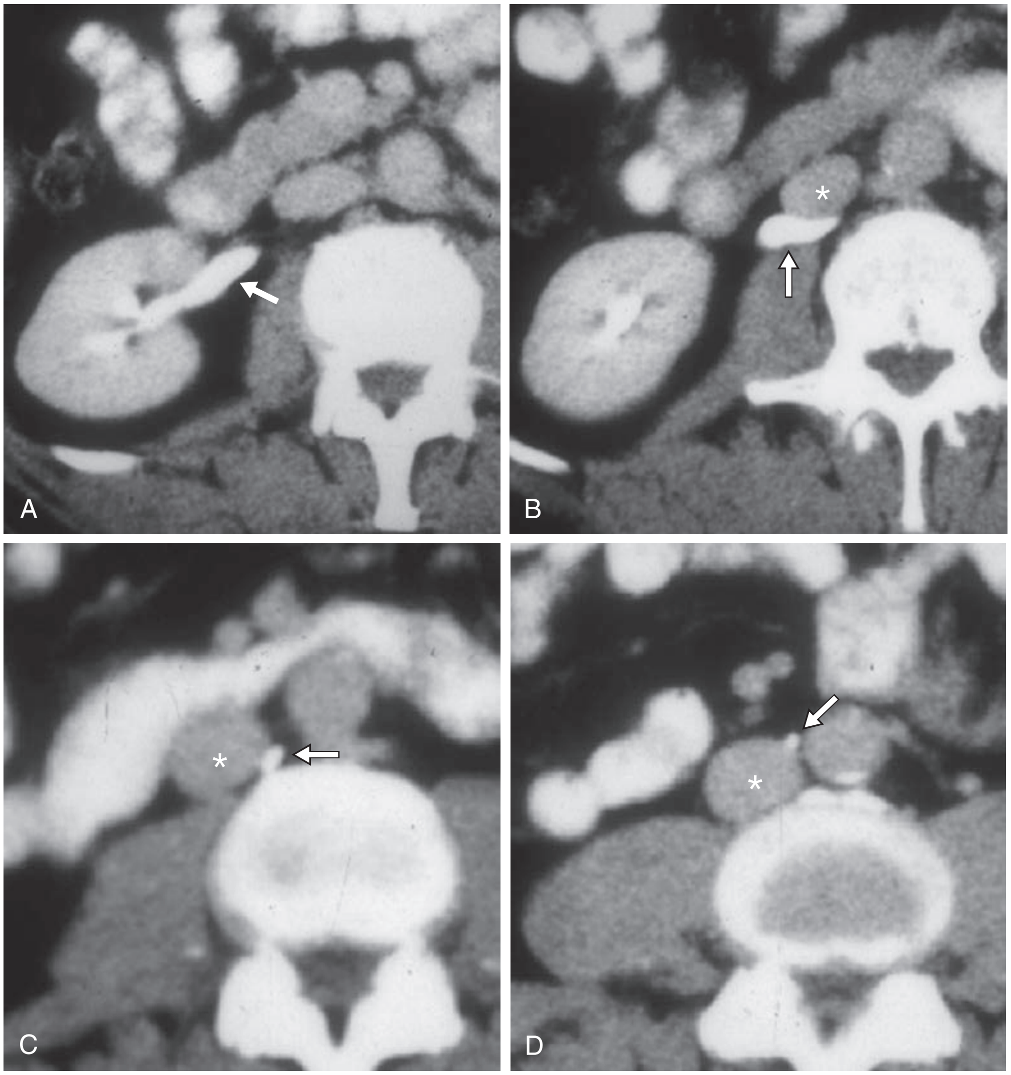
as a membrane-like filling defect when the entire ureter is opacified with contrast material or on heavily T2-weighted noncontrast MRU sequences. Renal scintigraphy will demonstrate impaired collecting system drainage suggesting obstruction.[26] Treatment consists of resection of the valve-containing ureteral segment and ureteral end-to-end anastomosis.[26]

***Congenital Ureteral Stricture.*** A congenital ureteral stricture is a discrete segment of congenital narrowing along the length of the ureter that does not involve the UPJ and UVJ. It is most commonly seen in the middle third of the ureter, typically where the ureter crosses the common iliac vessels, and is therefore often referred to as a “midureteral stricture” (Fig. 118.3). However, it can also occur in the proximal or distal ureter.[28] Unlike with ureteral valves, there are no mucosal folds present, and at pathology, a smooth funnel-shaped narrowing of the lumen is seen. The etiology is uncertain, with possibilities including focal abnormalities of ureteral wall musculature or relative focal ischemia during development. Association with multicystic dysplastic kidney (MCDK), either ipsilateral or contralateral to the involved ureter, is not uncommon.[28-31] Detection on prenatal imaging has been reported, but differentiating a midureteral stricture from the more common UPJ or UVJ obstruction is challenging. On postnatal imaging, findings will often be similar to those of ureteral valves, with distinction between the two entities generally made at pathology (e-Fig. 118.4).[29,32,33] Most congenital ureteral strictures require surgical management, but patients with preserved function and no symptoms may be managed conservatively.[28]

***Vascular Compression.*** A retrocaval or circumcaval ureter is an uncommon anomaly more often seen in males in which the right ureter passes posterior to the inferior vena cava (IVC), emerges between the cava and the aorta, and then curves around and in front of the cava to return to its normal position in the pelvis (e-Fig. 118.5). This anomaly results from anomalous development of the infrarenal IVC from the more laterally located right posterior cardinal vein rather than the more typical right supracardinal vein.[34,35] At least some degree of ureteral obstruction is common. However, patients are often asymptomatic, and the abnormality



**e-Figure 118.4. Right congenital ureteral stricture and solitary right kidney in a 1-month-old girl.** (A) Ultrasound of the solitary right kidney shows pelvocaliectasis *(asterisk)* as well as dilation of the imaged proximal ureter *(arrow).* (B) Posterior post-diuretic images from diuretic renography show poor drainage of the dilated proximal right collecting system *(arrow).* (C) Retrograde pyelogram demonstrates focal narrowing of the middle third of the ureter, with ureteral caliber change at the level of narrowing *(arrow).* Excision of the narrowed segment and ureteroureterostomy were subsequently performed, with pathology confirming a congenital ureteral stricture.



**e-Figure 118.5. Sequential cranial to caudal axial images of a retrocaval ureter on excretory phase contrast-enhanced CT.** (A) Contrast opacified right renal pelvis and proximal ureter *(arrow)*. (B) The right ureter *(arrow)* courses toward the posterior aspect of the IVC *(asterisk)*. (C) The right ureter *(arrow)* has passed posterior to the IVC *(asterisk)* and is seen along the posteromedial aspect of the IVC. (D) The ureter *(arrow)* has coursed between the aorta and IVC *(asterisk)*, and is seen along the anteromedial IVC in the aortocaval groove.

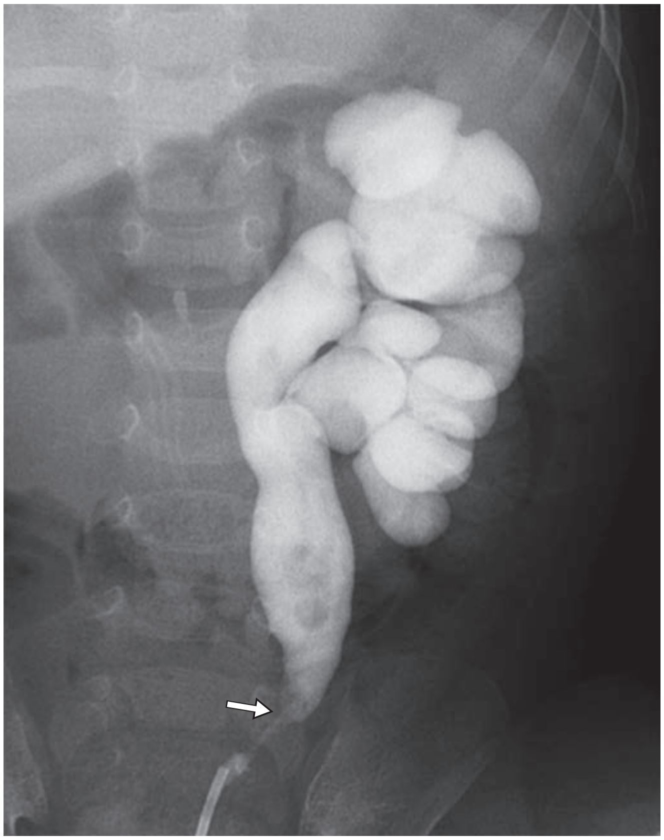


**Figure 118.3. Left congenital ureteral stricture in a 5-month-old girl.** Retrograde pyelogram demonstrates dilation of the left proximal ureter and pelvocalyceal system upstream to focal narrowing in the middle third of the ureter in the region where it crosses the iliac vessels *(arrow).* The left renal collecting system is duplicated, having a bifid appearance.

may be discovered on imaging for other reasons.[36,37] The anomaly may be demonstrated with contrast-enhanced CT, but MRU can establish the diagnosis and assess the degree of functional obstruction.[34,38,39] Surgery is performed when the patient is symptomatic or when there is decreased function of the affected kidney, and consists of division of the retrocaval ureter and ureteroureteric or ureteropelvic anastomosis anterior to the IVC.[36]

Crossing renal arteries and veins have been associated with urinary tract obstruction, particularly intermittent obstruction manifesting as recurrent renal colic and hydronephrosis.[40,41] These vessels typically cross anterior to the UPJ or proximal ureter and may be branches of the renal artery or vein, or accessory vessels (Fig. 118.6).[41,42] The crossing vessel may be demonstrated with either contrast-enhanced CT or MR angiography.[42,43] Normal vascular impressions can be seen on imaging but are not associated with secondary findings of obstruction. When a crossing vessel is identified in a patient with clinical and imaging findings suggesting intermittent obstruction and there is no intrinsic UPJ obstruction identified at surgery, a vessel transposition can be performed. When a crossing vessel is felt to be potentially aggravating an underlying intrinsic UPJ obstruction, a dismembered pyeloplasty is performed.[43]

## Acquired Obstruction

***Acquired Strictures.*** Acquired strictures of the ureter are uncommon in children. Potential causes are numerous and include: iatrogenesis (e.g., surgery, instrumentation, radiation therapy), chronic infection (e.g., tuberculosis, schistosomiasis, chronic granulomatous disease), inflammation from a passed stone, autoimmune etiologies (e.g., Henoch–Schönlein purpura and polyarteritis nodosa), and trauma (e-Fig. 118.7).[12,44–46] Strictures can be of variable length, can involve any segment of the ureter, and can be multiple. Fixed narrowing and associated upstream ureteral dilation can help differentiate strictures from physiologic narrowing, which is particularly common at the UPJ, pelvic brim, and UVJ.[12]

***Obstructing Filling Defects.*** Multiple different obstructing luminal filling defects can occur in the pediatric ureter, including crystalline debris, blood clots, calculi, and fungus balls.[12,47–51] Ultrasound may directly demonstrate an echogenic filling defect if it is contained within the visible ureter and may show posterior acoustic shadowing and twinkling artifact in the setting of urolithiasis. Ureteral dilation upstream of the filling defect suggests associated obstruction, but the degree of dilation may be very mild in the acute setting despite the patient having severe pain (Fig. 118.8). In this scenario, alterations in the bladder ureteral inflow jet on color Doppler sonography may be a helpful indirect sign of obstruction (Fig. 118.9).[52,53] All calculi except indinavir calculi are typically visible at noncontrast CT, with other types of filling defects visible at CT urography.[12] Although not typically used in the acute setting, contrast-enhanced MRU can confirm the presence of an obstructing filling defect and determine the level of the obstruction with high sensitivity.[18]

***Extrinsic Causes of Obstruction.*** Secondary ureteral inflammation and narrowing can result from adjacent infection, inflammatory bowel disease, or rarely retroperitoneal fibrosis (Fig. 118.10).[12,54] Mass-effect or encasement by adjacent tumor can also be associated with ureteral narrowing and obstruction (Fig. 118.11).[12] Imaging findings will be those of ureteral obstruction previously described with additional extraureteral findings dependent upon the extrinsic cause of obstruction.

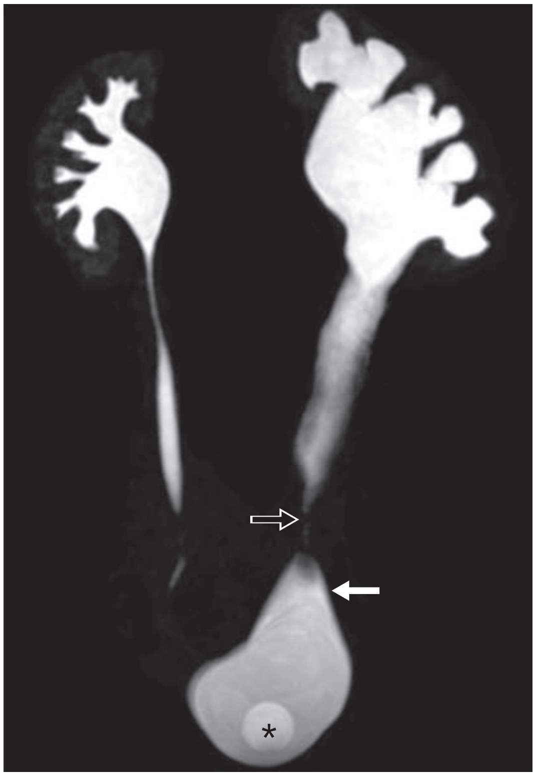
## DISORDERS OF URETERAL MOTILITY

Impaired ureteral motility in the form of hypoperistalsis or dyskinesia may be transient or permanent, and can be seen in association with acute or chronic obstruction, abnormal ureteral implantation, vesicoureteral reflux, instrumentation or surgery, urinary tract infection, and certain medications.[55,56] There may be associated functional obstruction and upstream ureteral dilation, with urine drainage relying on gravity. Overall drainage of the collecting system can be assessed with renal scintigraphy or MRU, and direct assessment of ureteral peristalsis may be achieved with ultrasound, renal scintigraphy, or MRU.[55–58]

## PRIMARY MEGAURETER

Megaureter is a generic term used to describe an abnormally dilated ureter and can be primary or secondary. The term primary megaureter is reserved for ureteral dilation due to intrinsic abnormality of the ureter or UVJ rather than downstream abnormality in the bladder or urethra, or other extrinsic cause.[59,60] Megaureters are categorized as obstructed, refluxing, nonobstructed and nonrefluxing, and, occasionally, obstructed and refluxing.[59]

***Primary Obstructed Megaureter.*** Primary obstructed megaureter is caused by a congenital adynamic distal ureteral segment, usually 0.5 to 4 cm in length, which prevents normal caudal propagation of ureteral peristalsis and results in functional obstruction. The exact cause for the aperistaltic segment is uncertain, but ureteral wall muscular derangement and increased collagen infiltration have been described at histology and electron microscopy. At endoscopy, the distal ureter and ureteral orifice are typically normal in caliber and appearance.[61] Primary obstructed megaureter may manifest as recurrent urinary tract infection (UTI), renal scarring, abdominal or flank pain, hematuria, palpable mass, or, rarely, renal failure. However, a primary megaureter may also be discovered incidentally in asymptomatic patients.[62–64]



**e-Figure 118.7. Postsurgical ischemic stricture in a teenage boy with history of left ureteroneocystostomy and psoas hitch procedure.** Coronal T2-weighted maximum intensity projection MRU image demonstrates a tethered, conical appearance of the left superolateral bladder *(white arrow)*, compatible with history of prior psoas hitch procedure. There is segmental distal left ureteral narrowing at the site of stricture *(black arrow)* with upstream ureteral dilatation. A Foley balloon is seen in the bladder *(asterisk).*

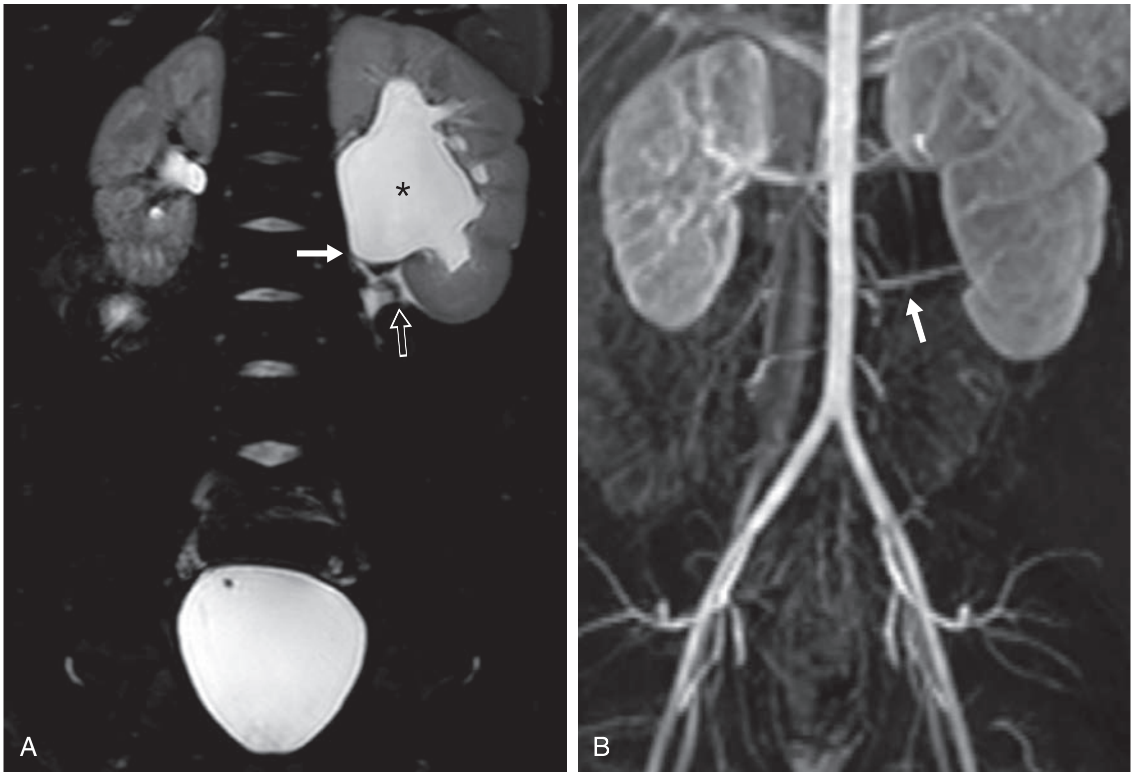


**Figure 118.6. UPJ obstruction due to a crossing vessel.** (A) Coronal T2-weighted MRU image demonstrates a dilated left renal pelvis and calyces *(asterisk)* with cutoff at the UPJ *(white arrow).* Inferior perirenal fluid *(black arrow)* may reflect forniceal rupture or urine transudation. (B) Coronal postcontrast maximum intensity projection MRU image shows a lower pole accessory artery *(arrow)* crossing the left collecting system at the level of the UPJ. UPJ obstruction due to a crossing vessel was confirmed at subsequent surgery.

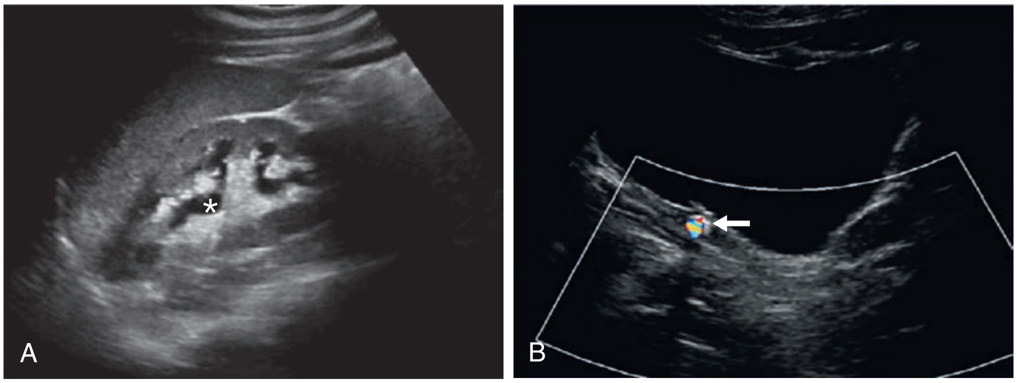

**Figure 118.8. Obstructing ureteral calculus in a 16-year-old girl with left flank.** (A) Gray-scale sonogram of the left kidney demonstrates mild pelvocaliectasis *(asterisk).* (B) An echogenic filling defect with posterior acoustic shadowing and twinkling artifact is present in the distal left ureter *(arrow).*

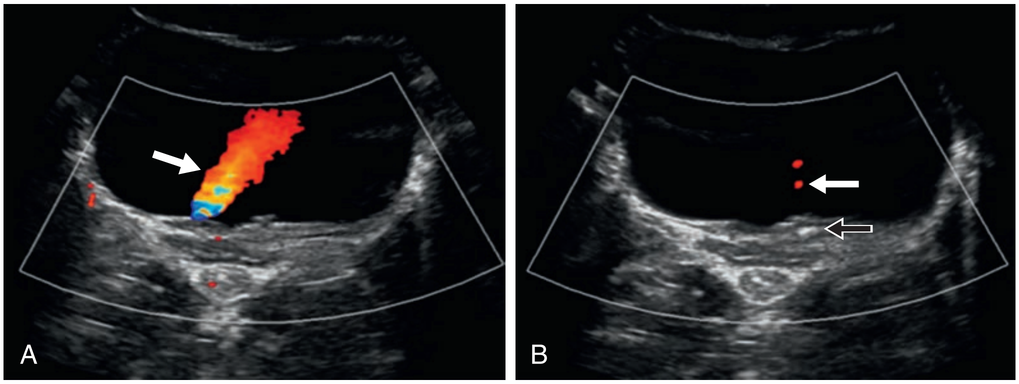

**Figure 118.9. Asymmetric ureteral jets in a teenage girl with left flank pain.** (A) Normal right ureteral jet *(arrow).* (B) Nearly absent left ureteral jet *(white arrow)* with echogenic filling defect *(black arrow)* seen in the distal left ureter at the UVJ, suggesting a partially obstructive left ureteral calculus.

On imaging, the affected ureter is variably dilated, typically affecting the lower ureter greater than the upper ureter and renal pelvis, with abrupt tapering to a relatively narrowed short distal segment (Fig. 118.12 and e-Fig. 118.13).[60] Absent peristalsis of the persistently relatively narrowed distal ureteral segment and/or abnormal to-and-fro peristalsis in the dilated upstream ureter may be seen at ultrasound.[65] Diuretic renal scintigraphy or MRU can be used to assess urinary tract drainage and obstruction. Vesicoureteral reflux (VUR) may occasionally be present in patients with obstructed primary megaureter. Patients with preserved renal function and no symptoms can be managed conservatively. However, resection of the aperistaltic segment and ureteral reimplantation

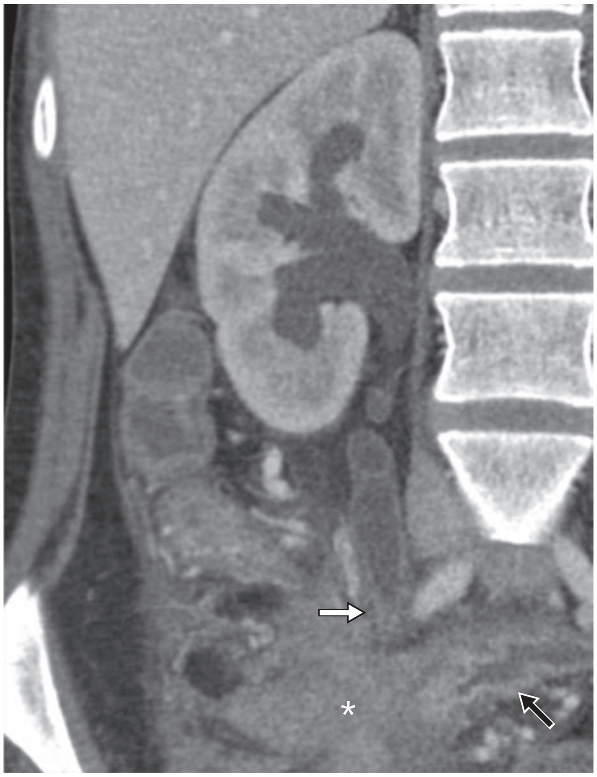

**Figure 118.10. Right ureteral obstruction from extensive bowel and mesenteric inflammation in a 16-year-old girl with Crohn disease.** Coronal postcontrast CT image shows narrowing of the midright ureter *(white arrow)* at the level of an inflammatory mass/phlegmon *(asterisk)*; inflamed bowel is present *(black arrow).* There is associated reactive ureteral wall thickening and upstream pyeloureteral dilation.

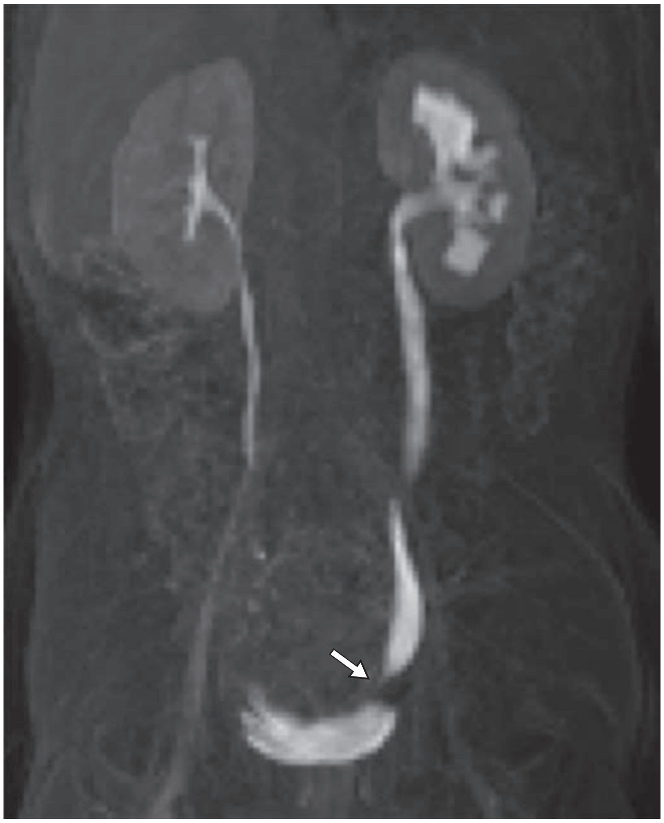

**Figure 118.12. Obstructed primary megaureter in a 12-year-old girl.** Coronal postcontrast T1-weighted excretory phase maximum intensity projection MRU image shows left collecting system and ureteral dilation that is most pronounced distally; there is abrupt narrowing of the very distal left ureter *(arrow).* There was substantially delayed passage of contrast material through the left collecting system and ureter compared with the contralateral side.

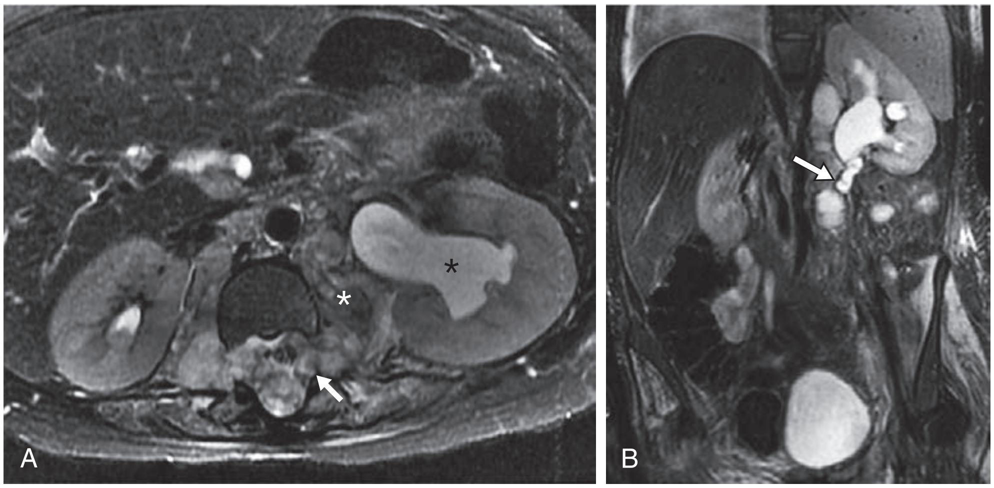

**Figure 118.11. Left ureteral obstruction due to compression by a malignant peripheral nerve sheath tumor in an 18-year-old girl.** (A) Axial T2-weighted MR image shows left pelvocaliectasis *(black asterisk)*. There is an immediately adjacent large predominantly retroperitoneal mass *(white asterisk)* with spinal canal invasion *(arrow)*. (B) Coronal T2-weighted MR image demonstrates abrupt cutoff of the ureter at the level of a portion of the mass *(arrow).*

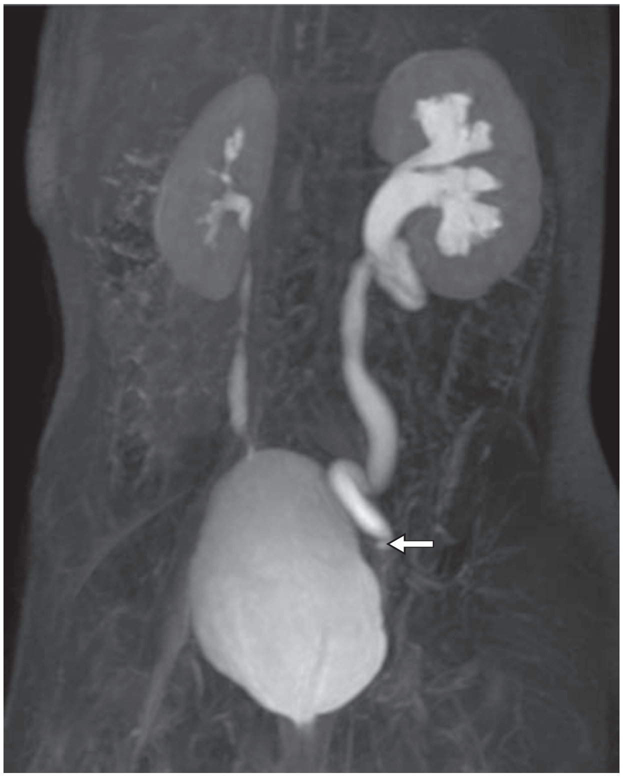

**e-Figure 118.13. Obstructed primary megaureter in a 6-year-old boy.** Coronal postcontrast T1-weighted excretory phase maximum intensity projection MRU image shows a dilated, tortuous left ureter with cutoff or high-grade transition of the distal ureter contrast column *(arrow)*. The narrowed distal ureteral segment is greater than 5 cm in length.

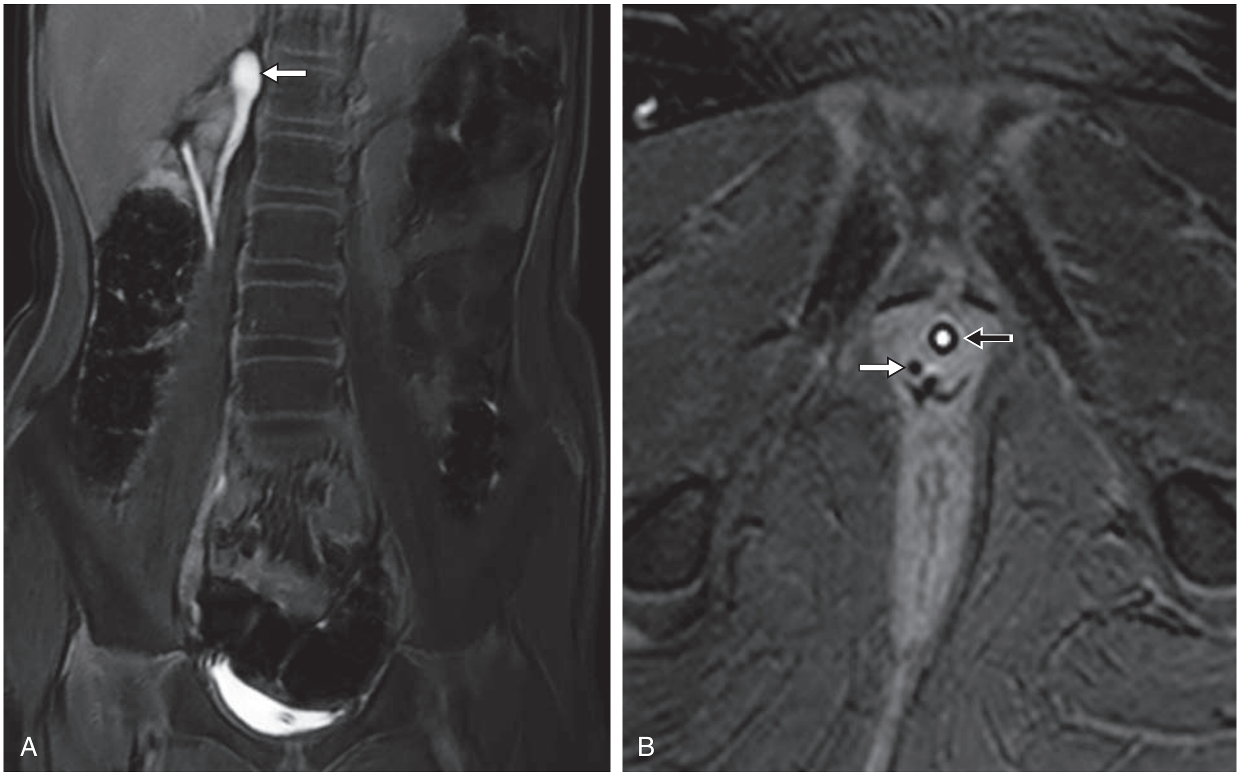

**Figure 118.14. Ectopic ureter in a 7-year-old girl with daytime and nighttime wetness.** (A) Coronal postcontrast T1-weighted excretory phase MRU image demonstrates a right duplex kidney with the upper pole ureter draining a single calyx *(arrow).* (B) Axial postcontrast T1-weighted fat-saturated MRU image through the lower pelvis shows the ectopic upper pole ureter *(white arrow)* coursing through the right anterolateral vaginal wall, appearing as a round hypointense focus. No contrast material is seen within the lumen due to obstruction. A bladder catheter with luminal contrast material demarcates the more anteriorly located urethra *(black arrow).*

may be performed for those with reduced renal function, recurrent pain, hematuria, multiple urinary tract infections, and urolithiasis. A temporizing procedure such as cutaneous ureterostomy or ureteral stent placement may be performed in neonates or infants before definitive surgery.[61]

***Primary Refluxing Megaureter.*** Refluxing megaureter may be the result of a short or absent intravesical ureter, or other abnormality of the UVJ, and is more fully discussed in the chapter on vesicoureteral reflux (see Chapter 119).[64] On imaging, a dilated ureter will be demonstrated in association with VUR. There should be no evidence of ureteral obstruction.

***Primary Nonobstructed, Nonrefluxing Megaureter.*** Nonobstructed, nonrefluxing megaureter is the most common form of megaureter detected in neonates. The cause is uncertain, but this form of megaureter may be the result of higher prenatal urine production seen in third trimester fetuses relative to postnatal urine production or impaired peristalsis as a result of delayed ureteral maturation. Regardless, nonobstructed, nonrefluxing megaureter typically resolves in the first 2 years of life.[61] As in any case of megaureter, voiding cystourethrography (VCUG) or radionuclide cystography should be performed to exclude VUR. Diuretic renal scintigraphy or MRU should be performed to exclude obstruction that may require surgery. This benign form of megaureter is generally managed conservatively.[60]

## URETERAL ECTOPIA

An ectopic ureter is one that drains to an abnormal site, either within the bladder outside the normal posterolateral angle of the trigone, or extravesically.[66] Ureteral ectopia is more common in girls than in boys. Although ectopic ureters can drain a single collecting system, they drain a duplicated collecting system in up to 80% of cases.[67–69]

In girls, the ectopic ureter may insert into the low bladder or urethra upstream of the external sphincter, preserving continence. However, commonly the ureter bypasses the sphincter complex and inserts into the vagina, vestibule, cervix, uterus, or into a Gartner duct cyst (Figs. 118.14 and 118.15).[60,70–72] As a result, female patients with an ectopic ureter commonly present with continuous dribbling of urine despite an otherwise normal voiding pattern.[60,70,73] While wetness often occurs during the day and at night, it may only occur during the day due to a capacious ectopic ureter or the vagina acting as a reservoir when the patient is recumbent at night.[70]

In boys, the ectopic ureter may insert into the low bladder, prostatic urethra, seminal vesicle, vas deferens, or ejaculatory duct.[60,70,74] Unlike in girls, the ectopic ureter inserts upstream of the sphincter. Therefore males do not present with incontinence but rather with pain, urinary tract infection, orchitis and/or epididymitis, or renal failure.[70,73] Ureteral ectopia to the genital ducts can manifest as a dilated, cystic mass behind the trigone of the bladder. In both sexes, the renal parenchyma drained by the ectopic ureter is commonly dysplastic, with some correlation between the degree of ectopia and the degree of renal dysfunction.[60,69,70,73]

Ultrasound is the initial imaging method of choice and can be diagnostic, particularly when the anomalous ureter is dilated and can be followed distally to its insertion. However, the renal parenchyma draining into an ectopic ureter often has poor excretion, limiting visibility of a nonobstructed ureter. In addition, the dysplastic renal parenchyma associated with an ectopic ureter may be small and subtle, often resulting in the dysplastic moiety or even an entire dysplastic kidney being missed.[60,68,75] CT acquired during the

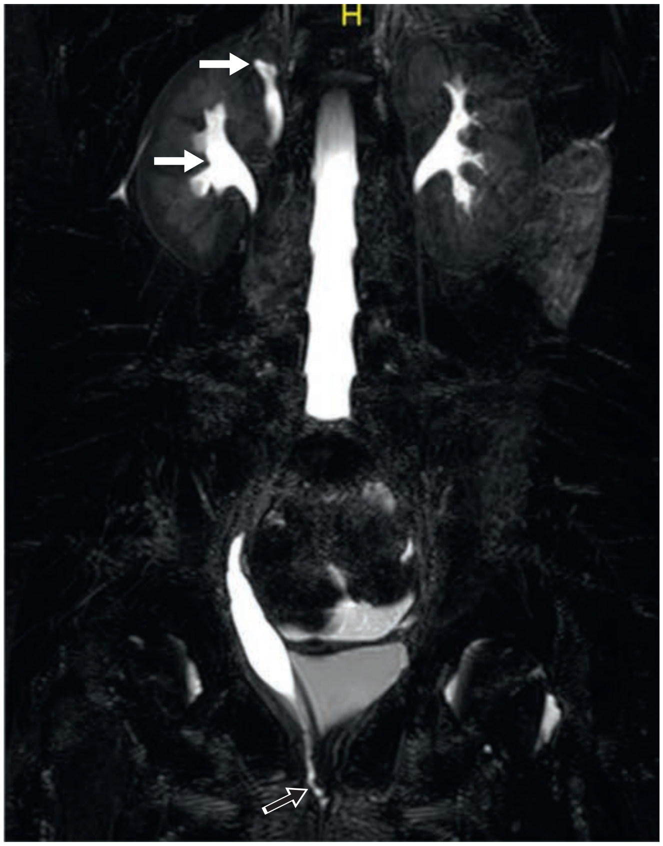

**Figure 118.15. Ectopic ureter in a 6-year-old girl with daytime and nighttime wetness.** Coronal T2-weighted MRU image shows a right duplex kidney *(white arrows).* An ectopic upper pole ureter courses past the bladder to the perineum *(black arrow).*

excretory phase of contrast enhancement may be more sensitive, with common findings being vaginal pooling of contrast material and a ureter coursing posterior to, and not inserting into, the bladder.[69] MRU has been shown to be highly accurate in depicting ectopic ureters, and in ruling out ureteral ectopia by demonstrating normal ureteral insertions. It can simultaneously assess renal function, which may play an important role in management decisions.[73]

Treatment depends on the functional status of the renal parenchyma drained by the ectopic ureter. If there is poor function, a partial or complete nephroureterectomy is performed in the setting of a duplicated system and single system, respectively. When renal function needs to be preserved, ureteroureterostomy or ureteral reimplantation can be performed.[68,69]

## URETEROCELE

A ureterocele is a cystlike submucosal expansion of the terminal segment of the ureter within the bladder or urethra. There are two subtypes: (1) intravesical ureterocele, located entirely within the bladder; and (2) ectopic ureterocele, in which some portion is situated permanently at the bladder neck or in the urethra.[66] In children, ureteroceles are most often associated with a duplicated system and have an ectopic insertion. In adults, they are commonly associated with a single system and insert orthotopically. In the setting of a duplicated system, ureteroceles are almost always associated with the upper pole moiety, but rare cases of lower pole moiety ureteroceles have been reported.[76,77] Ureteroceles are four to seven times more common in girls and are bilateral in 10% of cases.[78]

Ureteroceles may be associated with renal dysplasia or obstructive nephropathy (Fig. 118.16).[79] There is VUR into the ipsilateral lower pole moiety ureter or the contralateral ureter in 50% and 25% of children, respectively.[80] Large ureteroceles can obstruct the ipsilateral lower pole moiety ureter or the contralateral ureter. Bladder outlet obstruction by a ureterocele that has prolapsed into the urethra is rare, as most ureteroceles decompress during voiding but can occur and may necessitate emergent treatment (e-Fig. 118.17).[79]

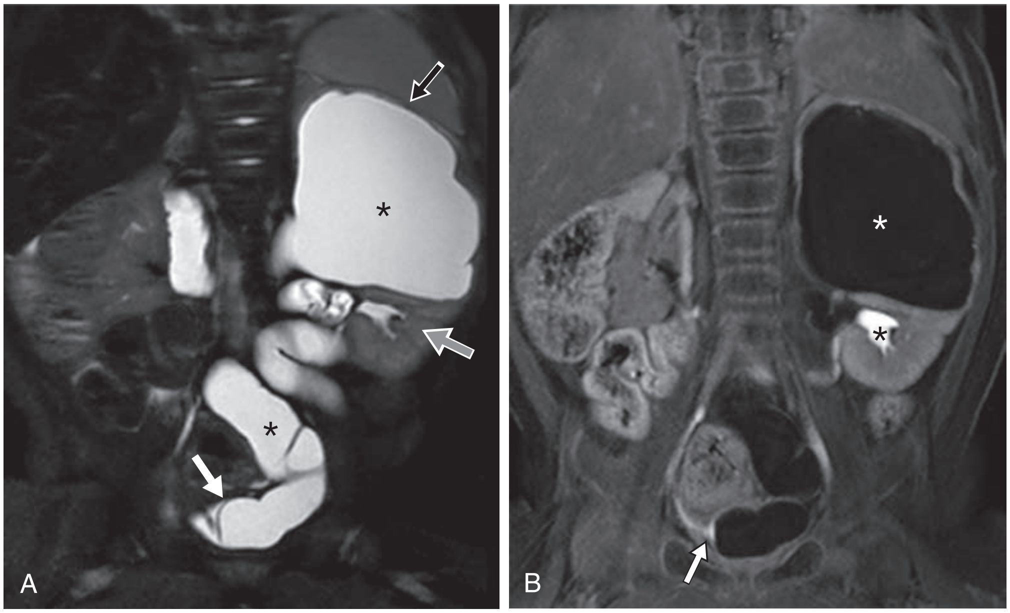

**Figure 118.16. Ureterocele-related obstructive nephropathy in a 6-month-old girl.** (A) Coronal T2-weighted fat-saturated MRU image demonstrates a left duplex system with severe upper moiety pyeloureteral dilation *(asterisk)* upstream of an intravesical ureterocele *(white arrow).* The ureterocele is surrounded by a small amount of urine in the bladder. The upper pole moiety parenchyma is markedly thinned *(black arrow).* The lower moiety collecting system is nondilated, and the parenchyma is normal *(gray arrow).* (B) Coronal postcontrast T1-weighted excretory phase MRU image shows contrast in the lower moiety collecting system *(black asterisk)* but no contrast within the upper moiety collecting system *(white asterisk)* due to obstruction and poorly functioning upper pole moiety parenchyma. A small amount of contrast is present within the bladder *(arrow).*

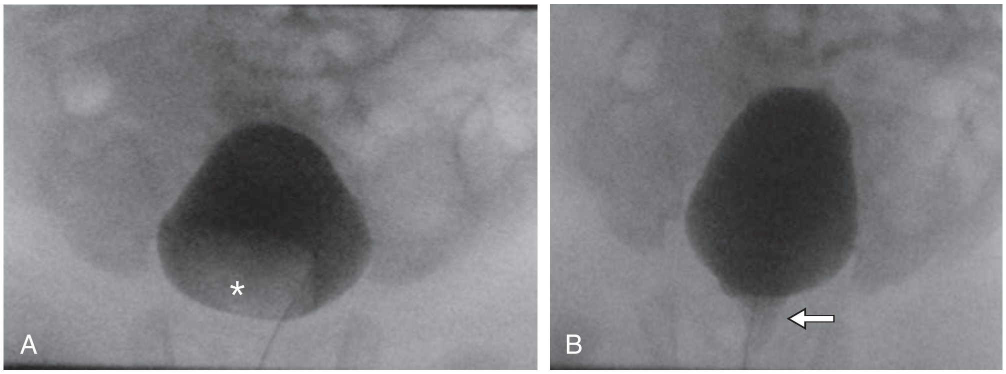

**e-Figure 118.17. Ureterocele decompression during voiding.** (A) Voiding cystourethrogram (VCUG) image acquired before voiding demonstrates a large, round filling defect *(asterisk)* in the right lower bladder, compatible with a ureterocele. (B) On a later image acquired during voiding, as demonstrated by contrast within the urethra *(arrow)*, the ureterocele has decompressed and is no longer visible.

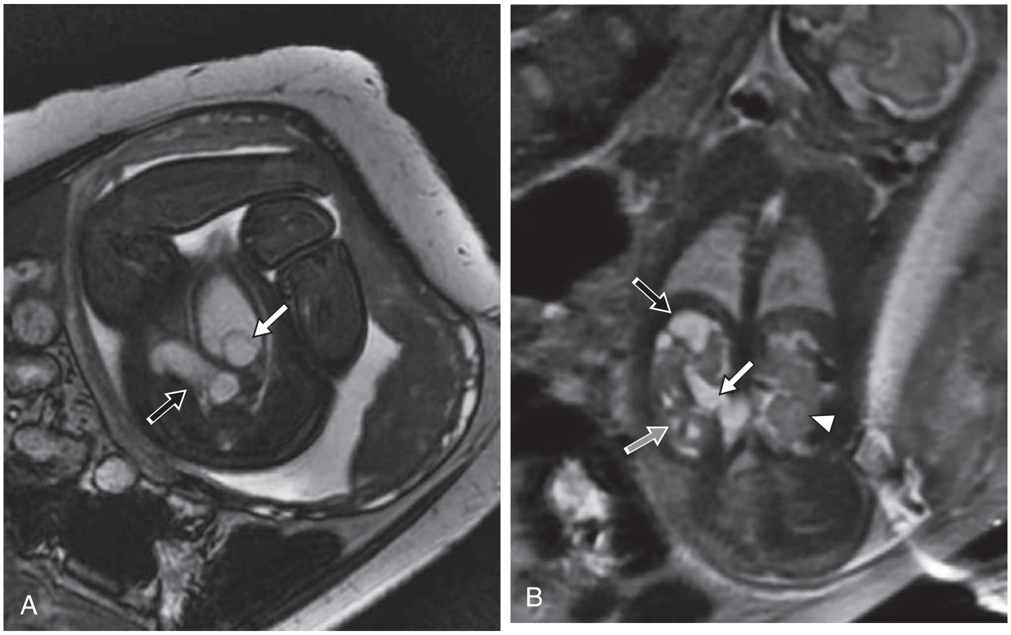

**Figure 118.18.** Ureterocele detected on fetal imaging. (A) Balanced steady-state free precession MR image in the axial plane of the fetus demonstrates a ureterocele *(white arrow)* with associated upstream ureteral dilation *(black arrow).* (B) Single-shot fast spin echo MR image in the coronal plane of the fetus shows the dilated ureter draining the upper moiety of a right duplex system *(white arrow).* There is cystic dysplasia of the upper moiety parenchyma *(black arrow).* There is also dilation of the lower moiety collecting system *(gray arrow)* that may be due to VUR or obstruction of the ureteral orifice by the large upper pole ureterocele. The left kidney is normal *(arrowhead).*

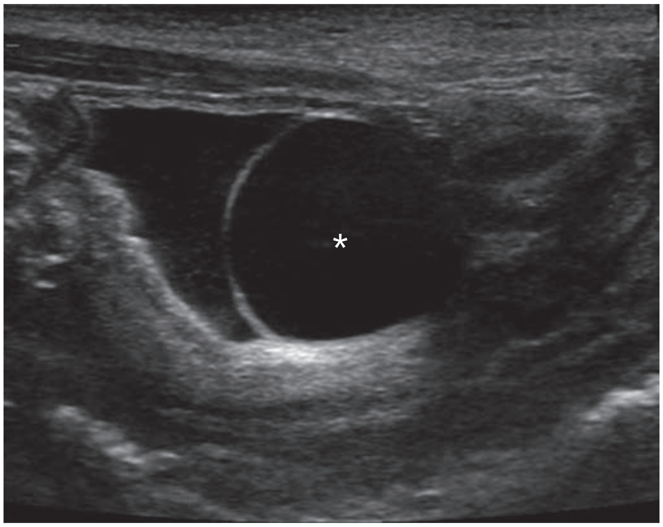

**Figure 118.19. Ureterocele in a 3-day-old girl.** Longitudinal sonogram of the bladder demonstrates a large ureterocele *(asterisk)* in the inferior bladder, giving a "cyst within a cyst" appearance.

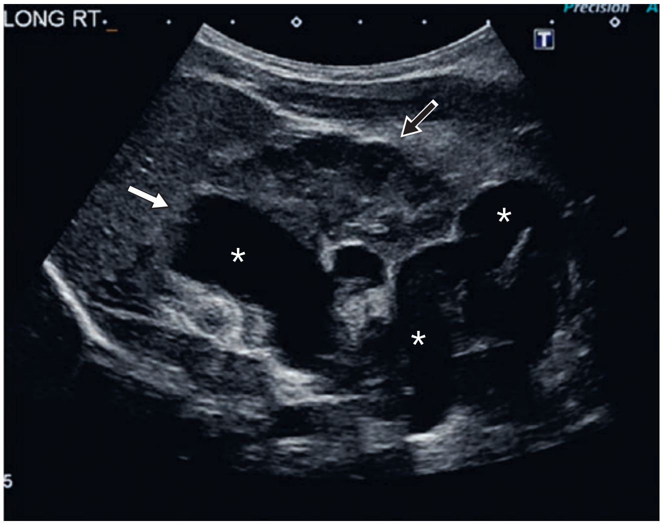

**Figure 118.21. Same 3-day-old girl with large ureterocele from Fig. 118.19.** Longitudinal sonogram shows dilation of the upper pole pelvocalyceal system and proximal ureter *(asterisks).* There is associated severe upper pole moiety parenchymal attenuation *(white arrow).* The lower pole moiety parenchyma is preserved *(black arrow).*

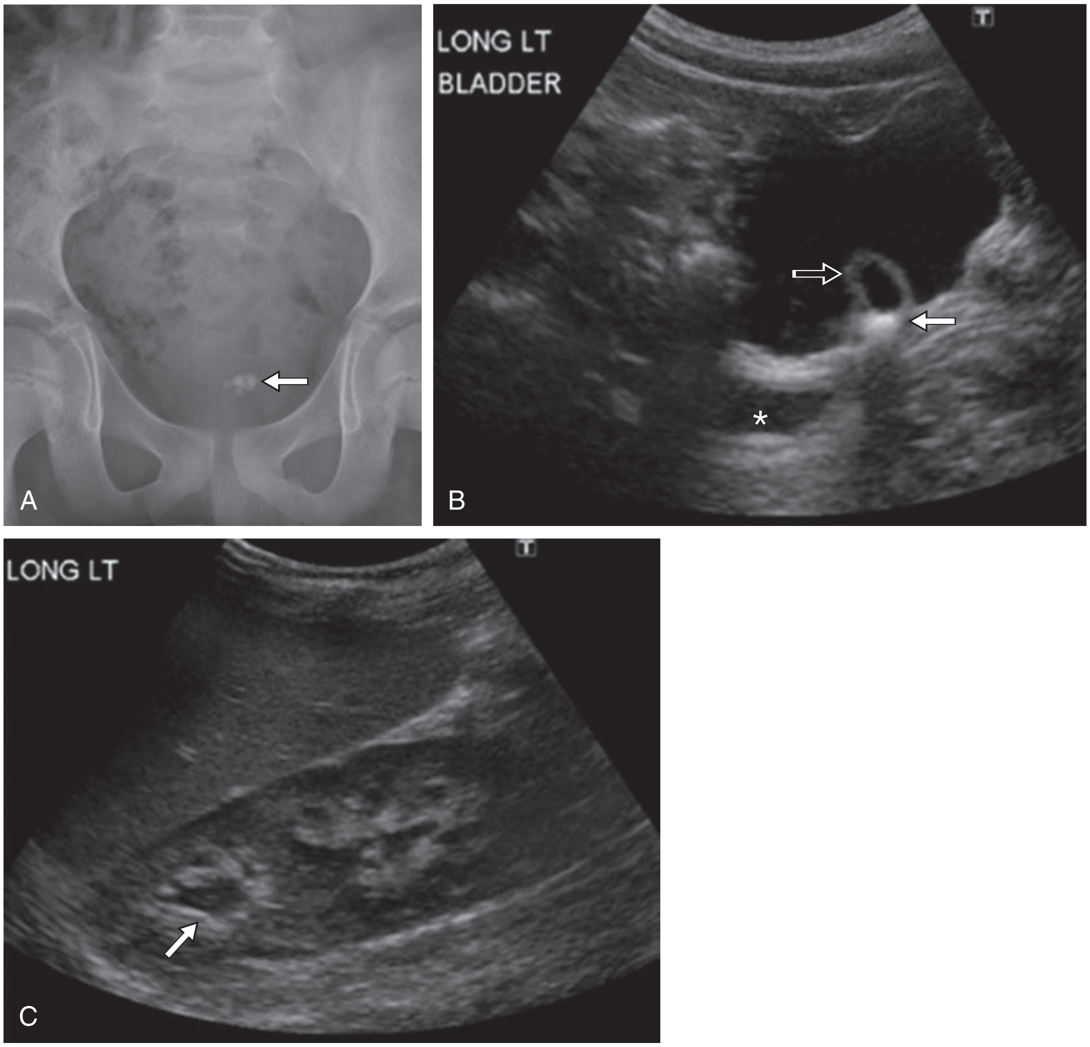
More than 90% of ureteroceles are discovered in children younger than 3 years of age and many are diagnosed prenatally (Fig. 118.18).[81] They commonly present clinically with UTI but can present as failure to thrive, abdominal or pelvic pain, hematuria, or acute bladder outlet obstruction. They may also be asymptomatic and incidentally detected.[78]

Ultrasound imaging of an intravesical ureterocele shows a cystic lesion of variable size attached to the posterolateral wall of the bladder and protruding into the lumen, giving a "cyst within cyst" appearance (Fig. 118.19).[60,78,79] An ectopic ureterocele will be seen as a cystic structure located more inferiorly than expected for an intravesical ureterocele.[60] Sometimes ureteroceles have a more complicated bilobed or septated appearance, and may contain debris or calculi (e-Fig. 118.20). On real-time sonography, partial or complete ureterocele collapse may be seen as a result of ureteral peristalsis.[60] There is often associated dilation of the upstream ureter as a result of obstruction (Fig. 118.21). However, even a large ureterocele can be associated with a diminutive ureter and calyces and minimal renal parenchyma, an entity known as "ureterocele disproportion."[82] Dilation of the contralateral ureter or of the ipsilateral lower moiety ureter in the case of duplication



**e-Figure 118.20. 6-year-old boy with left upper quadrant pain.** (A) Abdominal radiograph shows small calcifications in the left lower pelvis *(arrow).* (B) Longitudinal sonogram of the bladder demonstrates echogenic calculi with posterior acoustic shadowing *(white arrow)* seen in association with a left ureterocele *(black arrow).* There is upstream left ureteral dilation *(asterisk).* (C) Longitudinal renal sonogram shows a duplex left kidney with mild upper moiety caliectasis *(arrow).*

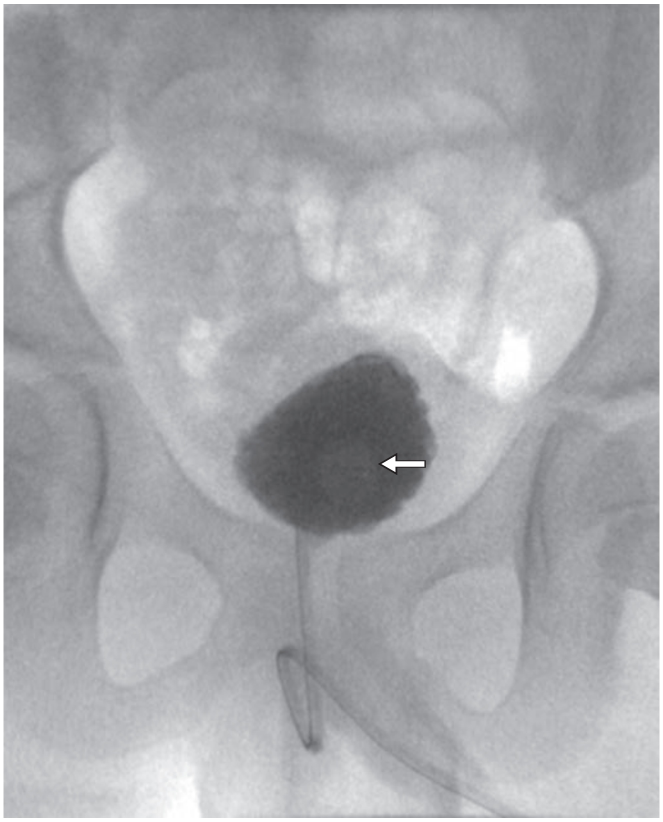


**Figure 118.22. Ureterocele on VCUG.** Frontal VCUG image acquired during early bladder filling demonstrates a round filling defect to the left of the midline.

may also be seen.[60,79] Ultrasound can also be useful for assessing the renal unit for findings of dysplasia or obstructive nephropathy, with the affected renal unit sometimes appearing as a cystic structure in cases of severe obstruction.

On VCUG, a ureterocele appears as a round or oval radiolucent filling defect within the bladder and is best imaged during early bladder filling (Fig. 118.22). As bladder luminal pressure rises with increased bladder filling, the ureterocele is compressed and flattened against the bladder wall, making it difficult to identify. With still higher bladder pressures, ureteroceles may even evert, simulating a paraureteral diverticulum. During voiding, a ureterocele may prolapse into the urethra. VUR into an untreated ureterocele is rare but common after endoscopic incision. Renal scintigraphy may reveal renal parenchymal functional impairment, particularly of an involved upper pole moiety. MRU can be useful for preoperative imaging because it provides functional information along with anatomic detail and can reveal any associated genitourinary abnormalities.[18]

Treatment depends on the type of ureterocele, the amount of renal function, and whether there is VUR into the ipsilateral lower pole moiety ureter and/or contralateral ureter. Endoscopic ureterocele incision alone can be successful for an intravesical ureterocele, but a second surgical procedure is generally required for an ectopic ureterocele. For an ectopic ureterocele with reasonably preserved renal function and no VUR of the lower pole moiety ureter, a ureteroureterostomy or ureteropyelostomy can be performed, connecting the upper and lower pole collecting systems. When there is poor renal function and no VUR, an upper pole partial nephrectomy is generally successful. In the setting of an ectopic ureterocele associated with poorly functioning upper pole moiety parenchyma and VUR of the lower pole moiety or contralateral ureter, an upper pole partial nephrectomy and likely second stage surgery consisting of ureterocele removal and double ureteral reimplantation is generally required.[79]

## URETERAL NEOPLASMS

Primary neoplasms of the upper urinary tract (renal pelvis and ureters), such as rhabdomyosarcoma or urothelial neoplasm, are extremely rare in children. The ureter is more often secondarily involved by tumors such as Wilms tumor, neuroblastoma, rhabdomyosarcoma, and malignant teratoma. Instances of benign and often pedunculated fibroepithelial polyps in the upper one-third of the ureter have been reported (e-Fig. 118.23) and can cause hematuria or rarely UPJ or ureteral obstruction. Ultrasound is only useful to detect large tumors with a significant extraureteral component or to visualize indirect signs of obstruction. Otherwise, imaging relies on CT or MRU.[83–89]

## POSTOPERATIVE IMAGING OF THE URETER

Postoperative imaging is heavily based on ultrasound. However, ultrasound is poor at assessing urinary drainage, and because a chronically dilated collecting system may remain dilated even after relief of obstruction, a functional scintigraphic or MRU study may prove helpful for distinguishing obstruction from chronic nonobstructive dilation. In the setting of postoperative ureteral obstruction (e.g., due to antireflux procedures, blood clots, or stricture), imaging may not only help in detection but also may assist interventions, such as ureteral balloon dilatation, ureteral stent placement, and percutaneous nephrostomy.

### KEY POINTS

- The ureter is more difficult to image than other parts of the urinary system.
- MRU is a powerful tool for imaging the upper urinary tract and can assess both anatomy and function without the use of ionizing radiation.
- Most ureteral obstructions occur at the UPJ or UVJ but can occur between these locations as a result of congenital or acquired causes.
- Megaureter may be obstructed, refluxing, nonobstructed and nonrefluxing, or obstructed and refluxing.
- A history of constant urine leakage in a girl with otherwise normal voiding should suggest extravesical ureteral ectopia.
- In children, ureteroceles are most often associated with the upper pole moiety of a duplicated system and have an ectopic insertion.
- Primary ureteral neoplasms are extremely rare in children, with secondary involvement of the ureter by extraureteral tumors more common.

# 119 Vesicoureteral Reflux

*Boaz Karmazyn and Brandon P. Brown*

## DEFINITION AND IMAGING OBJECTIVES

***Overview.*** Vesicoureteral reflux (VUR) refers to the retrograde passage of urine from the urinary bladder into the ureter and often to the renal collecting system.[1,2] VUR mainly affects infants and young children with a prevalence of 25% to 40% (Box 119.1).[1] VUR is a risk factor for the development of pyelonephritis, with consequent renal scarring.[3–6]

Current evidence suggests that the long-term risks associated with pyelonephritis and renal scarring are low and that preventive antibiotics and surgery may be useful in only a subset of patients.[7–12] Therefore most children with an uncomplicated initial urinary tract infection (UTI) will not benefit from imaging, and the focus in the evaluation of VUR should be patients who have complicated or recurrent UTIs, as some of them may benefit from prophylactic antibiotics or surgery.[8,11,13] Another common indication in the evaluation of VUR is prenatal hydronephrosis. VUR may also be associated with anomalies that require prompt surgical treatment to prevent renal damage.[13,14]

## ETIOLOGY

***Overview.*** The etiology of VUR is not entirely understood. It is possible that VUR in some infants is physiologic and will spontaneously resolve.[1,2] VUR may be caused by abnormal ureteric budding or interaction with the metanephric mesenchyme, resulting in a lateralized ureteral orifice, with a subsequent shortened submucosal ureter that is deficient in longitudinal muscle fibers.[1,2] Primary VUR has a familial association with genetic heterogeneity.[15–17]

Secondary VUR is seen in patients with other urinary tract anomalies (Box 119.2).[18–20] In addition, increased bladder pressure from bladder outlet obstruction (e.g., posterior urethral valves), as well as increased detrusor muscle tone or uncoordinated bladder contraction (e.g., neurogenic bladder) can cause VUR.[21–26]

**BOX 119.1** Common Features in Patients With Vesicoureteral Reflux (VUR)

- VUR is common in infants and young children.
- African Americans have lower incidence of VUR.
- VUR has a familial association (parent-child or sibling-sibling) with genetic heterogeneity.
- Most VUR will resolve spontaneously within the first decade of life.
- In utero VUR is associated with renal dysplasia.
- The main indications to evaluate for VUR are UTI and antenatal hydronephrosis.
- Children with VUR have increased incidence of pyelonephritis and renal scarring.
- Initial management in most children with VUR is to await spontaneous resolution.
- Children with VUR should be evaluated for bowel and bladder dysfunction.
- Treatment of bowel and bladder dysfunction increases resolution of VUR and improves surgical outcomes.
- Prophylactic antibiotic therapy decreases the risk of recurrent UTIs in children with VUR but not the risk of renal scarring.
- Surgery for VUR is reserved for children with breakthrough infections and progressive scarring.

## IMAGING TECHNIQUES

***Overview.*** The diagnostic imaging modalities preferred for the evaluation of VUR include voiding cystourethrogram (VCUG), radionuclide cystography (RNC), and ultrasound (US) (Box 119.3). The optimal imaging modality in the assessment of VUR depends on the indication, radiologist preference and experience, and availability. VCUG is the gold standard for depicting VUR and is especially useful as the initial imaging examination for boys, while contrast-enhanced voiding urosonography (ce-VUS) involves no ionizing radiation and may be used as the first study in girls and in follow-up studies. In the past, RNC was considered

**BOX 119.2** Causes of Vesicoureteral Reflux (VUR)

**PRIMARY**

- Developmental, idiopathic, or immature urinary tract
- Anomalous development at the ureterovesical junction

**SECONDARY**

- Bladder outlet obstruction, particularly posterior urethral valves
- Neurogenic bladder
- Bladder dyssynergia and dysfunctional voiding
- Bladder diverticula
- Prune-belly syndrome
- Postoperative bladder, including ureterocele incision

**BOX 119.3** Imaging of Vesicoureteral Reflux (VUR)

**VOIDING CYSTOURETHROGRAM (VCUG)**

- Gold standard study for grading of VUR
- Defines anatomy (bladder, urethra, and refluxing ureters and ureterovesical junctions)

**RADIONUCLIDE CYSTOGRAPHY**

- Allows continuous imaging
- Similar accuracy in grading VUR as compared with VCUG
- Limited anatomic details (decreased ability to see the urethra in boys)
- Can be used as the initial study in girls, or as a follow-up study for boys or girls

**CONTRAST-ENHANCED UROSONOGRAPHY**

- No radiation
- Similar accuracy in grading VUR as compared with VCUG
- Smaller field-of-view as compared with VCUG
- Provides anatomic information regarding kidneys and urinary tract

## Abstract:

Vesicoureteral reflux (VUR) is common in infants and young children. VUR can be evaluated with voiding cystourethrogram (VCUG), radionuclear cystography or contrast-enhanced voiding urosonography. VCUG has the advantage of demonstrating detailed anatomy and is therefore the imaging of choice for initial evaluation in boys.

In children with urinary tract infection (UTI), VUR is a risk factor for the development of pyelonephritis, with consequent renal scarring. The long-term risks associated with pyelonephritis and renal scarring including hypertension and decreased renal function are low, and preventive antibiotics and surgery may be useful in only a subset of patients. Therefore, most children with an uncomplicated initial UTI will not benefit from imaging. The focus in the evaluation of VUR should be in patients who have complicated or recurrent UTIs who may benefit from preventive antibiotics or surgical intervention.

Another common indication in the evaluation of VUR is prenatal hydronephrosis. VUR may be associated with anomalies that require prompt surgical treatment to prevent renal damage.

to have lower levels of ionizing radiation compared with VCUG; however, with the use of modern fluoroscopy techniques, VCUG has been found to result in significantly lower radiation dose.[27]

For studying the renal parenchyma, US is useful in the evaluation of underlying congenital abnormalities; however, US has limited sensitivity for the detection of pyelonephritis and renal scarring.[28–30] Dimercaptosuccinic acid (DMSA) scintigraphy, contrast-enhanced computed tomography (CT), and magnetic resonance imaging (MRI) have higher accuracy for the detection of pyelonephritis and renal scarring.[31–33] Either CT or MRI can be used for evaluation of pyelonephritis complicated with an abscess.

## GRADING

The international criteria for grading VUR is based on the VCUG (Fig. 119.1).[34] Similar grading scales exist for nuclear cystography and ce-VUS.[35,36] In recent years, a simplified classification of nondilated (grades I and II; Fig. 119.2) versus dilated (grades III, IV, and V; Fig. 119.3) VUR has been used for evaluation of the effect of treatment on children with UTI.[37–39]

In patients with VUR to the level of the calyces, intrarenal reflux of material may be visualized (Fig. 119.4). Intrarenal reflux occurs through the presence of compound (concave) papillae that are a

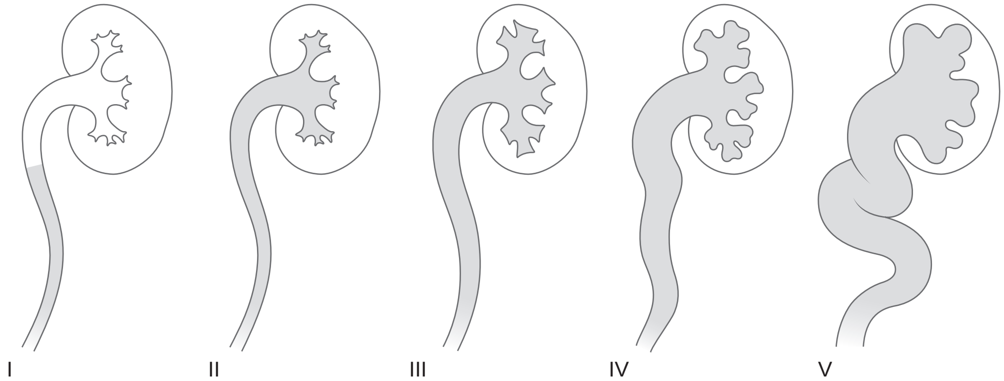

**Figure 119.1. Vesicoureteral reflux grading.** A schematic drawing demonstrating the vesicoureteral reflux grading system on a voiding cystourethrogram. *(From Lebowitz RL, Olbing H, Parkkulainen KV, et al. International reflux study in children: international system of radiographic grading of vesicoureteral reflux: International Reflux Study in Children.* Pediatr Radiol*. 1985;15:105.)*

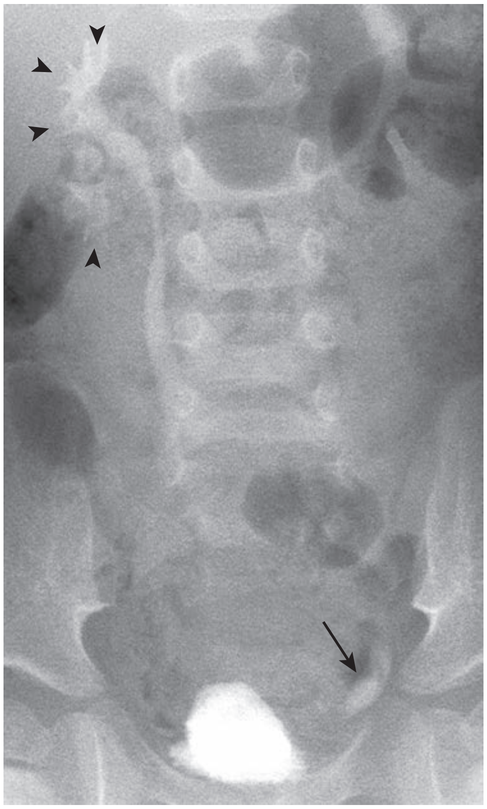

**Figure 119.2. Vesicoureteral reflux.** Voiding cystourethrogram image in a 2-year-old girl shows right grade II vesicoureteral reflux with thin and delicate calyces *(arrowheads)* and left grade I reflux in the distal ureter *(arrow)*.

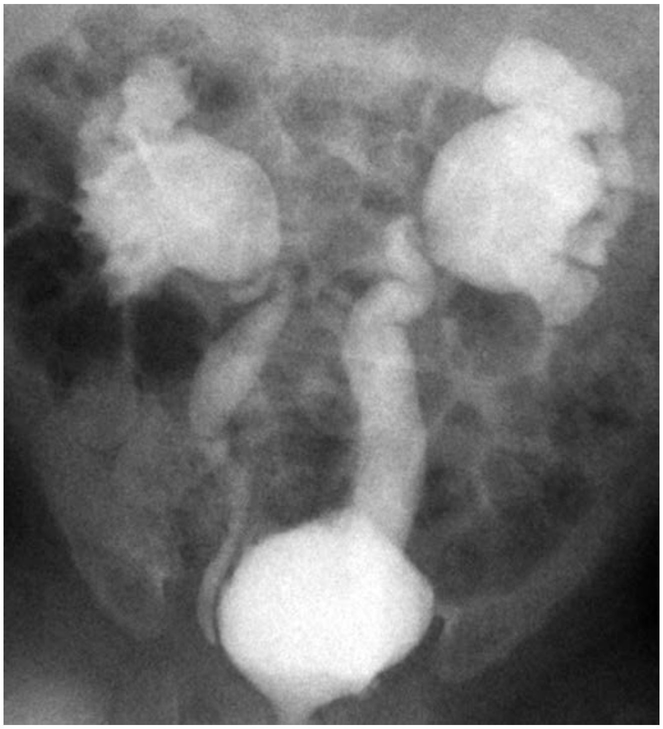

**Figure 119.3. Vesicoureteral reflux.** Voiding cystourethrogram image in a 2-month-old girl shows bilateral dilated vesicoureteral reflux. There is right grade IV vesicoureteral reflux with moderate dilatation and tortuosity of the ureter with extensive dilation of the renal pelvis, but the papillary impressions remain visible in the majority of calyces. There is left grade V vesicoureteral reflux with gross dilatation of a tortuous ureter, renal pelvis, and calyces; no papillary impressions are visible in the majority of calyces.

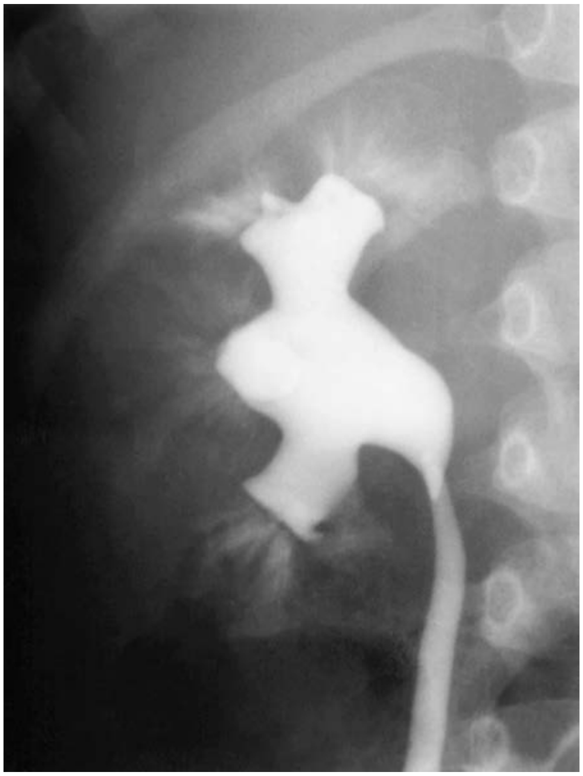

**Figure 119.4. Intrarenal reflux.** Vesicoureteral reflux in a 2-year-old girl shows right high-grade vesicoureteral reflux and diffuse intrarenal reflux, most pronounced at the poles.

result of fusion of two or more simple papillae. At the concave center of the compound papillae, the ductal orifices are open compared with the typical simple (convex) papillae that have oblique orifices that close with increased intrarenal pressure.[40,41] The compound papillae are more frequently seen at the upper and lower poles.[40,41] Intrarenal reflux is associated with increased risk of renal scarring. However, there is no consensus regarding whether the presence of this finding should change management.[42,43] Intrarenal reflux is not included in the international grading system,[34] and its presence should therefore be specifically mentioned in addition to grading of the VUR.

Consistency of the grading system based on VCUG is high when compared between radiologists who work in the same institution.[44] Nevertheless, a significant interobserver variability in grading VUR was found between radiology reports from different institutions.[45]

Reflux in ce-VUS is ranked in grades I to V similar to that for VCUG.[46] The RNC classification of reflux differs from the VCUG classification and is less exact. In RNC grade 1, activity is limited to the ureter, while in RNC grade 2, activity reaches the collecting system with no or minimal activity in ureter. RNC grade 3 is diagnosed when the collecting system and ureter are dilated.[47]

VUR grading does not take into consideration other important factors such as the age and sex of the patient, urinary tract obstruction, renal function and scarring, high- or low-pressure VUR, early or late VUR, slow or quick clearance from the upper collecting system, cystoscopic findings, and the presence or absence of associated disorders (e.g., ureteral duplication, ureteral ectopia, ureterocele, bladder diverticula, prune-belly syndrome, urethral obstruction, megacystis-megaureter association, or neurogenic bladder). This additional information can be essential for making decisions regarding therapy.

## VESICOURETERAL REFLUX IMAGING

### Voiding Cystourethrogram

VCUG may cause anxiety for both parents and children. The anxiety increases early during catheterization and later with discomfort from full distension of the bladder.[48] Sedation and nonsedation methods have been described for decreasing anxiety and pain during VCUG, although the degree of sedation use varies.[49–54] Sedation may especially help in the case of the child who has had previous traumatic experience with catheterization, a history of sexual abuse, or with older children who are known to be unable to cooperate. In older males, a retrograde transurethral infusion of 2% lidocaine can be used to decrease sensation.[55,56] Bladder catheterization is performed in a sterile fashion, and a 5 French catheter is often used in young infants, with an 8 French catheter used in older children.[55,56]

VCUG is performed following “as low as reasonably achievable” principles with the use of pulsed fluoroscopy collimated to the area of interest, with the tower as close as possible to the patient while the examination is performed, and commonly with image acquisition via the last image hold function.[27,57,58] Fluoroscopic observation of the early filling phase has the advantage of increased detection of small ureteroceles.[55,56] Near the end of the filling phase, and especially when VUR has been detected, oblique projections are obtained to evaluate the ureterovesical junctions. The maximal degree of urinary tract dilation should be documented, and then imaging should be continued intermittently during voiding, as about 20% of VUR occurs only during voiding. The urethra is evaluated in the anteroposterior projection in girls and oblique projection in boys. The catheter should not be removed before having an optimal documentation of the anatomy of the urethra when voiding around the catheter. Cyclic infusion of contrast, in which the examination is performed during a series of filling and voiding cycles, has been shown to increase the detection of VUR and severity of the VUR.[59–62]

In about 5% of the patients, VUR may be associated with ureteropelvic junction (UPJ) obstruction. Most commonly it is a coincidental association of these two most common urinary anomalies.[63,64] In some cases UPJ obstruction can be secondary to local scarring from infection or anatomic kinks in the ureter (Fig. 119.5). It is important to recognize this association as antireflux treatment can exacerbate UPJ obstruction.[63,64] The imaging signs suggesting coexistent VUR and UPJ obstruction are a disproportionally dilated renal collecting system compared with the ureter, dilution of the contrast within the renal collecting system, and delayed emptying. It is important to recognize pseudo-UPJ obstruction when pelvic dilatation is visualized on the VCUG, but drainage films or antegrade studies document good drainage (e-Fig. 119.6).[64]

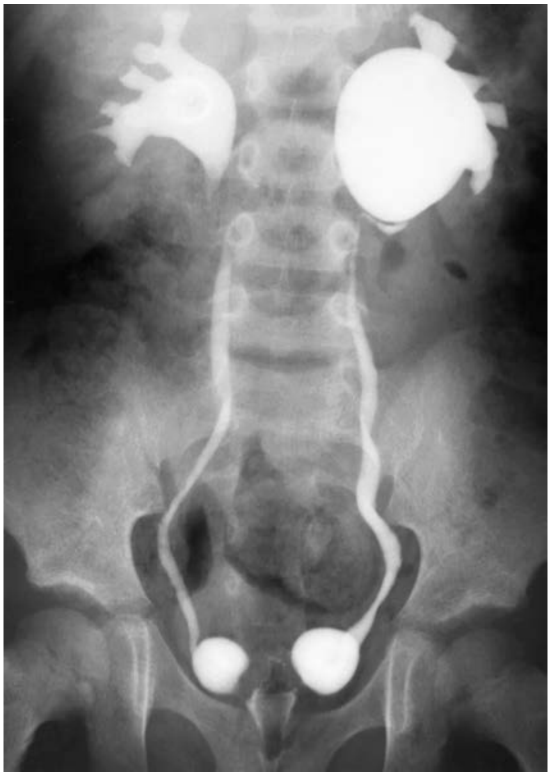
### Radionuclear Cystography

RNC is performed after bladder catheterization, with normal saline mixed with Tc-99m pertechnetate (or other radiopharmaceutical) and administrated via gravity through the bladder catheter. The examination table is covered with plastic-lined absorbent paper to contain spilled radiopharmaceutical and reduce contamination of the table. Images are obtained at a rate of 3 to 5 seconds per frame.[47,65,66]

RNC has similar or higher sensitivity for detection of VUR compared with VCUG.[65–69] However, it has limited spatial resolution and anatomic details are inferior to those seen on a VCUG (Fig. 119.7). Therefore RNC should not be the first imaging evaluation in boys when there is a need for detailed anatomy of the urethra.

### Ultrasound

US without the use of intravesical contrast material has low sensitivity for detection of VUR and does not correlate with severity of



**e-Figure 119.6. Vesicoureteral reflux and left pseudoureteropelvic junction obstruction.** VCUG image after voiding shows right grade IV and left grade V vesicoureteral reflux with ballooning of the left renal pelvis. Intrarenal reflux is present as well. The intravenous urogram image (not shown) was entirely normal. Bilateral paraureteral (Hutch) diverticula also are present.

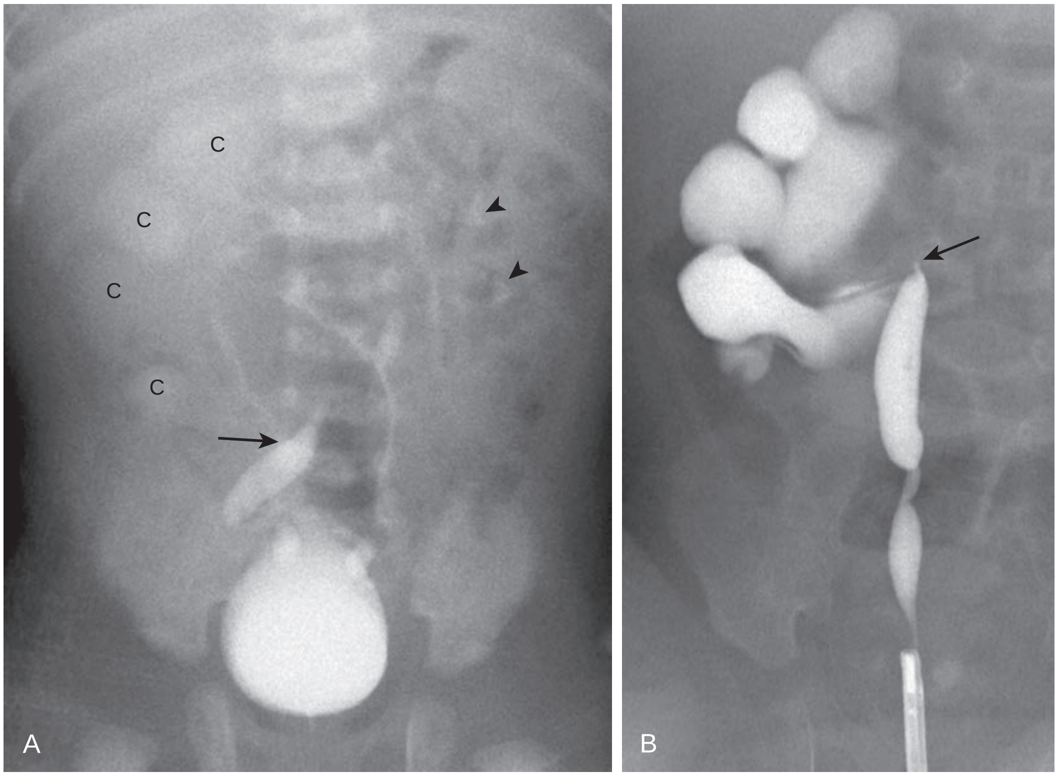


**Figure 119.5. Vesicoureteral reflux and right ureteropelvic junction obstruction.** (A) Voiding cystourethrogram image in a 12-day-old boy shows right prominent ureter *(arrow)* with disproportionally marked distended collecting system (C-calyces) with dilution of contrast. In the presence of ureteropelvic junction obstruction, it is not possible to grade the VUR. There is left VUR as well *(arrowheads)*. (B) Intraoperative retrograde study shows the narrowed ureteropelvic junction *(arrow)*.

VUR.[70,71] The ureters and pelvicalyceal system of patients with VUR often appear normal on sonography even if they appear dilated on VCUG (e-Fig. 119.8). Indirect sonographic signs for VUR are hydronephrosis, hydroureter, urothelial thickening, and changing diameter of the pelvocalyceal system and ureter during the examination.[72,73]

ce-VUS uses US microbubble contrast material instilled into the urinary bladder via transurethral catheterization.[36,46,74–79] The kidneys, bladder, and lower ureters are scanned alternately, and the urethra is scanned during voiding (Fig. 119.9 and e-Fig. 119.10). This method enables depiction of VUR as well as renal, upper urinary tract, and lower urinary tract anatomy.[36,46,74] The sensitivity and specificity of ce-VUS is similar to VCUG.[36,46,74–79]

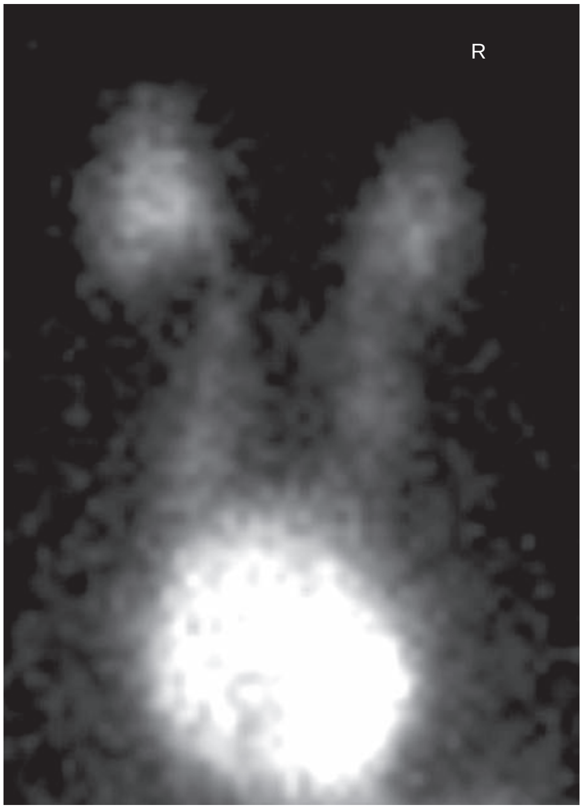

**Figure 119.7. Vesicoureteral reflux and radionuclide cystography.** Posterior view image of Tc-99m pertechnetate cystogram demonstrates radionuclide classification left grade 3 and right grade 2 vesicoureteral reflux.

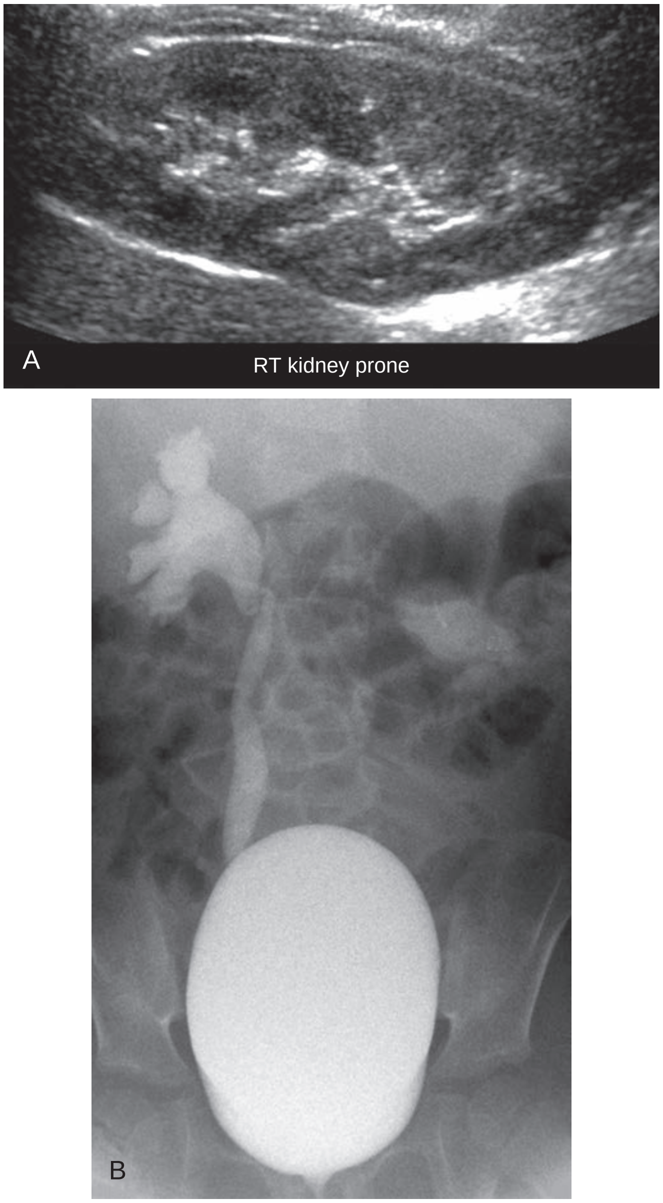
## NATURAL HISTORY

***Overview.*** Most VUR resolves spontaneously during the first decade of life.[80] This tendency is attributed to a maturation process of the UVJ with age, with an increase in the length of the intramural ureter and strengthening of its musculature. In general, as the grade of the VUR increases, spontaneous resolution is seen with less frequency and often takes a longer time.[80–83] Complete resolution is achieved in 83% of nondilated (grades I–II) VUR and in 73% of dilated (grades III–V) VUR within 10 years.[80] The median time for resolution is 2.5 years for nondilated and 4.5 years for dilated VUR.[80] Dilated VUR is also associated with a higher risk of renal scarring.[84–86] There are multiple factors that affect the rate of VUR resolution. Higher rates are associated with presentation in children younger than 1 year, prenatal hydronephrosis, and reflux when bladder volume is greater than 50% of predicted capacity.[82,87] UTI, bilateral VUR, and voiding dysfunction are associated with lower rates of resolution.[82] Dysfunctional elimination syndromes (Fig. 119.11) are associated with delayed VUR



**e-Figure 119.8. Normal renal ultrasound with high-grade vesicoureteral reflux.** (A) A 3-year-old girl with normal longitudinal gray-scale sonogram of the right kidney. (B) Voiding cystourethrogram image shows right high-grade vesicoureteral reflux.

resolution and an increased rate of breakthrough UTI.[88] Rates of spontaneous resolution of reflux to the lower moiety of a duplicated system (Fig. 119.12), and in the presence of paraureteral (Hutch) diverticula, were found to be similar to rates among patients with single, typical ureteral systems.[19,89,90]

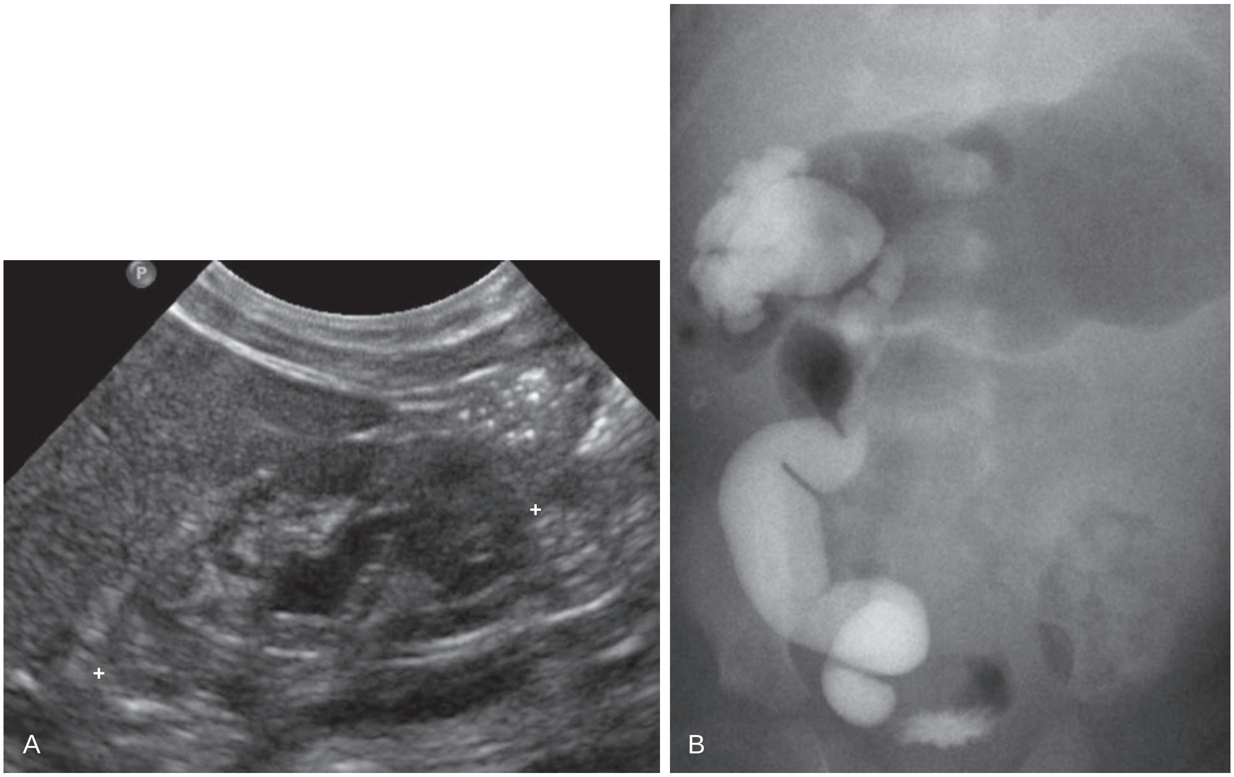
## RENAL SCARRING AND VUR

***Overview and Pathophysiology.*** In children with normal kidneys, the likelihood of developing chronic kidney disease or hypertension from renal scarring derived from pyelonephritis is very low.[1,91–94]

From prenatal US screening, it was found that in most children with VUR, decreased renal function, and parenchymal abnormalities, the underlying mechanism is not renal scarring secondary to pyelonephritis but rather preexistent congenital hypoplastic/dysplastic kidneys (e-Fig. 119.13).[3,95] VUR is associated with hypoplastic and dysplastic kidneys, mainly in boys.[3,95] Many different types of gene signaling are involved during the interaction of the mesonephric duct with the metanephric mesenchyme during development of the embryonic kidney.[96] Failure of any of the molecular interactions can lead to unique congenital anomalies.[95,96] Another possibility is that intrauterine high-pressure VUR to the immature kidneys causes damage to the immature renal parenchyma.[3]

A meta-analysis of 33 studies found that among children with a first episode of UTI, 57% (95% confidence interval [CI]: 50%–64%) develop pyelonephritis and 18% (95% CI: 14%–23%) developed renal scarring.[84] The risk of renal scarring increases with recurrent pyelonephritis.[97] The prevalence of VUR also increases in children with recurrent UTIs.[97] In children with VUR, there is increased risk of pyelonephritis (relative risk [RR] = 1.5) and renal scarring (RR = 2.6).[83] Children with dilated VUR have about twice the risk to develop renal scarring compared with children with nondilated VUR,[83,97] yet many children with pyelonephritis and renal scarring will not have VUR.[96,98]

Accurate estimations of the long-term clinical consequences of febrile UTIs are difficult to ascertain, as available studies have wide population heterogeneity, limited follow-up, and there is a lack of prospective studies with a control group.[91] From a review of eight prospective studies (1029 children), it was found that only 0.4% of children with initially normal renal function presented with decreased renal function during later follow-up.[92] The risk of end-stage renal disease from acquired scarring is extremely



**e-Figure 119.13. Congenital hypoplastic dysplastic kidney with vesicoureteral reflux.** (A) Longitudinal gray-scale sonogram of the right kidney in a 1-month-old boy demonstrates a small kidney (length = 3.3 cm) with echogenic parenchyma with poor corticomedullary differentiation, urothelial thickening, and mild hydronephrosis. (B) Voiding cystourethrogram image shows right grade V vesicoureteral reflux.

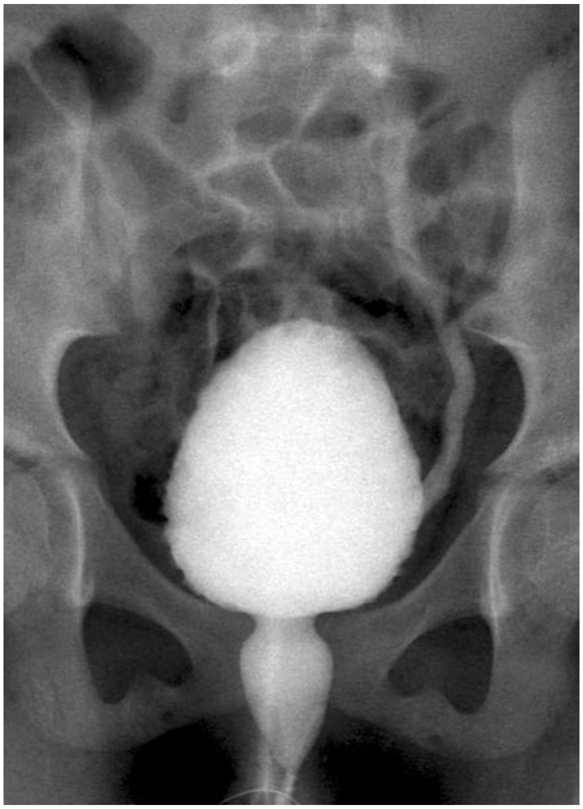


**Figure 119.11. Vesicoureteral reflux and detrusor sphincter dyssynergia.** Voiding cystourethrogram image in a 10-year-old girl with recurrent urinary tract infections and dysfunctional elimination syndrome shows trabeculation of the bladder, ballooning of the urethra ("spinning top" urethra) and left vesicoureteral reflux. Urodynamic study demonstrated abnormally high bladder pressure and dyssynergia with urination.

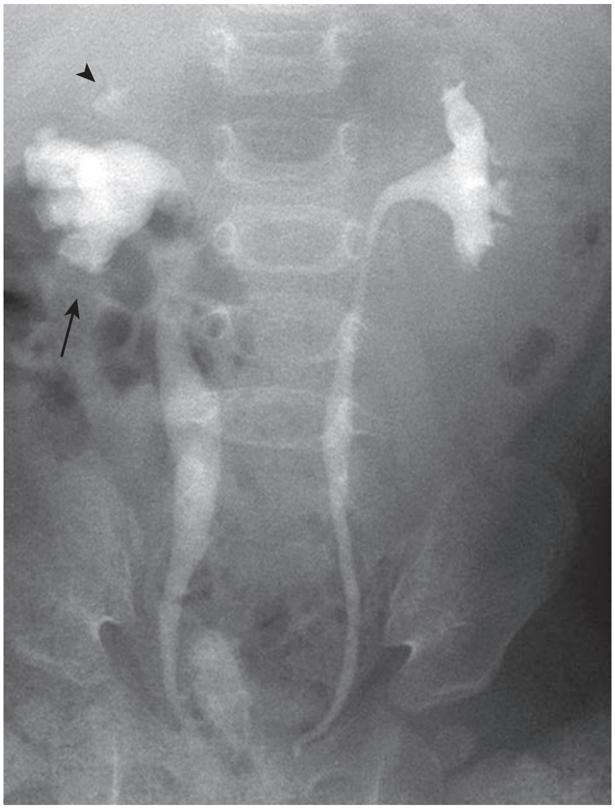

**Figure 119.12. Vesicoureteral reflux (VUR) affecting a duplex kidney.** Voiding cystourethrogram image in a 9-month-old girl demonstrates high-grade VUR into the lower moiety of the right duplex kidney. The collecting system is inferiorly displaced ("drooping lily" sign, *arrow*). There is also reflux into the right upper moiety *(arrowhead)* and left grade II reflux.

low. The overall incidence of end-stage renal disease (ESRD) in children ranges from about 7 (5–9 age group) to 31 (18–21 age group) per million.[99] Registries of children with end-stage renal disease or renal transplantation have reported that reflux nephropathy accounts for 2.6% to 5.1% of ESRD.[99,100]

The prevalence of hypertension secondary to renal scarring in most studies varies between 2% to 6%.[92] In a 10-year international prospective study, hypertension was reported in 1.6% (4/252) of children with VUR.[101]

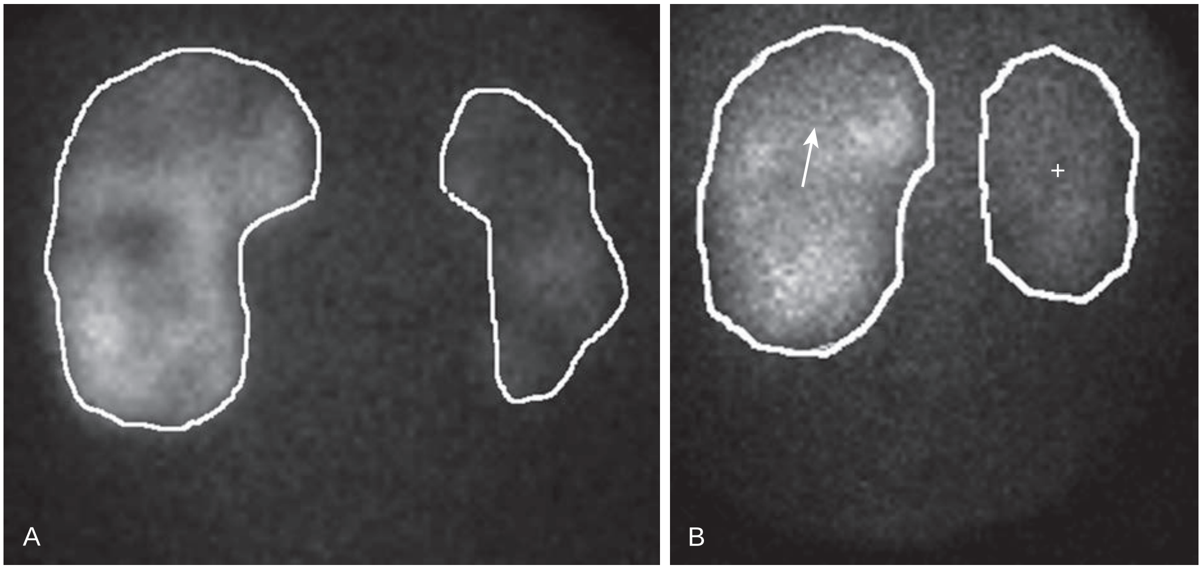
***Imaging.*** Gray-scale renal US is the primary imaging modality for evaluation of the renal parenchyma in children with febrile UTI. However, gray-scale US has low sensitivity for detection of acute pyelonephritis and parenchymal scarring.[28,102,103] A few studies have suggested moderate to high (74%–89%) sensitivity and varied specificity (53%–81%) of power Doppler in the diagnosis of pyelonephritis.[30,31,104] The sensitivity of power Doppler in detection of renal scarring is low.[104] The parenchymal changes of pyelonephritis are increased or decreased echogenicity, loss of corticomedullary differentiation, and focal or diffuse renal enlargement.[102] Color Doppler imaging shows decreased vascularity.[30,104] Renal scarring may be depicted by US as focal or diffuse parenchymal thinning and areas of depression in the outline of the kidney with or without dilated and distorted adjacent calyces (Fig. 119.14).[28,104] Nuclear scintigraphy, using a cortical agent such as DMSA, contrast-enhanced MRI, and contrast-enhanced CT have all demonstrated high accuracy for detection of pyelonephritis.[31,105] DMSA is considered the gold standard for evaluation of renal scarring.[31,85,106,107] Focal areas of decreased or absent renal cortical uptake on DMSA that persist for months as well as distortion or indentation of the renal parenchyma can both indicate renal scarring (e-Fig. 119.15).[31,105] Recent studies suggest that MRI has high accuracy and can replace DMSA for evaluation of renal scarring (Fig. 119.16).[108,109]

## TREATMENT OF VUR

***Overview.*** The goal of VUR treatment is to prevent recurring febrile UTIs, avoid renal injury, and minimize morbidity.[13] The preferred initial management in most children with VUR is conservative, awaiting spontaneous resolution.[13] Preventive antibiotics in children with VUR have been shown to decrease the risk of recurrent UTIs but not renal scarring.[8]

Abnormal bowel and bladder dysfunction and VUR are associated with each other and with UTI. Children should be evaluated for symptoms of bowel and bladder dysfunction, such as urinary frequency and urgency, prolonged voiding intervals, daytime wetting, constipation, and encopresis. Treatment of bowel and bladder dysfunction increases the resolution rate of VUR, lowers the recurrence rate of febrile UTIs, and improves the outcome of endoscopic treatment for VUR.[13,24,110]

There is a trend toward increasingly minimal intervention for primary VUR in pediatric hospitals, as children with VUR but without pyelonephritis are observed to do well under conservative management.[111] Antireflux procedures are considered for patients with recurrent breakthrough UTIs despite preventive antibiotic treatment or after complicated UTIs.[13] The success rate of ureteral surgical reimplantation is high (98%).[13] Postoperatively, US can



**e-Figure 119.15. Pyelonephritis and renal scarring on Tc-99m dimercaptosuccinic acid (DMSA) scan.** (A) Posterior view Tc-99m DMSA image of the kidneys in a 5-year-old boy with pyelonephritis demonstrates diffusely scarred right kidney and multiple photopenic areas in the left kidney. (B) Four months later, follow-up posterior view Tc-99m DMSA image shows decreased but persistent left upper pole photopenic area *(arrow)* consistent with renal scarring.

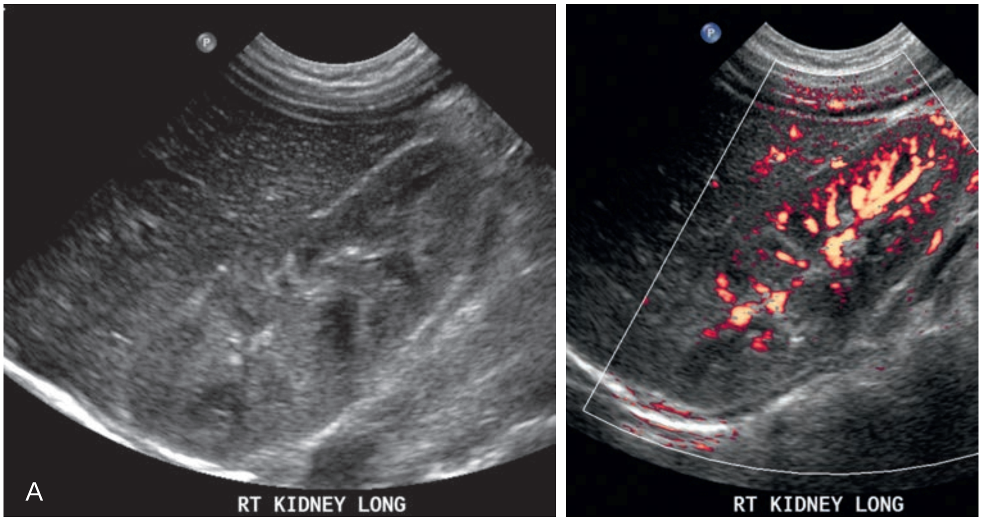


**Figure 119.14. Acute pyelonephritis in an 8-month-old girl with febrile urinary tract infection.** (A) Longitudinal gray-scale sonogram shows swelling and increased echogenicity of the upper pole. (B) Longitudinal power Doppler sonogram shows decreased vascularity in the upper pole.

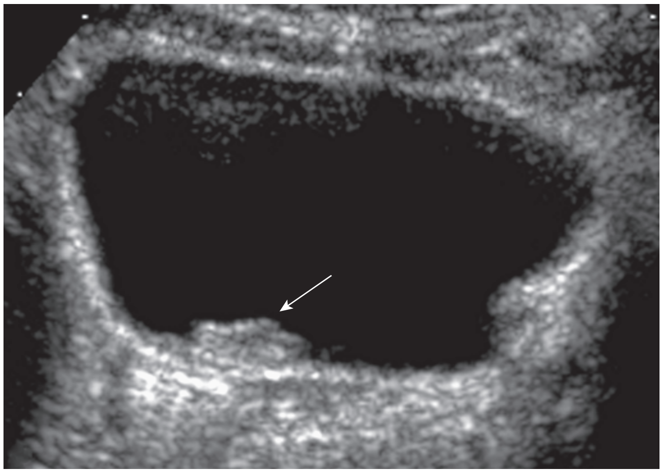
(B) Four months later, follow-up MR image demonstrates cortical scarring *(arrow)*.

demonstrate focal thickening of the posterior bladder wall and pseudodiverticular sacculations (e-Fig. 119.17).[112] Alternative therapies, such as endoscopic intravesical injection of a small amount of material (e.g., Silicon, Teflon paste, or dextranomer/hyaluronic acid [Deflux]) into the bladder wall behind the submucosal ureteral tunnel, are also available (Fig. 119.18).[113] The injected material elevates and narrows the ureteral tunnel and causes a localized protrusion of the bladder wall at the lateral angle of the trigone containing the ureteral orifice.[113] The injected material is well visualized by US as a round, echogenic focus that can calcify (Fig. 119.19).[114] The main limitation of this treatment is the lower success rate, which ranges from 50% to 92%.[13,115–118]

## IMAGING ALGORITHMS FOR EVALUATION OF VUR

***Overview.*** The most common indications for evaluation of VUR are prenatal hydronephrosis and UTI. Prenatal hydronephrosis is diagnosed in approximately 1% to 2% of all pregnancies. The grading of hydronephrosis and the clinical practice for evaluation of these children varies widely.[119] The purpose of postnatal imaging in patients with prenatally diagnosed hydronephrosis is to identify underlying urologic abnormalities and those that may benefit from treatment to prevent renal damage and morbidity.

The imaging of VUR in children with febrile UTI is controversial.[120] Overall, as there is no clear benefit of treatment for



**e-Figure 119.17. Postoperative appearance of ureteral reimplantation.** Gray-scale sonogram of the bladder shows nodularity at the site of ureteral reimplantation *(arrow)*.

children with a first episode of uncomplicated febrile UTI, the tendency is to evaluate for VUR selectively in children with a higher risk of underlying urologic abnormalities or renal scarring. The main controversy is whether renal scintigraphy can be used as the first study (the "top down" approach), thus saving some children from the discomfort associated with the VCUG study. The main limitation of such an approach is that renal scintigraphy is associated with higher radiation dose and that it cannot reliably select all patients with VUR who may benefit from treatment. A meta-analysis study on use of DMSA in cases of acute UTI yielded sensitivity and specificity of 79% and 53%, respectively, for dilated VUR; however, there was marked statistical heterogeneity between the studies. The authors concluded that acute-phase DMSA renal scanning cannot be recommended as replacement for VCUG in the evaluation of young children with a first febrile UTI.[121]

***Imaging Algorithm.*** Evaluation for VUR is indicated in children with antenatal or postnatal moderate or severe hydronephrosis and hydronephrosis associated with oligohydramnios, abnormal renal parenchyma, presence of hydroureter, and bladder wall thickening.[14,122] There is no consensus regarding the need for all children with postnatal mild hydronephrosis to be evaluated for VUR (Fig. 119.20).[119,122,123]

In children older than 2 months with a first episode of uncomplicated febrile UTI, routine imaging of VUR is no longer recommended.[97] Imaging for VUR should still be considered for children with recurrent UTI, as they have been shown to have increased risk of VUR and renal scarring, and also in children with complicated febrile UTI to evaluate for underlying congenital urologic abnormalities.[97] For neonates, the presence of a UTI is associated with a higher percentage of underlying congenital urinary tract anomalies, and urinary infection is more commonly complicated with sepsis. Therefore evaluation with VUR should be considered

in newborn boys, as it is important to identify the presence of posterior urethral valves.[124]

In boys, VCUG is the preferred first study as it is best for evaluation of the urethral anatomy. In girls and with all follow-up studies, ce-VUS or RNC can be used for evaluation of VUR (Fig. 119.21).[125] The additional use of DMSA or MRI can be beneficial for select pediatric patients with recurrent UTI to more accurately identify renal scarring. The identification of renal scarring may change medical management with antibiotics or surgical antireflux procedures.[125] Follow-up studies for VUR to document resolution depends on the VUR grading. The follow-up interval should increase with increased VUR grading, as the resolution rate in these more severe cases is slower.[80,81]

## KEY POINTS

- VUR does not cause UTI.
- VUR can be either primary or secondary to other urologic abnormalities.
- VUR is a risk factor for the development of pyelonephritis, with consequent renal scarring and potential long-term sequelae.
- Most VUR resolves spontaneously.
- The rate and time for resolution of VUR depends on the grade of VUR, with higher grades resolving more slowly.
- In children older than 2 months with uncomplicated first febrile UTI, imaging for VUR is usually not necessary.

# 120 Bladder and Urethra

Hollie C. West and Christopher G. Anton

## URACHAL ANOMALIES

***Overview.*** The urachus is the fetal channel connecting the bladder and the allantosis. Fibrotic regression of the urachus typically extends from the umbilicus toward the bladder and results in the median umbilical ligament. Usually, this process is completed by 4 to 5 months of gestational age.[1,2] Failure of urachal regression may result in: (1) patent urachus, (2) urachal sinus, (3) urachal diverticulum, and (4) urachal cyst (Fig. 120.1). While many urachal anomalies are asymptomatic, symptoms can include umbilical discharge, localized or urinary tract infection (UTI), and lower abdominal pain.[3]

***Imaging.*** Ultrasound (US), voiding cystourethrography (VCUG), and fistulography are the primary imaging tools for initial evaluation of suspected urachal anomalies. A patent urachus results in a vesicoumbilical fistula and is the most common urachal anomaly (Fig. 120.2). US demonstrates a midline tubular connection between the bladder dome and umbilicus, which may be confirmed with bladder catheterization via the umbilicus (e-Fig. 120.3) or by VCUG. Echogenic debris within the urachal channel and surrounding inflammation suggest infection; abscesses may occur in some children. Clinically, a patent urachus typically presents with urine leakage from the umbilicus and is detected in the neonatal period.

A urachal sinus is defined as a blind-ending pouch extending from the umbilicus without continuity with the bladder, typically depicted by US and confirmed by umbilical catheterization or fistulography (sinography). This sinus may periodically produce discharge. A urachal diverticulum is usually asymptomatic and results from the failure of obliteration at the vesicular end only, resulting in an outpouching from the dome of the bladder. This is commonly demonstrated on both US and VCUG (Fig. 120.4). A urachal cyst forms when the urachus is obliterated at both the vesicular and umbilical ends but remains patent at some point along its length, usually the lower one-third of the urachus. Imaging with US, computed tomography (CT), or magnetic resonance imaging (MRI) will typically demonstrate a fluid-filled cyst with or without signs of superinfection (e-Fig. 120.5).[3,4]

***Treatment.*** Urachal remnants in children younger than 6 months have been reported to resolve with nonoperative management and initially may be managed conservatively. If resolution does not occur, resection is performed to minimize infection risk and the potential for neoplasia later in life.[1,2]

## BLADDER DIVERTICULA

***Overview.*** Bladder diverticula may be primary (congenital), secondary, or iatrogenic (postoperative). Congenital diverticula are the most common type and may be idiopathic or related to various syndromes including Ehlers-Danlos, Menkes, and Williams. They are more common in boys, and typically occur near the ureterovesicular junction (UVJ). While many children are asymptomatic, depending on the location and proximity to the ureteral orifice, these may contribute to vesicoureteral reflux, prenatal hydronephrosis, or result in bladder outlet obstruction. Secondary bladder diverticula are the result of prolonged bladder outlet obstruction (usually in the setting of posterior urethral valves or neurogenic dysfunction). Iatrogenic diverticula are seen most often in the anterior wall of the bladder at the site of a previous vesicostomy or suprapubic drainage catheter, and at the UVJ after ureteral reimplantation.[5] Patients with diverticula may present with recurrent UTI, urinary retention, incontinence, stone formation, vesicoureteral reflux (VUR), and ureteral and bladder outlet obstruction.

***Imaging.*** VCUG is the most sensitive method for detecting bladder diverticula. Diverticular outpouchings may enlarge or become visible during voiding when bladder contraction forces urine into the diverticulum (Fig. 120.6). A paraureteral diverticulum located lateral and cephalad to the ureteral orifice in an otherwise normal patient with a smooth-walled bladder is commonly referred to as a *Hutch diverticulum* (e-Fig. 120.7). Altered voiding dynamics may result in retained urine and VUR. If the diverticulum is large, it may engulf the ureteral orifice and the ureter may empty into the diverticulum (e-Fig. 120.8).[6,7] Multiple diverticula are commonly observed in the settings of bladder outlet obstruction and neurogenic bladder.

***Treatment.*** Though symptomatic patients with associated VUR have traditionally been managed with diverticulectomy and ureteral reimplantation, recent evidence has demonstrated comparable VUR resolution rates among patients with and without associated diverticula.[8] However, a diverticulum is more likely to be associated with high-grade VUR and recurrent UTI, and ureteral reimplantation is necessary for those cases in which the ureteral orifice is incorporated into the diverticulum.[9] Primary bladder diverticula not in a paraureteral location and not associated with VUR or obstruction are more likely to contribute to infection and voiding dysfunction when over 3 cm, and are often excised.[10]

## NEOPLASMS OF THE BLADDER

### Rhabdomyosarcoma

***Overview.*** Genitourinary rhabdomyosarcoma (RMS) accounts for about 20% of all RMS and includes those tumors arising from the bladder or prostate gland (often infiltrating both structures), testes and paratesticular structures, penis, perineum, vagina, cervix, and uterus. RMS is the most frequent bladder neoplasm in children in the first 2 decades of life, presenting typically in the ages between 2 to 6 years with a second peak at 15 to 19 years.[11] Histologically, RMS is divided into three main subtypes in children, which are distinguished cytogenetically: (1) embryonal, (2) alveolar, and (3) pleomorphic (mainly seen in adult patients and rarely in children). Embryonal RMS accounts for approximately 90% of all genitourinary RMS and has a more favorable prognosis. The embryonal botryoid variant has the most favorable prognosis, accounts for one-quarter of cases, and has a lobulated, polypoid appearance that resembles a bunch of grapes (hence the name sarcoma botryoides).[12,13]

Genitourinary RMS spreads by local extension to regional and retroperitoneal lymph nodes and adjacent soft tissues. Distant tumor spread (usually to lungs or bone) is present at the time of diagnosis in 10% to 20% of patients.[14] Presenting symptoms depend upon site of origin but may include bladder outlet obstruction and hydroureteronephrosis, hematuria, abdominal mass, painless scrotal enlargement, or a mass prolapsing into the vaginal introitus.[12]

***Imaging.*** US is the first study for a child with suspected bladder RMS. The tumor within the bladder may appear hyperechoic or

## Abstract:

In this chapter, we reviewing the radiologic evaluation of the pediatric urinary bladder and urethra. Common as well as less common congenital anomalies and neoplasms (benign and malignant) are discussed. The clinical presentation, imaging, and management of bladder outlet obstruction in the male child is also presented.

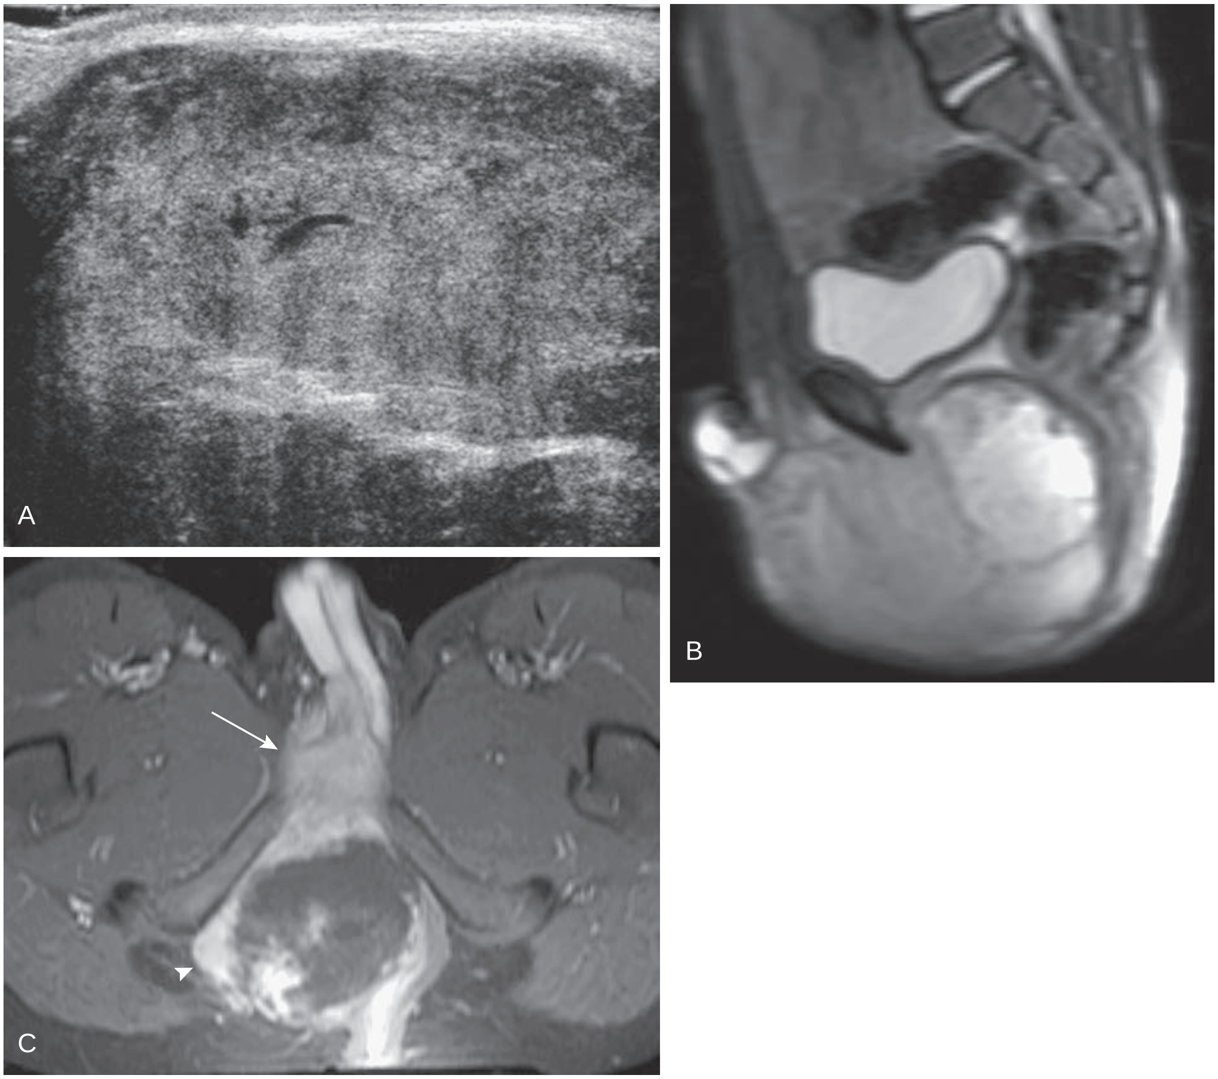
(B) Longitudinal sonogram shows a urine-filled patent urachus *(arrowheads)* extending from the dome of bladder *(B)* to the umbilicus *(arrow)*.

hypoechoic and may have focal anechoic regions representing necrosis, hemorrhage, or cystic areas. Color and spectral Doppler evaluation show hyperemia and increased diastolic flow. VCUG is less often used for screening but when obtained most often shows a filling defect in the posteroinferior aspect of the bladder (Fig. 120.9). When originating in the prostate gland (Fig. 120.10 and e-Fig. 120.11), the cystogram, CT, or MRI will show an upward displacement of the bladder floor or a smooth, lobulated mass at the base of the bladder. Contrast-enhanced CT often identifies RMS as a bulky bladder mass of heterogeneous attenuation that may invade periurethral and perivesical tissues or may extend into the ischiorectal fossa. Calcification is rare. Vaginal tumors arising high in the anterior vaginal vault may be indistinguishable from a primary bladder tumor. On MRI, RMS demonstrates low-signal intensity on T1-weighted sequences and high-signal intensity on T2-weighted sequences. After the administration of gadolinium-based contrast material, RMS typically enhances heterogeneously. Metastatic workup includes CT of the chest, bone scan, and



**e-Figure 120.11. Prostatic rhabdomyosarcoma.** (A) Longitudinal transperineal sonogram demonstrates a large, heterogeneous mass. (B) Sagittal T2-weighted MR image shows a large, lobulated, heterogeneously hyperintense mass extending from the bladder base to the perineum. The bladder base is elevated. bone marrow biopsy.[11,12,14] F-18-fleurodeoxyglucose (FDG) positron emission tomography (PET)/computed tomography (CT) may also be used to evaluate for sites of metastatic disease.

***Treatment.*** The Children's Oncology Group and Intergroup Rhabdomyosarcoma Study staging system for genitourinary RMS is presented in Box 120.1.[11] Treatment combines surgical removal of as much of the tumor as possible, chemotherapy, and radiation therapy. Tumors of the urinary bladder and prostate gland may require pelvic exenteration and urinary reconstruction, and have an overall 5-year survival rate of approximately 70%. Genitourinary RMS originating from nonbladder/prostate gland sites and botryoid histology have more favorable prognoses and a better overall 5-year survival rate.[15]

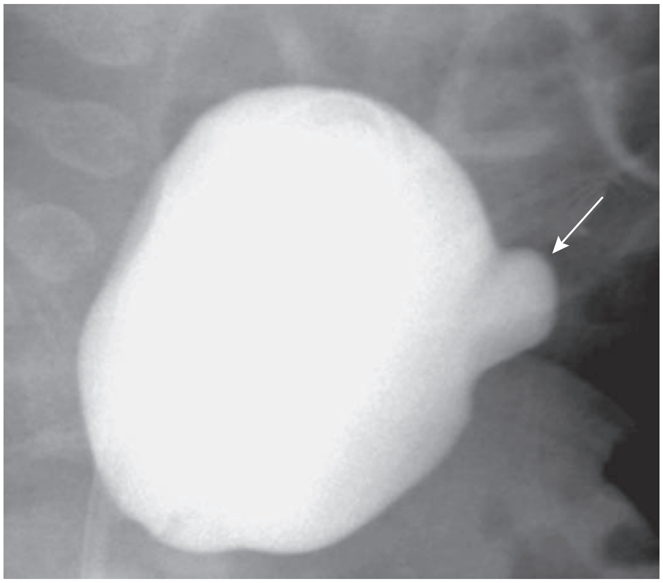

**Figure 120.4. Urachal diverticulum.** Lateral voiding cystourethrogram image shows a urachal diverticulum *(arrow)* extending from the bladder dome.

## BENIGN NEOPLASMS

***Overview and Imaging.*** Hemangioma or venous malformation of the bladder is probably the most common benign bladder "mass." Hemangioma typically presents as a discrete solitary mass of variable size (<1 cm to more than 10 cm) projecting from the posterior or lateral walls of the bladder. Hematuria is the most common clinical presentation. US will demonstrate bladder wall thickening, intramural anechoic spaces, and occasional calcification. CT and MRI may be required to fully define the extent of the lesion and for preoperative planning as cystoscopy may only reveal a small portion of the mass.[16]

Nephrogenic adenoma is a rare benign papillary lesion of the bladder and is considered a chronic metaplastic response to urothelial injury. In most cases, a history of UTI, inflammation, trauma or recent surgery (ureteral reimplantation), calculi, or catheterization is present. The bladder is the most common site in children. While the incidence is highest in adult males, pediatric patients are more commonly female. Dysuria and hematuria are the most common presenting symptoms and generally resolve after transurethral resection and fulguration. However, the recurrence rate is up to 80% in pediatric population and peaks at around

### BOX 120.1 Intergroup Rhabdomyosarcoma Study Staging System for Neoplasms of the Bladder

**Stage I:** Localized tumor, completely resected
**Stage IIA:** Localized tumor, grossly resected with microscopic residual
**Stage IIB:** Tumor with regional disease or lymph node involvement, completely resected
**Stage IIC:** Tumor with regional disease or involved lymph nodes, grossly resected with microscopic residual
**Stage IIIA:** Gross residual tumor after biopsy only
**Stage IIIB:** Distant metastases present at diagnosis

See e-Fig. 120.11.

4 years posttreatment. Though considered a precursor to malignancy in adults, this is not the case in children.[17]

Inflammatory myofibroblastic tumor (IMT), or inflammatory pseudotumor, is a rare entity that may occur at multiple sites throughout the body. While rare, the bladder is the most common site of genitourinary involvement, with the tumor usually arising from the bladder dome in children (versus the lateral walls in adults). While the malignant potential of these lesions has been debated, the World Health Organization classifies these lesions as intermediate soft tissue tumors composed of spindle cells and an inflammatory infiltrate, including plasma cells. Many of these tumors demonstrate anaplastic lymphoma tyrosine kinase (ALK) gene rearrangements. IMT usually presents with gross hematuria, irritative or obstructive dysuria, and abdominal pain but may occasionally present with a palpable mass or fever and weight loss (postulated to be cytokine induced). Average size of the lesions is approximately 5.5 cm, but they may become quite large. These lesions can be indistinguishable on imaging from bladder RMS, and biopsy is required for diagnosis (Fig. 120.12). While metastatic disease and local recurrence may occur, this has not been reported with pediatric bladder IMT, and treatment with surgical resection and imaging surveillance are generally considered sufficient.[18]

## BLADDER OUTLET OBSTRUCTION AND POSTERIOR URETHRAL VALVES

***Overview.*** Lower urinary tract obstruction occurs in 1 per 5000 births with up to 90% of patients being boys. Approximately 70% to 80% of cases are due to the presence of posterior urethral valves (PUV) or membranes.[19,20] Additional less common anomalies of the male urethra resulting in lower urinary tract obstruction include anterior urethral valves, anterior urethral diverticulum, and megalourethra. These entities are generally considered together because of common features and transitional forms suggesting a

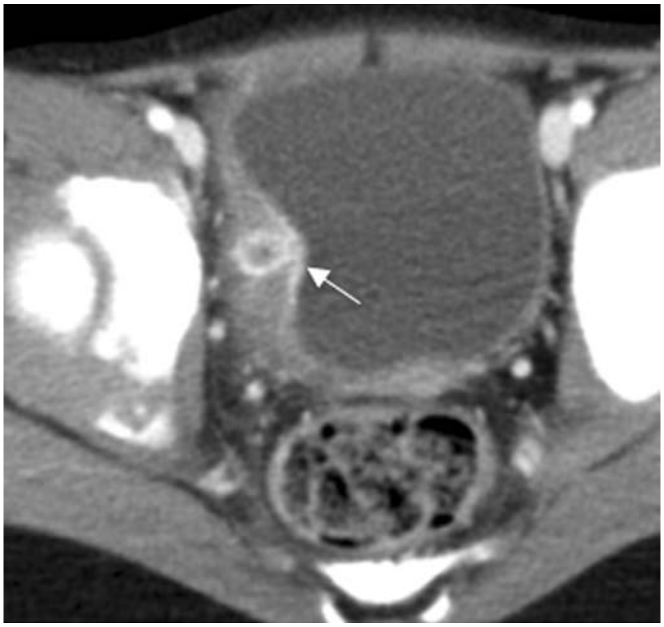

**Figure 120.12. Inflammatory myofibroblastic tumor.** Axial contrast-enhanced CT image demonstrates right bladder wall thickening and hyperenhancement *(arrow)*. Biopsy confirmed inflammatory myofibroblastic tumor, or inflammatory pseudotumor.

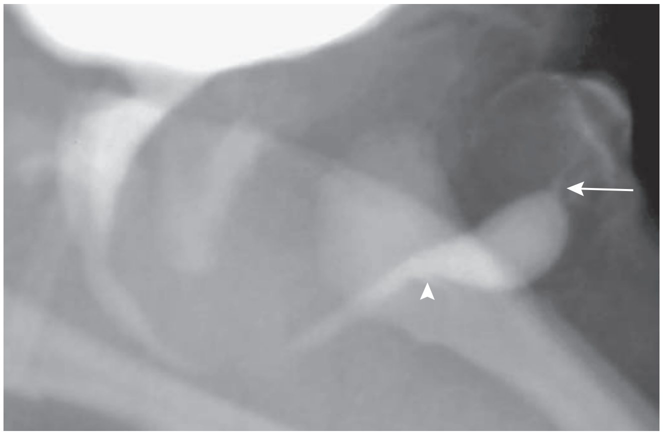

**Figure 120.13. Anterior urethral valve.** Oblique voiding cystourethrogram image shows a focal saccular dilation of the distal anterior urethra. Distally, an acute angle is formed at the junction with the narrowed urethra *(arrow)*. Proximally, an obtuse angle is present *(arrowhead)*. *(From Bates DG, Coley BD. Ultrasound diagnosis of the anterior urethral valve.* Pediatr Radiol. *2001;31:634–636.) See also* e-Fig. 120.14.

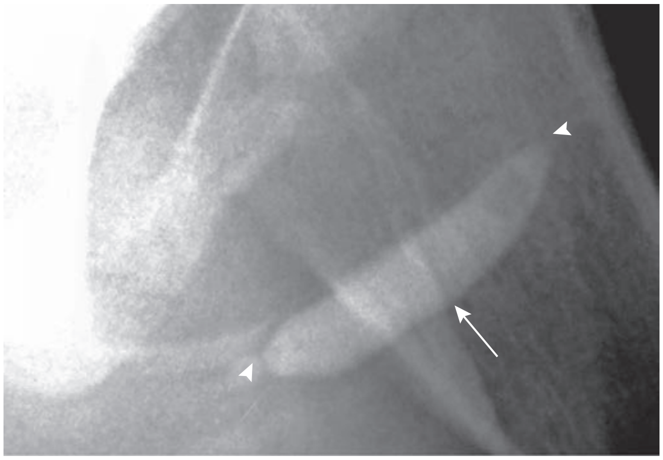

**Figure 120.15. Urethral diverticulum.** Oblique image during voiding cystourethrogram shows saccular outpouching *(arrow)* along the ventral urethra. Acute angles are formed at the junction of the anterior and posterior lips with the urethra *(arrowheads)*.

spectrum of related deformities, differing primarily in their relationship to the corpus spongiosum. VCUG is the initial diagnostic study of choice for all causes of bladder outlet obstruction.

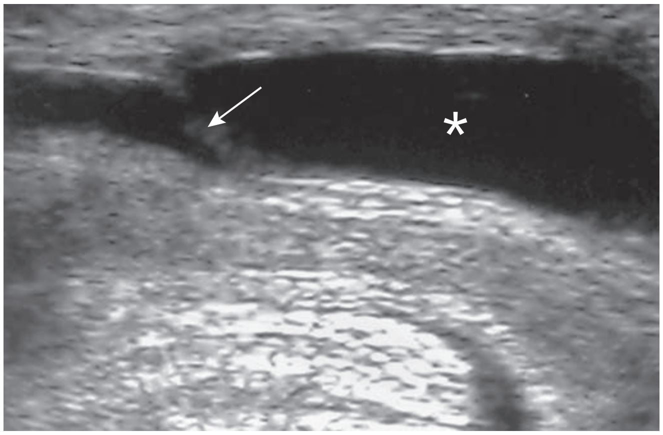
Anterior urethral valves (AUV) are congenital mucosal folds located distal to the membranous urethra that obstruct the flow of urine (Fig. 120.13 and e-Fig. 120.14).[21] AUV may cause more proximal dilatation of the urethra mimicking a diverticulum; however, these “pseudodiverticula” form an obtuse angle with the ventral floor of the urethra (unlike true anterior urethral diverticula).

An anterior urethral diverticulum is an often quite large saccular outpouching of the ventral aspect of the anterior urethra into the corpus spongiosum, often near the penoscrotal junction, with intact corpora cavernosa (Fig. 120.15).[22–24] The more proximal urethra is commonly dilated, the proximal margin of the diverticulum forms an acute angle with the floor of the ventral urethra, and these lesions are commonly occult at retrograde urethrography (RUG). Clinical presentations include urinary dribbling, weak urinary stream, and UTI. The urethral diverticulum may be anatomically linked to the megalourethra, in which the corpus spongiosum (scaphoid megalourethra), corpora cavernosa (fusiform megalourethra), or both are deficient (e-Figs. 120.16 and 120.17).[25] Scaphoid megalourethra is more common, generally less severe, and saccular (as opposed to fusiform) in appearance.

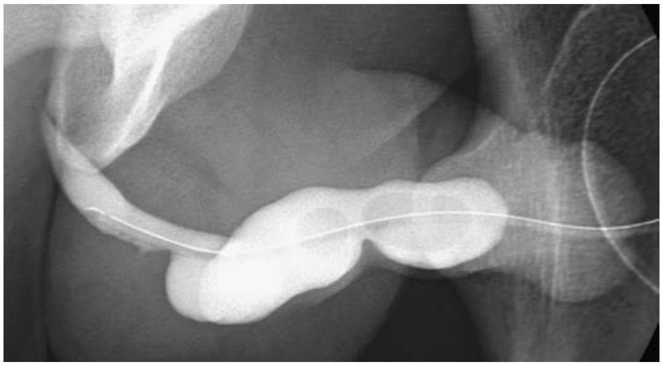
## POSTERIOR URETHRAL VALVES

***Overview.*** Originally classified by Young into three types, all PUV are now considered to be the same type (Young’s type 1) and are formed by a membrane of Wolffian duct origin. The membrane originates in the region of the verumontanum and courses obliquely to the distal prostatic urethra.[20,26] The rigidity of the membrane along the line of fusion results in variable degrees of obstruction. When detected prenatally, obstruction is usually severe with renal dysplasia resulting from pressure damage to the developing renal pelvis, collecting ducts, and parenchyma as well as pulmonary hypoplasia secondary to oligohydramnios. If the fetus survives, up to 45% will develop renal insufficiency or end-stage renal disease requiring renal dialysis or transplantation before 5 years of age.[27–29] Those children who escape antenatal detection may present in the first months or years of life with UTIs, sepsis, voiding disorders, hematuria, vomiting, failure to thrive, urinary retention, hydronephrosis, ascites, and congestive heart failure. Patients with milder forms of the disease may escape detection until late as adolescence. These children may present with functional voiding disorders or UTIs.[30]

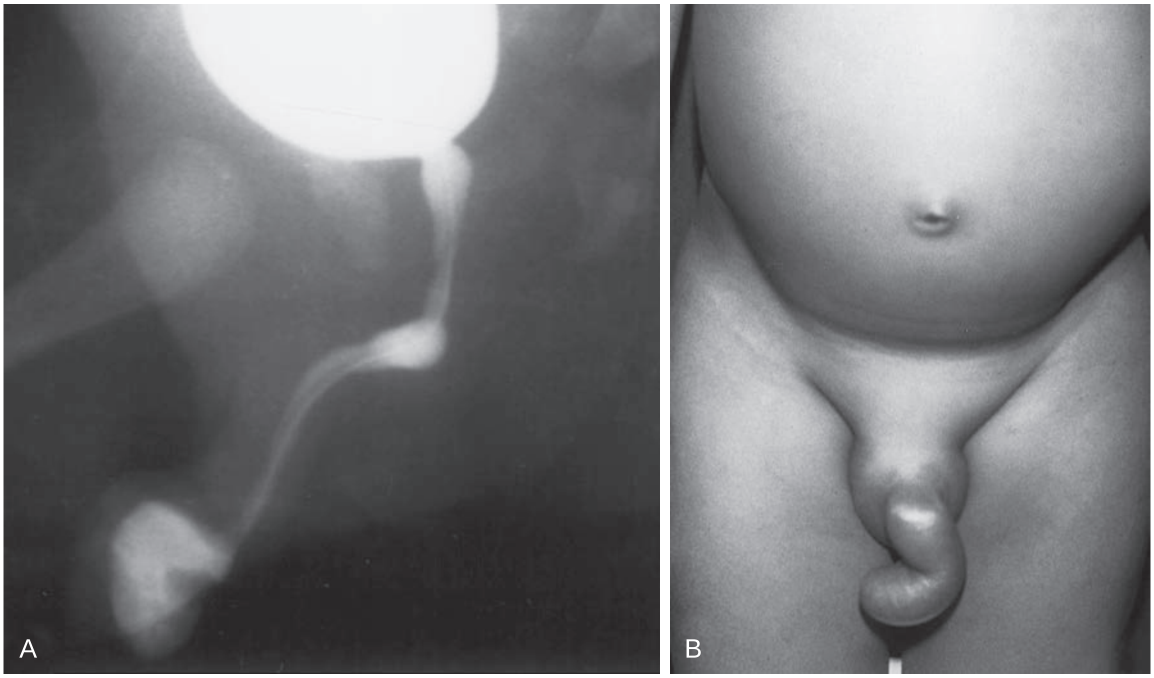
***Imaging.*** Antenatal and postnatal MRI and US show varying degrees of hydroureteronephrosis and bladder wall thickening (e-Fig. 120.18). Dysplastic kidneys with increased echogenicity, decreased corticomedullary differentiation, and cortical cyst formation may be seen. Perinephric fluid collections (urinomas) are usually related to forniceal rupture (Fig. 120.19 and e-Fig. 120.20). When unexplained ascites is discovered in a male fetus or newborn, the diagnosis of urinary tract obstruction caused by PUV should be strongly considered (Fig. 120.21). Associated hydroureteronephrosis may not be present because the forniceal rupture and communication to the peritoneal cavity act as a “pop off” mechanism, allowing one or both kidneys to decompress and therefore



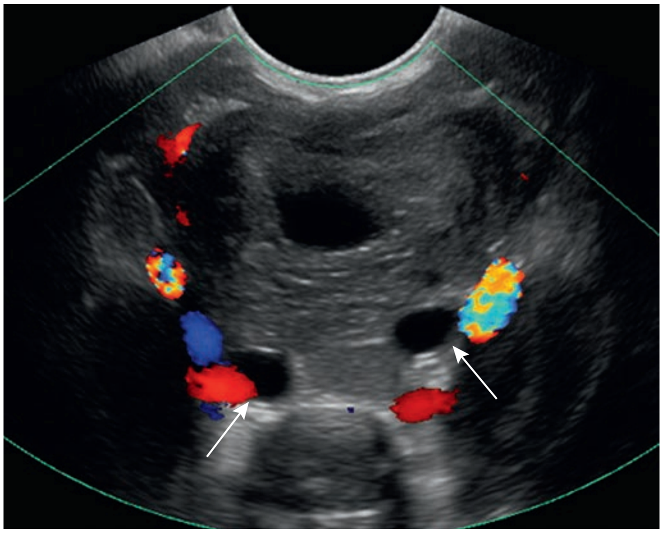
**e-Figure 120.14. Anterior urethral valve.** Longitudinal ultrasound image of the urethra during voiding shows thin echogenic valve traversing the urethra *(arrow)*. Proximal to the valve, urethral dilation is seen *(asterisk)*. *(From Bates DG, Coley BD. Ultrasound diagnosis of the anterior urethral valve.* Pediatr Radiol*. 2001;31:634–636.)*



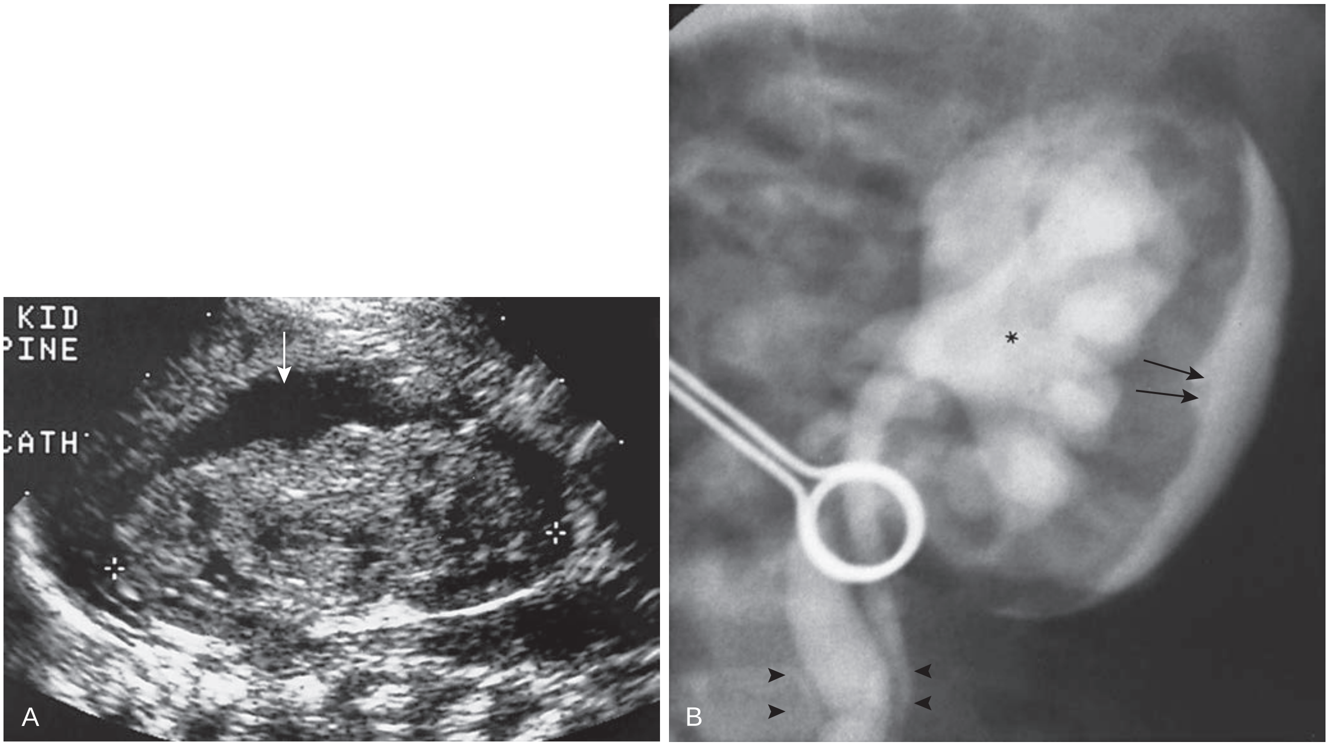
**e-Figure 120.16. Megalourethra.** An oblique image from a retrograde urethrogram shows fusiform dilation of the penile urethra.



**e-Figure 120.17. Megalourethra.** (A) Voiding cystourethrogram shows dilation of the anterior penile urethra. (B) Postvoid photograph of the same child.



**e-Figure 120.18. Posterior urethral valves.** Transverse color Doppler sonogram shows marked bladder wall thickening and trabeculation due to outlet obstruction. The distal ureters *(arrows)* are dilated.



**e-Figure 120.20. Posterior urethral valves and perinephric fluid collection.** (A) Longitudinal gray-scale sonogram in a neonate shows a perinephric fluid collection *(arrow)*, likely a urinoma. No dilation of the intrarenal collecting system is present because it has decompressed into the subcapsular space. (B) Voiding cystourethrogram in a neonate with posterior urethral valves shows grade IV/V vesicoureteric reflux *(asterisk)*, intrarenal reflux, and either transparenchymal flow of contrast material into the subcapsular space or forniceal rupture with contrast material in the same location as the arrow on image (A) *(arrows)*. Contrast material also tracks down along the ureter *(arrowheads)*.

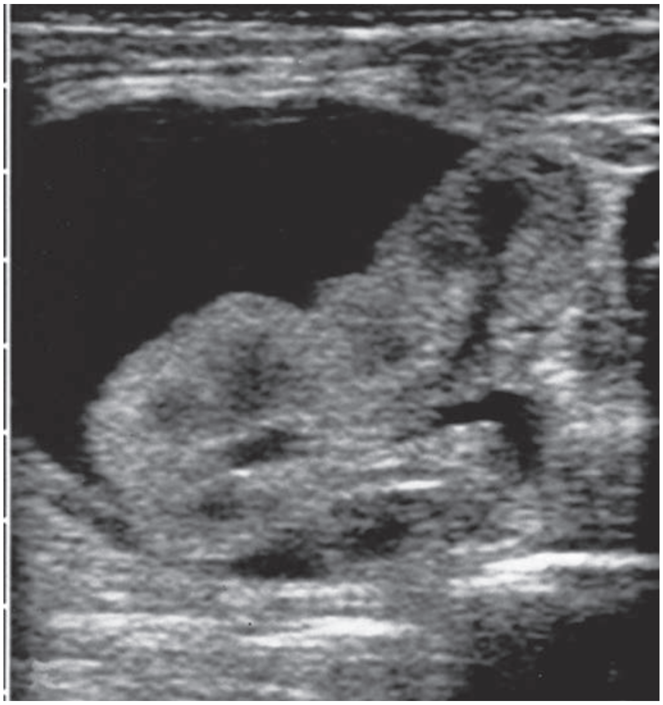


**Figure 120.19. Posterior urethral valve and perinephric fluid collection.** Transverse prone gray-scale sonogram shows a urinoma with mass effect on the left kidney.

attenuating the degree of renal damage. US can show the dilated posterior urethra, especially if the child is voiding at the time of the examination (e-Fig. 120.22).[31–36]

VCUG is the diagnostic study of choice for PUV (e-Fig. 120.23). VCUG directly shows the PUV and its effect on the urinary bladder: wall thickening, trabeculation with cellulae and sacculi, diverticula, and hypertrophy of the interureteric ridge (e-Fig. 120.24). The membrane itself may be visualized as a thin linear defect in the contrast-filled posterior urethra in some children (Fig. 120.25). VUR occurs in about one-half to two-thirds of boys with PUV, of whom approximately two-thirds have unilateral reflux (e-Fig. 120.26 and Box 120.2).[20,26,37,38]

***Treatment.*** When identified antenatally, severe obstruction can be treated with vesicoamniotic shunting; more recently developed fetoscopic laser ablation techniques are still considered experimental.[39] After birth, transurethral valvulotomy under direct visualization remains the treatment of choice. Residual valve tissue with obstruction is not uncommon, and stricture formation at the site of previous urethral valves or in the membranous urethra may occur.[40–43]

## POSTERIOR URETHRAL POLYPS

***Overview.*** Urethral polyps are benign growths usually of fibroepithelial histology that occur most commonly in boys 8 to 10 years of age. They typically arise from the posterior urethra in the region of the verumontanum as an elongated mobile mass.[44] The classic clinical triad includes intermittent urinary retention, intermittent hematuria, and intermittent lower urinary tract symptoms caused

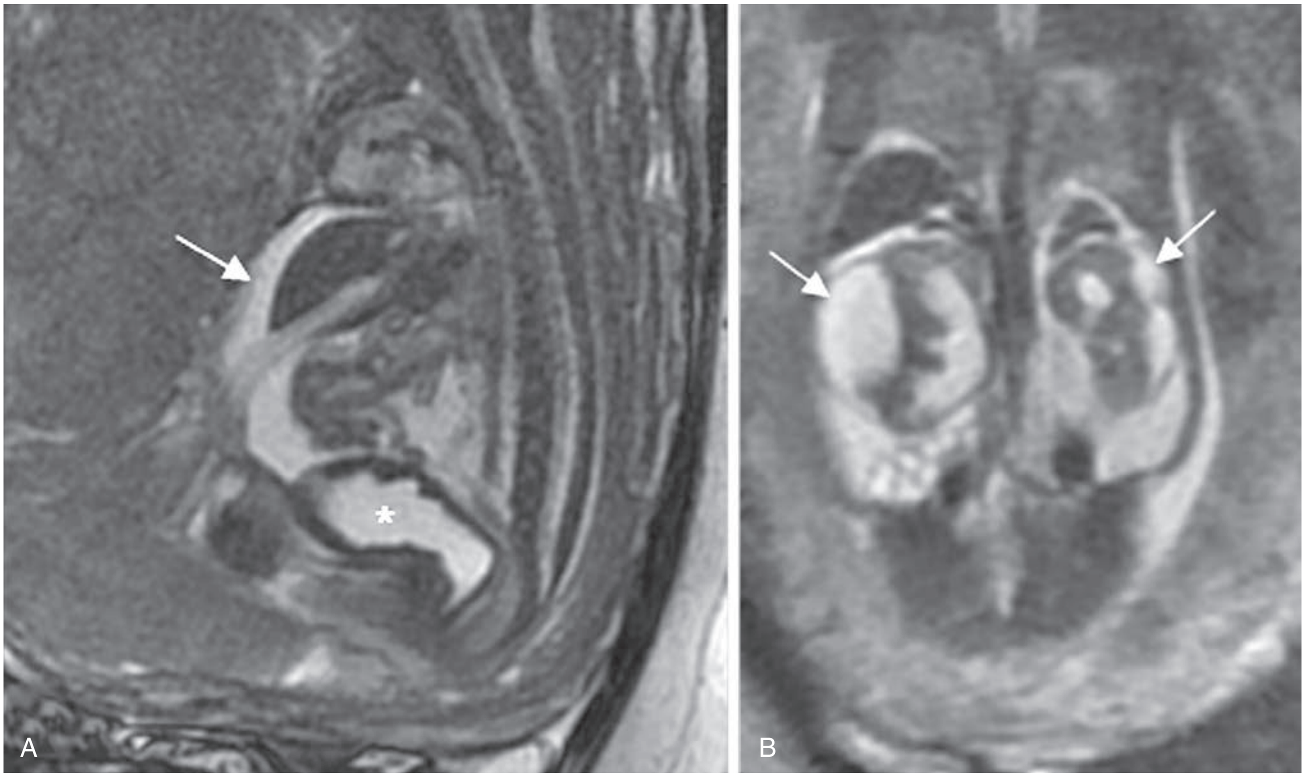

**Figure 120.21. Posterior urethral valves in a fetus.** (A) Sagittal T2-weighted MR image shows a dilated, thick-walled bladder *(asterisk)* and dilated posterior urethra. Ascites is also present *(arrow)*. (B) Coronal T2-weighted MR image through the kidneys shows bilateral pelvicaliectasis and subcapsular fluid collections *(arrows)*.

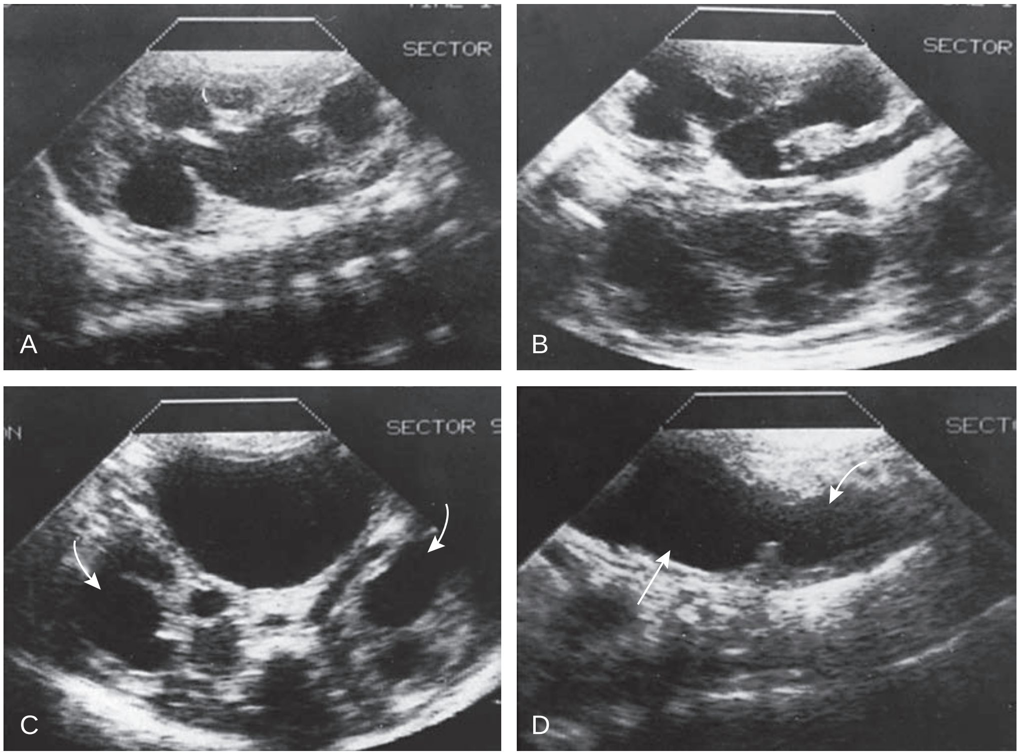
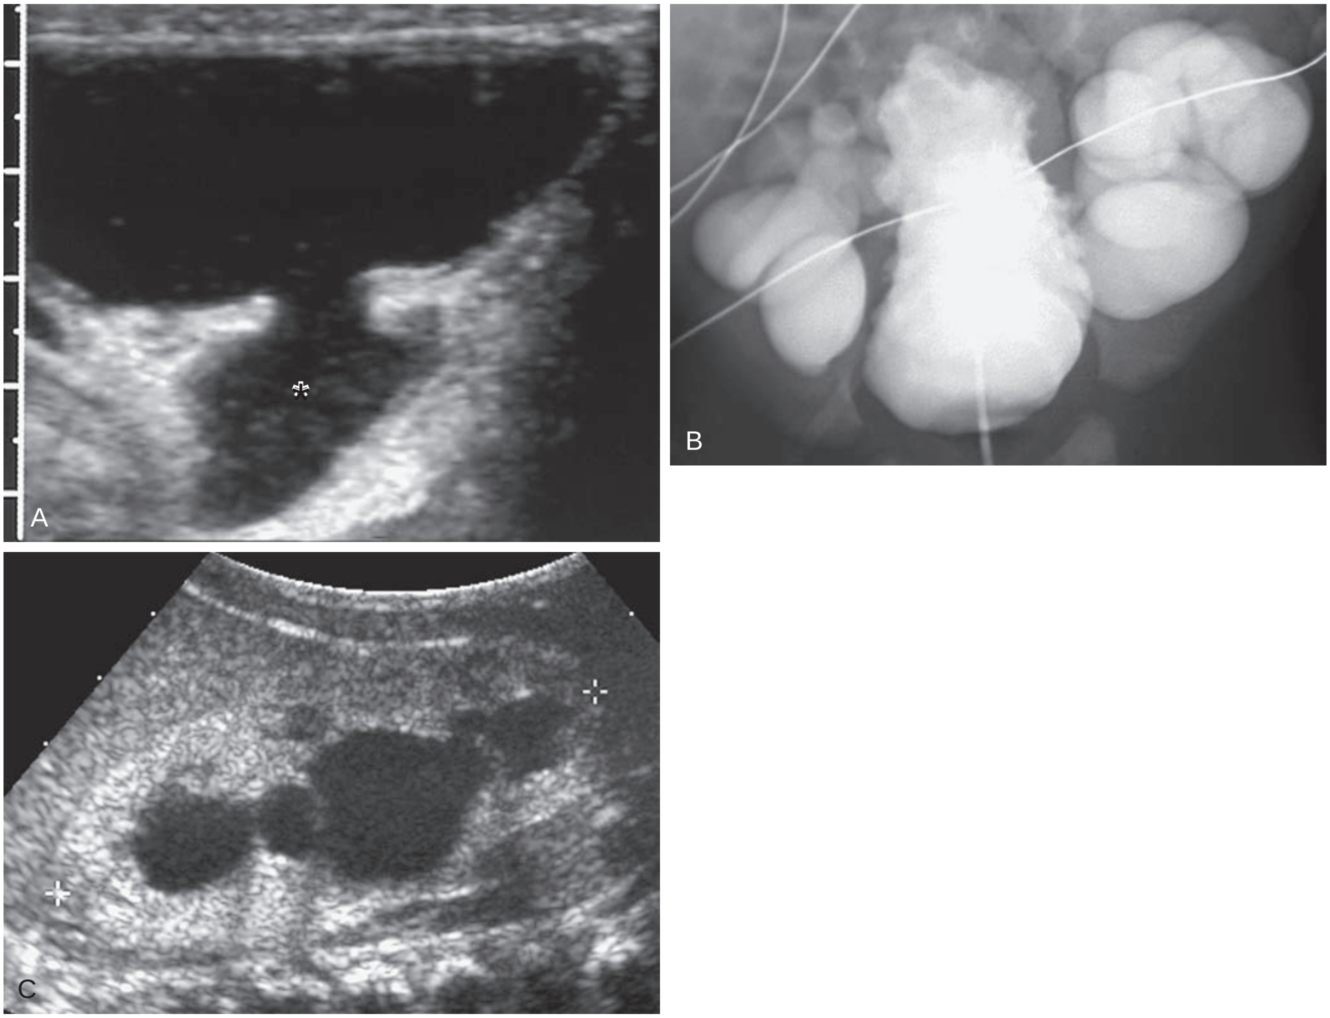
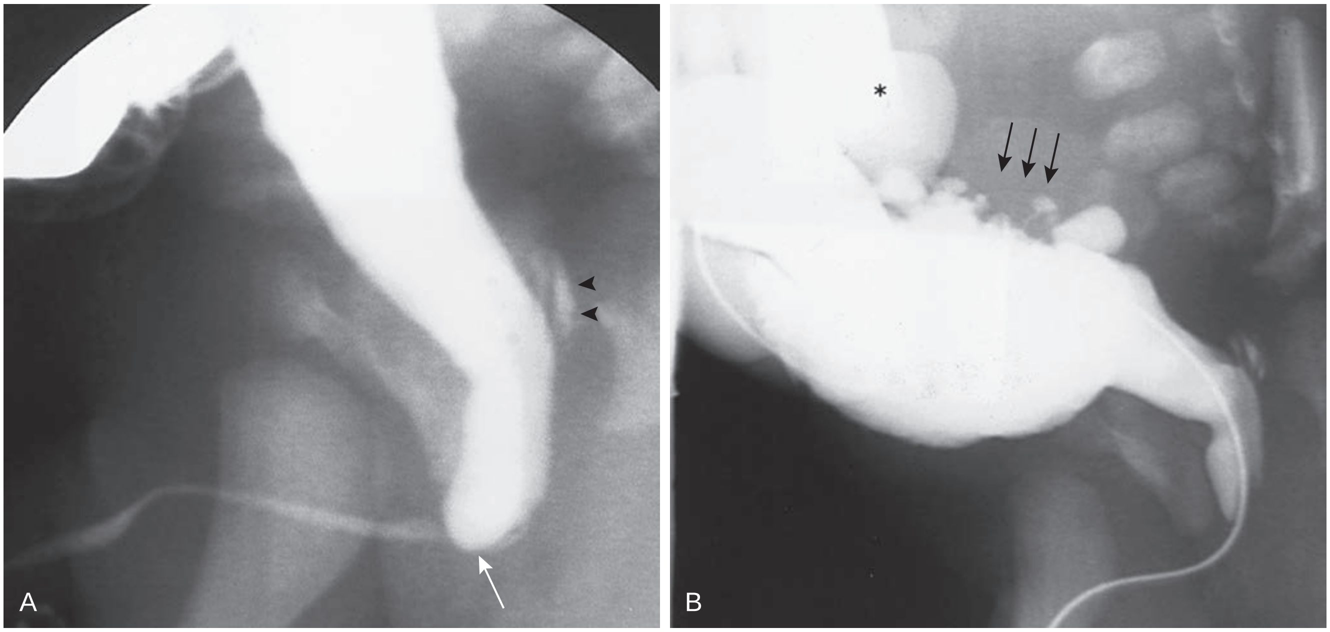


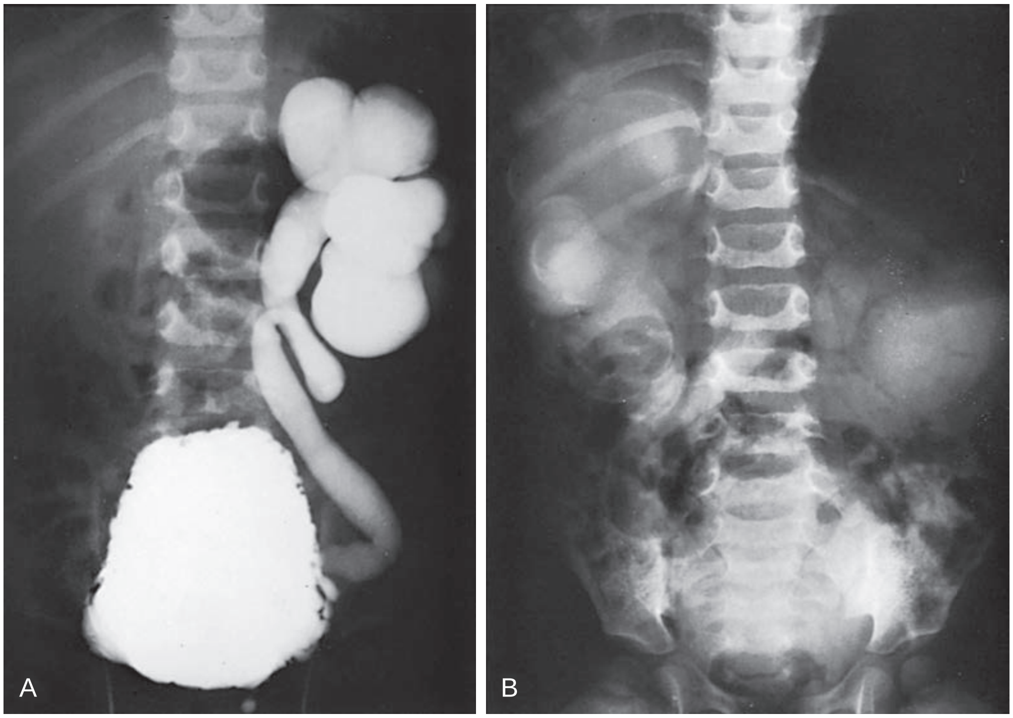
**e-Figure 120.22. Posterior urethral valves in a 7-day-old male infant strongly suspected on the basis of a fetal ultrasound examination.** (A and B) Longitudinal gray-scale sonogram of the right kidney (A) and left kidney (B) show bilateral dilation of the pelvicalyceal systems. (C) Bilateral ureterectasis also is present extending caudally to the bladder *(arrows)*. The bladder was markedly distended. (D) Midline longitudinal sonogram of the bladder with the transducer directly caudally shows dilation of the posterior urethra *(curved arrow)*. *Straight arrow* points to the bladder.



**e-Figure 120.23. Posterior urethral valves.** (A) Transverse gray-scale sonogram of the bladder shows a dilated posterior urethra *(asterisk)*, representing the "keyhole" sign. (B) Anterior image from a voiding cystourethrogram of the same patient demonstrates a trabeculated bladder with severe bilateral vesicoureteral reflux. (C) Longitudinal gray-scale sonogram of the same patient demonstrates an echogenic right kidney with absent corticomedullary differentiation and hydronephrosis indicating renal dysplasia.



**e-Figure 120.24. Posterior urethral valve on voiding cystourethrogram.** (A) Steep oblique view from a voiding cystourethrogram shows posterior urethral valves *(arrow)*. The valves are clearly seen at the bottom of the verumontanum, with the distal urethral lumen eccentric and posterior in position. The posterior urethra related to the obstruction is dilated, and reflux into the ejaculatory ducts is seen *(arrowheads)*. (B) VCUG of the same neonate shows a trabeculated bladder with cellulae and sacculi *(arrows)*. Left-sided vesicoureteric reflux *(asterisk)* is seen.



**e-Figure 120.26. Infant with posterior urethral valves.** (A) Voiding cystourethrogram shows severe left-sided reflux and bladder wall thickening. (B) Excretory urogram shows poor renal function and severe upper tract dilation bilaterally. Rim sign on the right represents a dense collection of contrast material in tubules around the dilated calyces.

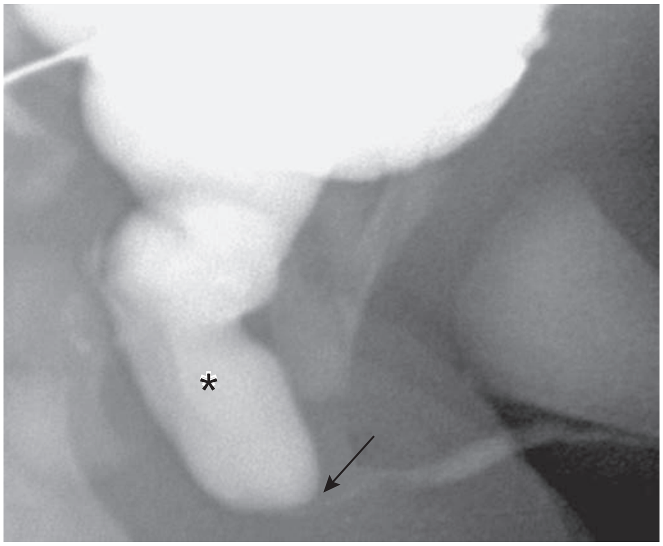


**Figure 120.25. Posterior urethral valves.** Oblique voiding cystourethrogram image shows a dilated posterior urethra *(asterisk)* with abrupt transition at level of valves *(arrow)* to a narrow anterior urethra. Incidental reflux into the ejaculatory ducts is seen.

**BOX 120.2** Imaging Findings in Patients With Posterior Urethral Valves

**ULTRASONOGRAPHY**

Renal cysts (dysplasia)
Bilateral (unilateral) hydronephrosis
Thick-walled bladder
Dilated posterior urethra
Membrane in posterior urethra

**VOIDING CYSTOURETHROGRAPHY**

Dilated posterior urethra
Membrane in posterior urethra
Reflux into prostatic ducts, ejaculatory ducts, or both
Thick bladder neck
Trabeculated bladder
Vesicoureteral reflux

by obstruction of the urethral lumen during voiding. Not uncommonly, patients may carry a diagnosis of psychosomatic voiding dysfunction due to the intermittent nature of the symptoms.[45] When females are affected, the most common presentation is an interlabial mass and external bloody discharge secondary to irritation of the polyp. Important differential considerations include prolapsed ectopic ureterocele, paraurethral cyst, hydrometrocolpos, and botryoid RMS.[46]

***Imaging.*** VCUG remains the imaging test of choice. Before voiding, the tip of the polyp is frequently located at the level of the bladder neck, causing a small rounded filling defect. In the voiding phase, the polyp moves downward into the distal posterior urethra and occasionally into the bulbar urethra (Fig. 120.27). At the end of voiding, the polyp is displaced retrograde to the level of the bladder outlet by the contraction of the external urethral sphincter. US may demonstrate a mobile pedunculated mass at the bladder base and indirect signs of bladder outlet obstruction (hydronephrosis and a large bladder with or without bladder wall hypertrophy).[47,48]

***Treatment.*** Treatment is transurethral resection with fulguration of the base of the polyp, and the risk of recurrence is nearly zero. Open surgery is reserved for when transurethral or endoscopic suprapubic resection is not feasible.[45]

## PROSTATIC UTRICLE

***Overview.*** The prostatic utricle is an epithelium-lined diverticulum of the prostatic urethra and is thought to be the remnant of the fused caudal ends of the Müllerian ducts. It is located at the level of the verumontanum between the openings of the two ejaculatory ducts. Normally, the urogenital sinus does not respond to Müllerian inhibiting factor but instead masculinizes in response to testosterone secretion in males. Abnormal hormonal input or sensitivity leads to development of the prostatic utricle and commonly varying degrees of hypospadias.[49] The increasing severity of the hypospadias correlates with increasing size of the utricle. While there is some debate, these are distinguished from Müllerian duct cysts in their earlier presentation, increased association with hypospadias and intersex disorders, and tubular shape. Though many are asymptomatic, poor emptying may lead to urine retention and stasis. Clinically, this presents as lower urinary tract voiding symptoms, urinary retention, UTI, epididymitis, stone formation, or postvoid dribbling caused by delayed utricle drainage.[50]

***Imaging.*** VCUG and RUG define the utricle size and its origin from the prostatic urethra and any associated hypospadias. Direct catheterization of the bladder during VCUG may be difficult secondary to preferential passage into the utricle (e-Fig. 120.28).

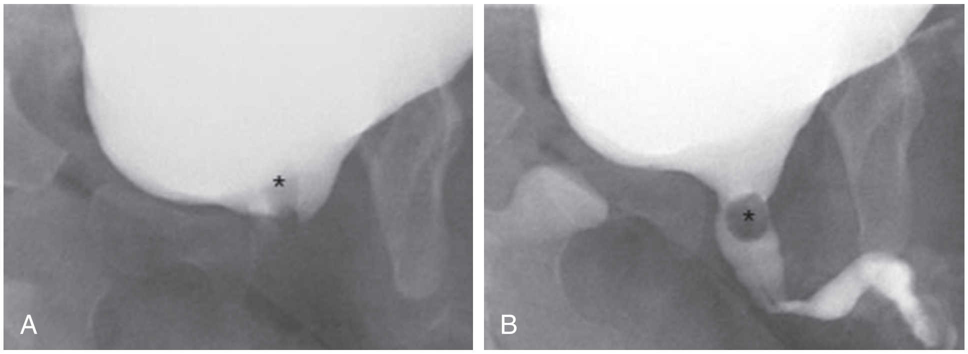

**Figure 120.27. Urethral polyp.** (A) Oblique image during voiding cystourethrography shows a lobular filling defect in the base of the bladder during initial filling phase *(asterisk)*. (B) The defect prolapses into the posterior urethra during voiding phase representing a polyp on a stalk *(asterisk)*.

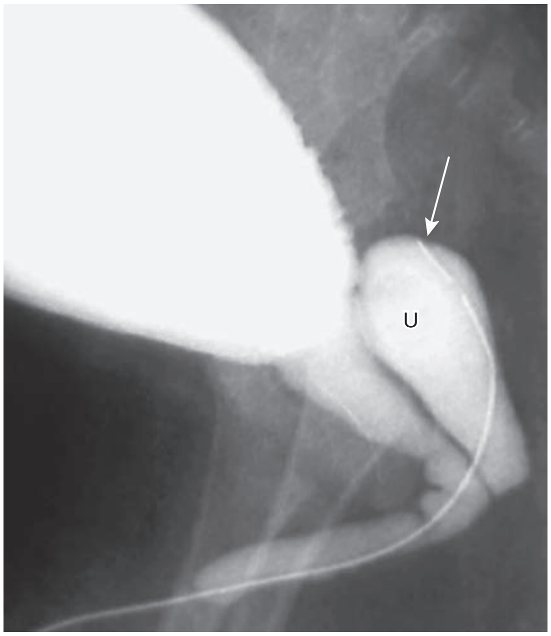

**e-Figure 120.28. Utricle.** Oblique voiding cystourethrogram image shows the catheter *(arrow)* positioned in the utricle *(U)*. Bladder filling and voiding were achieved without repositioning of the catheter.

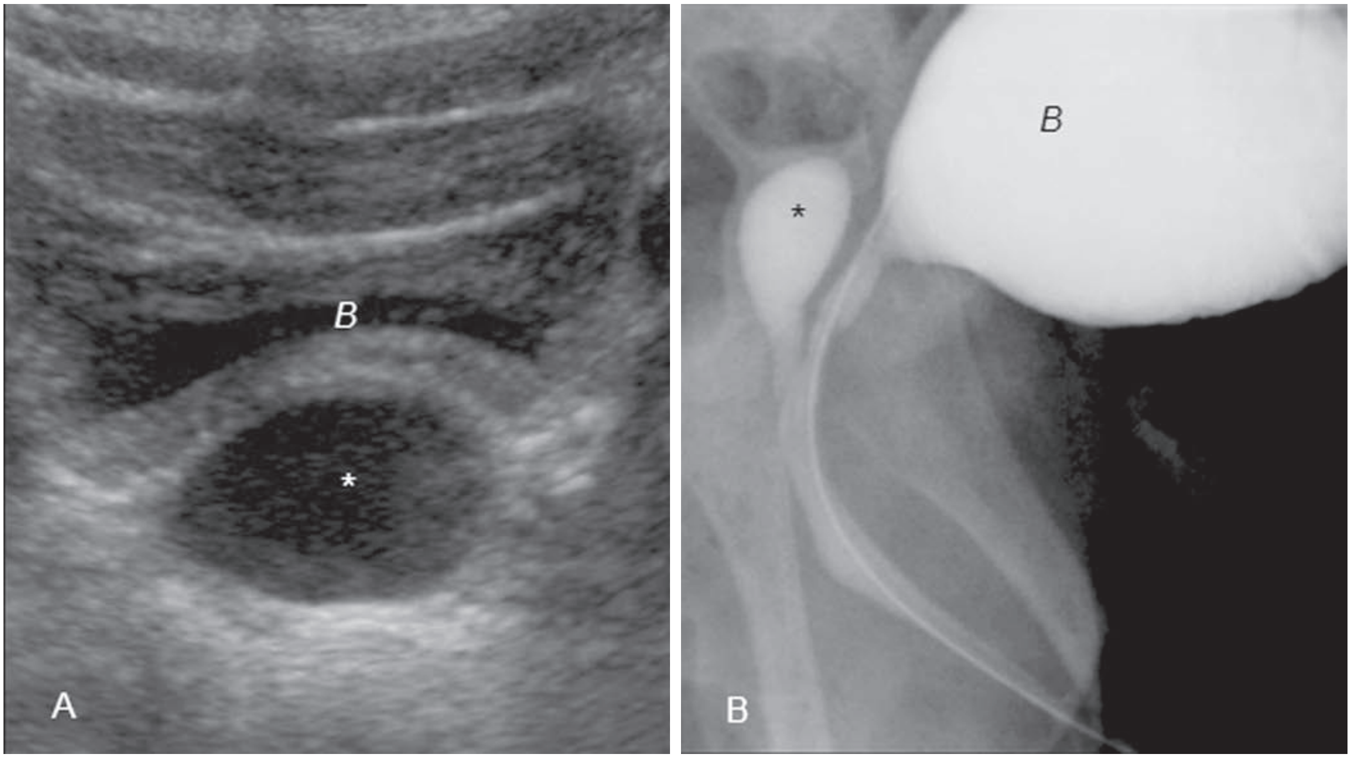

**Figure 120.29. Prostatic utricle.** (A) Transverse gray-scale sonogram through the level of the bladder demonstrates a fluid-filled cystic structure *(asterisk)* posteriorly. (B) Oblique voiding cystourethrogram demonstrates filling of a tubular structure arising from the verumontanum, consistent with a prostatic utricle.

Rarely the utricle may not be visible on RUG or VCUG, in which case US may be useful. Transabdominal US may demonstrate a retrovesical cystic mass, with or without internal debris, tapering to the expected location of the posterior urethra. CT and MRI will demonstrate a thin-walled cystic lesion originating from the prostatic urethral region, with or without associated mass effect on the bladder and ureters (Fig. 120.29).[51,52]

***Treatment.*** Surgical excision is the definitive treatment of symptomatic Müllerian duct remnants. Surgical management remains challenging because of the intimate association of these lesions to the ejaculatory ducts, vas deferens, ureters, pelvic nerves, and rectum.[53] More recently, laparoscopic excision has been reported with good success.[54]

## ABNORMALITIES OF COWPER'S GLANDS

***Overview.*** Bulbourethral (Cowper's) glands arise from the urethra in response to dihydrotestosterone and secrete a clear substance that serves as a lubricant. There are two pairs of glands, with the main pair within the urogenital diaphragm and an accessory pair within the bulbospongiosal tissue. The ducts measure 2 to 3 cm in length and course anteriorly to empty along the ventral surface of the bulbar urethra.[55,56]

***Imaging.*** The clinical significance of Cowper's glands in children usually lies in their recognition as a normal entity when visualized as a contrast-filled tubular structure paralleling the undersurface of the bulbar urethra during VCUG (e-Fig. 120.30). Rarely, a dilated gland and duct (syringocele) may be present (either congenital or acquired) and result in variable clinical presentation depending on whether or not the orifice is open (postvoid dribbling, uretheral discharge, UTI, and hematuria) or closed (obstructive symptoms, dysuria, urinary retention, and perineal pain).

These have been previously classified into four groups by Maizels et al according to morphology and symptoms: simple, perforate, imperforate, and ruptured.[57] When the orifice of the syringocele is open, contrast can be seen refluxing into the dilated duct, while when closed there will be smooth extrinsic mass effect along the ventral surface of the bulbar urethra (Fig. 120.31). On transperineal US, syringocele will appear as a generally anechoic cystic lesion within the characteristic location posterior to the bulbourethra. MRI may be useful for visualization of otherwise radiographically

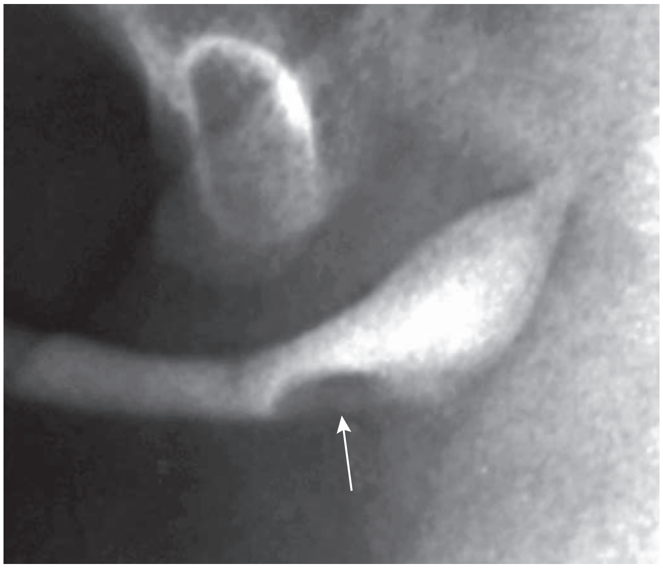

**Figure 120.31. Cowper's duct cyst (syringocele).** Oblique retrograde urethrogram image shows a lobular filling defect *(arrow)* along the ventral surface of the bulbar urethra.

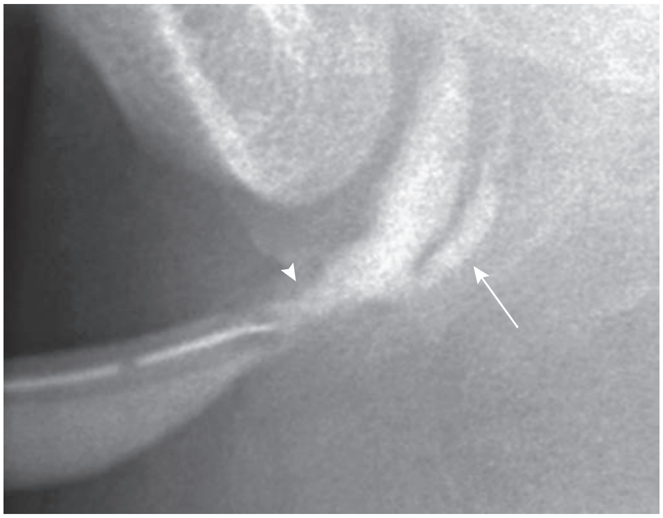

**e-Figure 120.30. Cowper's duct.** Oblique image from a retrograde urethrogram in a patient with a bulbar urethral stricture *(arrowhead)* shows retrograde filling of a ventral tubular structure *(arrow)* paralleling the urethra.

occult closed syringoceles which do not opacify with VCUG. Occasionally, asymptomatic retention cysts may be visualized as filling defects along the floor of the urethra during VCUG performed for other unrelated symptoms. When symptomatic, retention cysts will usually enlarge posteriorly and result in perineal masses or abscesses in the absence of voiding symptoms.[55,56,58,59]

Treatment when symptomatic is usually endoscopic incision. An important component of management is identification of secondary or coincidental pathology, which has been reported in up to 83% of patients, including minor urethral valves, VUR, ureteropelvic junction obstruction, and megaureter.[60]

## URETHRAL DUPLICATION

***Overview.*** These developmental anomalies are characterized by the presence of a complete or partial accessory urethral channel, which may arise anywhere from the bladder neck to the distal urethra and may occur in the sagittal plane (most common, with a ventral and dorsal urethra) or coronal plane (usually occurring in the setting of bladder duplication). It is important to remember that in almost all cases of sagittal duplication, the ventral urethra is the functioning channel and contains the sphincter mechanism and verumontanum.

A single unifying theory does not explain all the various forms of duplication, and more than one classification scheme exists in the literature, the most commonly referenced being the classification described by Effman et al.[61] In females, they are almost exclusively complete duplications with associated bladder duplication. In males, however, they most commonly occur as incomplete duplications that end blindly in the periurethral tissue or as a second meatus anywhere along the dorsal (epispadic variant, most common) or ventral (hypospadic variant) aspect of the penis.[62–66]

In the epispadic type, an incomplete accessory channel has a dorsal opening in the penis and ends blindly. The complete or partial forms originate from the bladder neck or proximal urethra and course through the dorsal aspect of the penis to end in an epispadic position anywhere between the glans and the root of the penis. Rarely, they originate from a minute cavity (nonfunctional sagittal plane duplicated bladder) located behind the pubic symphysis and in front of the normal bladder. The ventral urethra is normally positioned and ends in the glandular meatus (but may rarely be hypospadic).[65,66]

In the hypospadic type, an incomplete accessory channel has a ventral opening in the penis or originates from the normal proximal urethra and ends blindly in the periurethral tissue, similar in appearance to a urethral diverticulum or Cowper's duct. Complete or partial duplications arise from the bladder or proximal urethra and course through the ventral aspect of the penis to end in a hypospadic position along the shaft.[63,65,67] An important form of urethral duplication of the hypospadic type is referred to as *Y-type duplication*. The ventral urethra originates from the midprostatic urethra and terminates in the anal canal or on the perineum. Urine flows preferentially through this ventral channel and is considered the more functional urethra as it traverses the sphincter mechanism. A normally positioned dorsal urethra is usually stenotic or partially atretic.[68–71]

The congenital urethroperineal fistula has a similar location to the Y-type duplication, but is a distinctly different developmental anomaly (Fig. 120.32 and e-Fig. 120.33). The normally positioned dorsal channel is the functioning urethra in this case, and micturition is normal. Clinically, only a few drops of urine are present at the perineal opening.[72,73]

Accessory urethras may be asymptomatic or may cause a double urinary stream, urinary incontinence, UTIs, and urinary retention.

***Imaging.*** Appropriate evaluation of urethral duplication includes anatomic evaluation of all channels (rarely more than two channels may be seen), recognition of the functional urethra, and identification of associated anomalies.[64,65] VCUG is adequate if all urethral channels can be clearly identified (Fig. 120.34 and e-Fig. 120.35). RUG may be necessary for hypoplastic channels not visualized on VCUG. Cystoscopy may be performed to confirm the radiographic findings and to precisely identify which urethra contains the sphincteric mechanism and normal verumontanum.[63,67]

***Treatment.*** Preservation and surgical reconstruction of the functional urethral channel is the primary goal of treatment and must be individualized to the patient's unique anatomy. Ventral channel excision in congenital urethroperineal fistula is curative.[63,65,67,70,74]

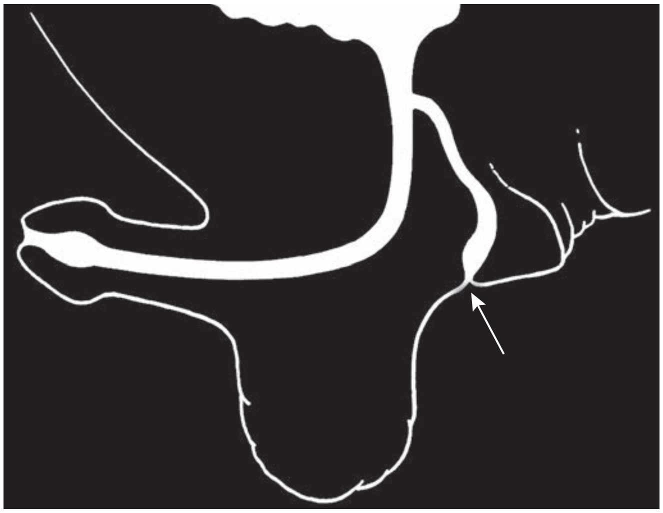

**Figure 120.32. Urethroperineal fistula.** Schematic diagram showing the perineal fistula *(arrow)* originating from the normal dorsal urethra. This is the exception to the rule that the ventral urethra is the normal urethra in duplications. *(From Bates DG, Lebowitz RL. Congenital urethroperineal fistula.* Radiology. *1995;194:501–504.) See* e-Fig. 120.33.

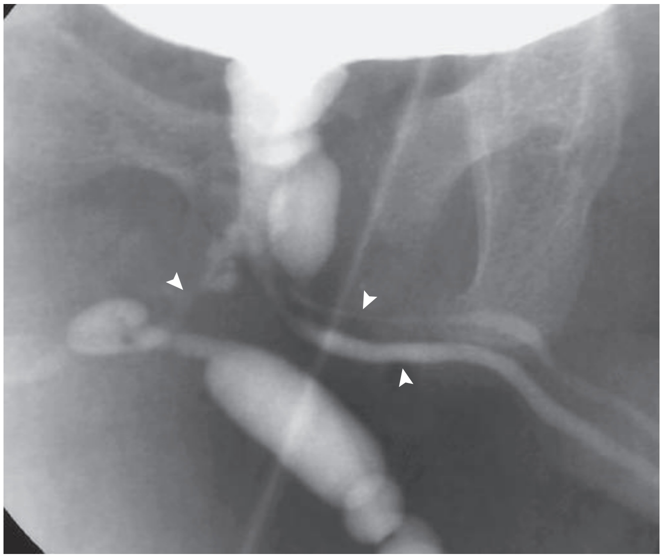

**Figure 120.34. Urethral duplications.** A voiding cystourethrogram oblique image shows triplication of the urethra *(arrowheads)* originating from the prostatic urethra.

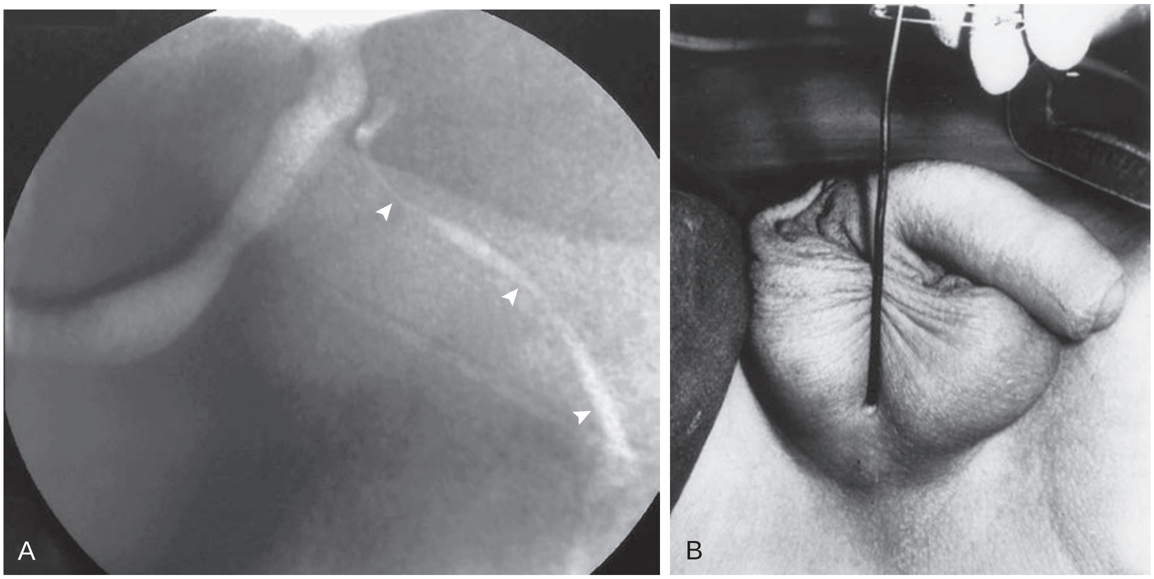
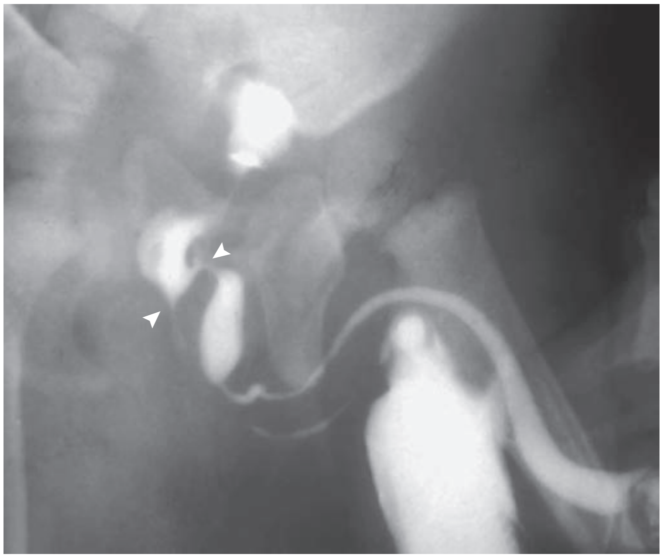
## URETHRAL STRICTURES

***Overview.*** While sometimes congenital, most pediatric urethral strictures are secondary to trauma. Iatrogenic strictures account for about two-thirds of urethral strictures in children, located



**e-Figure 120.33. Urethroperineal fistula.** (A) Oblique VCUG image shows a congenital perineal fistula *(arrowheads)* originating from the prostatic urethra. (B) A photograph of another patient, showing a probe within the perineal urethra. *(From Bates DG, Lebowitz RL. Congenital urethroperineal fistula.* Radiology. *1995;194:501–504.)*



**e-Figure 120.35. Urethral duplications.** An oblique image from a retrograde urethrogram after simultaneous injection of both the glandular and ventral penile openings shows partial duplication of the urethra originating at the prostatic urethra *(arrowheads)*.

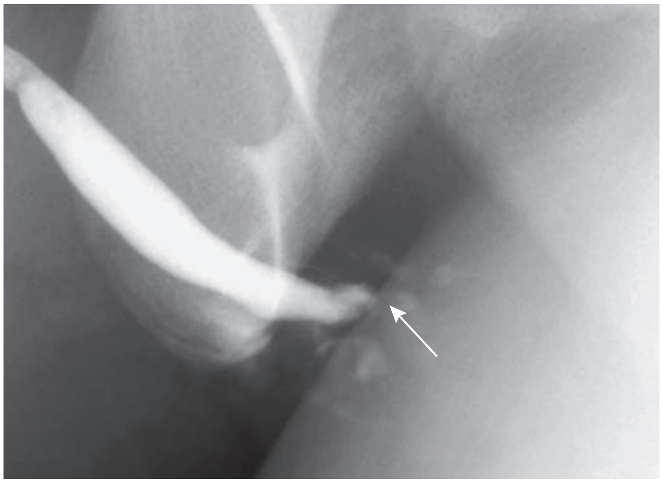


**Figure 120.36. Straddle injury.** A retrograde urethrogram shows bulbar urethral disruption *(arrow)* and contrast extravasation.

predominantly near the penoscrotal junction, an area that is particularly vulnerable to internal trauma. External trauma resulting in stricture disease may result from pelvic fractures, penetrating injuries, direct blows to the perineum, and straddle injuries. Urethral infections are uncommon causes of urethral strictures in children as opposed to young adults, in whom they are often due to *Neisseria gonorrhoeae* infection.[75–78] Urethral strictures of unknown cause in symptomatic boys are not rare and may be the result of unrecognized external trauma or urethritis, Cowper's duct infection, or rupture of a Cowper's duct cyst. They may also be secondary to incomplete dissolution of the urogenital membrane at the junction of the cloaca and genital groove (Cobb's collar) within the anterior urethra.[79] The clinical manifestations of urethral strictures include blood at the meatus after known trauma, poor urinary stream, straining to void, urinary retention, painful urination, hematuria, UTI, and recurrent epididymitis.

***Imaging.*** The diagnosis of urethral stricture is readily established by VCUG when the bladder can be catheterized. Compression of the distal penis during voiding or RUG results in distention of the normal urethra and better delineation of the true extent of the stricture. Strictures from straddle injuries are usually located in the bulbar urethra (Fig. 120.36 and e-Fig. 120.37). Congenital strictures also are located most often in the bulbar urethra and are usually very short and diaphragm-like. In the interpretation of the urethrogram, it is important to keep in mind those normal areas of narrowing at the level of the urogenital diaphragm or narrowing caused by spasm of the bulbocavernosus or external sphincter muscles that may simulate a stricture.[77,80–82] Complementary or alternative techniques to fluoroscopic evaluation that have emerged relatively recently include transperineal sonography and magnetic resonance (MR) urethrography, with the latter possessing the added ability to provide information about bladder and periurethral tissues in additional to accurately defining urethral anatomy.[80,82]

***Treatment.*** Three major forms of treatment exist for urethral stricture: (1) *urethral dilation*, which is the oldest and simplest treatment; (2) *open reconstruction with urethroplasty*, which is regarded as the gold standard; and (3) *internal urethrotomy*, by incising or ablating the stricture transurethrally.[83,84]

## KEY POINTS

- Failure of the urachus to normally regress can result in several anomalies: patent urachus (most common), urachal sinus, urachal diverticulum, and urachal cyst.
- Bladder diverticula may be primary (congenital), secondary, or iatrogenic (postoperative).
- Rhabdomysarcoma is the most common neoplasm of the lower genitourinary tract. The embryonal form is most common, accounting for approximately 90% of cases.
- Late renal insufficiency or failure may develop in 25% to 40% of patients with PUV throughout adolescence and into adulthood.
- Large prostatic utricles are commonly associated with male hypospadias.
- In Y-type urethral duplication, the ventral channel is considered the normal urethra. In congenital urethroperineal fistula, the normally positioned dorsal channel is the functioning urethra.
- Iatrogenesis accounts for about two-thirds of urethral strictures in children.

# Congenital and Neonatal Conditions

Oscar M. Navarro and Alan Daneman

## NORMAL ADRENAL

The adrenal glands in the neonate are easily visualized on ultrasonography; they are relatively large because of the presence of the fetal adrenal cortex, which accounts for about 80% of the gland (Fig. 121.1).[1]

On ultrasonography, the normal adrenal gland has a central hyperechoic stripe surrounded by a hypoechoic rim. The peripheral hypoechoic rim represents fetal as well as definitive cortex (see Fig. 121.1). The central hyperechoic stripe includes the medulla, the central veins of the adrenal, connective tissue, and the inner part of the fetal cortex.[2] Morphologically, the normal adrenal gland has an inverted Y-shape. The surface of the adrenal gland is smooth or only slightly undulating. The easiest and most useful measurement of the adrenal gland is the limb width, which should normally be less than 4 mm.[3]

Computed tomography (CT) and magnetic resonance imaging (MRI) are rarely required to visualize the adrenals in a neonate unless a mass is present.

## STRAIGHT OR DISCOID ADRENAL

***Overview and Imaging.*** A straight or discoid shape of the adrenal gland is seen on ultrasonography in association with certain congenital anomalies of the ipsilateral kidney, in which the kidney either is absent from its normal position in the renal fossa or is extremely small as a result of antenatal damage and dysplasia.[4] The adrenal gland otherwise develops normally but assumes a flattened, discoid shape (Fig. 121.2). The adrenal retains its normal pattern of echogenicity. Straight adrenal glands are longer than otherwise normal glands, and they tend to be slightly thicker.

## HORSESHOE ADRENAL

***Overview and Imaging.*** Horseshoe adrenal gland is a rare congenital anomaly in which the right and left adrenal glands are fused. It is often associated with anomalies of the kidneys and the central nervous system, asplenia with visceral heterotaxy, and other anomalies.[5]

A horseshoe adrenal gland appears on ultrasonography as a band of normal adrenal tissue crossing the midline in the upper abdomen above the kidneys (e-Fig. 121.3). The adrenal gland maintains normal echogenicity. The isthmus of the horseshoe adrenal gland usually passes behind the aorta, but in asplenia it usually passes in front of the aorta.[5]

## ADRENAL CONGESTION

***Overview and Imaging.*** Adrenal congestion may occur in perinatal asphyxia or stress. On ultrasonography, the glands are enlarged but maintain their general overall shape and smooth surface (Fig. 121.4). This usually occurs bilaterally but may be seen unilaterally or focally within one gland.[2] Loss of the normal central echogenic stripe occurs, and the fetal cortex may become a broad band of slightly increased echogenicity. A very thin peripheral anechoic rim that represents the definitive cortex may be present. Follow-up ultrasonography may show development of focal hypoechoic areas that represent hemorrhage or infarction.[2] The changes may be reversible and the sonographic pattern may return to that of normal adrenal glands in patients who survive.

## CONGENITAL ADRENAL HYPERPLASIA

***Overview.*** Congenital adrenal hyperplasia (CAH) refers to a group of autosomal recessive disorders in which an enzymatic defect occurs in the pathway for cortisol biosynthesis in the adrenal cortex. The most common defect is a deficiency of the enzyme 21-hydroxylase, which affects females much more than males.[3] This leads to ambiguous sexual development in newborn girls or salt-losing crisis in newborns of either sex.

The diagnosis of CAH is confirmed by the presence of elevated serum 17-hydroxyprogesterone (17-OHP). In addition, in female neonates with genital ambiguity, normal internal genitalia are seen on pelvic ultrasonography, and there is a normal (46, XX) karyotype. The 17-OHP level is diagnostic only when measured after the third day of life because a relatively high level is present in the immediate neonatal period in normal newborns. Furthermore, 17-OHP assays may not be easily available. These delays, although relatively short, may contribute to the diagnostic uncertainty and heighten parental anxiety. Therefore ultrasonography in the immediate neonatal period may play a role as some specific signs of CAH are seen on ultrasonography.[3]

***Imaging.*** Ultrasonography has shown to have a diagnostic sensitivity of 92% and a specificity of 100% for the diagnosis of CAH in the presence at least two of these three characteristics: adrenal gland size (limb width > 4 mm), surface characteristics (cerebriform or crenated appearance), and internal echo pattern (diffusely stippled pattern of echogenicity or less commonly diffuse thickened band of increased echogenicity) (Fig. 121.5).[3] These changes may be present focally within the adrenal glands or may be asymmetric between both adrenal glands.[3] Rarely, the adrenal glands may appear normal, emphasizing the fact that the absence of the signs does not exclude the diagnosis of CAH.

The sonographic changes in the adrenal glands with CAH are reversible with the introduction of therapy. Administration of corticosteroids to the mother of the affected fetus results in a normal sonographic appearance of the adrenal glands at birth.

## WOLMAN DISEASE

***Overview.*** Wolman disease is a rare disorder of lipid metabolism (familial xanthomatosis). This inherited deficiency of lysosomal acid lipase leads to an accumulation of cholesterol esters and triglycerides in many organs, particularly the adrenal glands.[6] The disorder manifests in the early weeks of life, and hepatosplenomegaly, jaundice, vomiting, steatorrhea, abdominal distension, and growth failure may exist. The disease is rapidly progressive, and death occurs within the first year.

***Imaging.*** Marked enlargement of both adrenal glands, which retain their overall shape, is seen on imaging. This is associated with marked, diffuse, punctate calcification (e-Fig. 121.6).[6] This can be recognized on plain radiographs of the abdomen and cross-sectional imaging. On ultrasonography, the calcification in Wolman disease appears as dense punctate or granular hyperechogenicities with

## Abstract:

Normal adrenal glands in neonates are easily visualized on ultrasonography because of the presence of the fetal adrenal cortex. They have an inverted Y-shape with a hyperechoic central stripe, a hypoechoic rim, smooth contours, and a limb thickness < 4 mm. Computed tomography or magnetic resonance imaging are rarely required unless a mass is present.

A straight or discoid shape of the adrenal gland is an indicator of an ipsilateral renal anomaly. Congenital adrenal hyperplasia (CAH), usually due to 21-hydroxilase deficiency, presents with either ambiguous genitalia in girls or salt-losing crisis. Ultrasonography can help in diagnosis before final biochemical confirmation. In CAH, the adrenal is thicker, has a cerebriform shape, and shows increased echogenicity with loss of central echogenic stripe. In Wolman disease, a rare lipid metabolism disorder, the adrenal glands are enlarged and diffusely calcified.

Neonatal suprarenal masses include adrenal hemorrhage, usually associated with perinatal stress. On ultrasonography, it shows variable echogenicity with absence of Doppler blood flow and can be difficult to differentiate from neuroblastoma. Follow-up ultrasonography is useful in diagnosis of hemorrhage by showing decrease in size and changes in echogenicity. Neuroblastoma is the most common neonatal adrenal tumor with variable size, echogenicity and blood flow, and may present with metastases to the liver, skin and bone marrow.

Pulmonary sequestration may present as a neonatal suprarenal mass, more often left-sided and diagnosed earlier than neuroblastoma, in the second trimester. On ultrasonography, it is an echogenic mass many times with cystic spaces because of a congenital pulmonary airway malformation component.

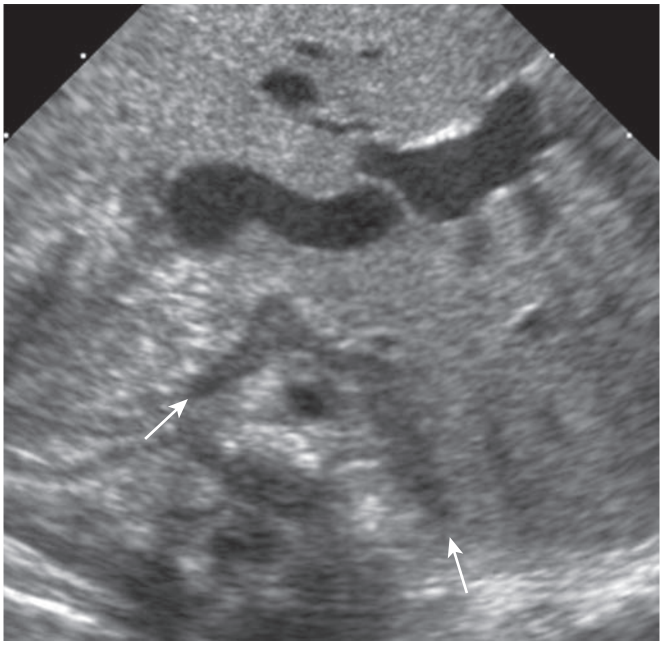
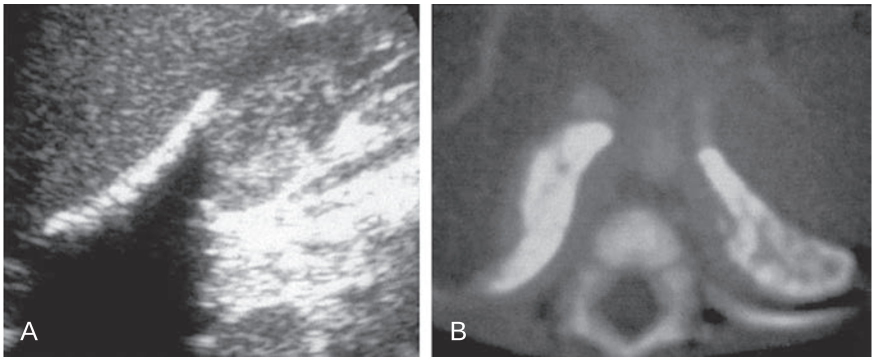
Pulmonary sequestration
Wolman disease



**e-Figure 121.3. Horseshoe adrenal gland *(arrows)* in a patient with heterotaxy syndrome (asplenia).** Transverse sonogram of the upper abdomen shows that the adrenal glands are fused across the midline, giving a horseshoe shape. The central echogenic stripe and surrounding hypoechoic zone and smooth surface are maintained. The gland lies anterior to the aorta, which is to the right of the midline, and behind the inferior vena cava, which is to the left. *(Courtesy Dr. Ulrich Willi, Kinderspital, Zürich, Switzerland.)*



**e-Figure 121.6. Wolman disease.** Marked calcification and enlargement of both adrenal glands are seen. (A) A longitudinal sonogram of the right adrenal shows linear echogenicity in the anterior part of the gland with a strong acoustic shadow posteriorly. (B) On the computed tomography scan, the calcification appears to be more peripheral within the cortex of both adrenal glands.

posterior acoustic shadowing, the latter seldom seen with adrenal hemorrhage. On CT, the large size of both adrenal glands and the diffuse pattern of calcification differentiate this condition from resolving adrenal hemorrhage, in which the adrenal glands are smaller with more globular calcification.

## SUPRARENAL MASSES

***Overview.*** Adrenal masses in the neonate can be caused by hemorrhage or neoplasm, particularly neuroblastoma. Extraadrenal masses are rare with the most common being extralobar pulmonary sequestration. An accurate diagnosis is important for appropriate management. However, diagnoses may be difficult because of overlapping imaging features and thus may not be established on the initial imaging findings alone, often requiring follow-up imaging, correlation with clinical history, and measurement of urine catecholamines. Because of the relatively good prognosis of perinatal neuroblastoma, initial conservative management is often warranted. CT and MRI have a lesser role in the diagnosis of these lesions and are mainly indicated to assess extent and for staging of a suspected neuroblastoma.

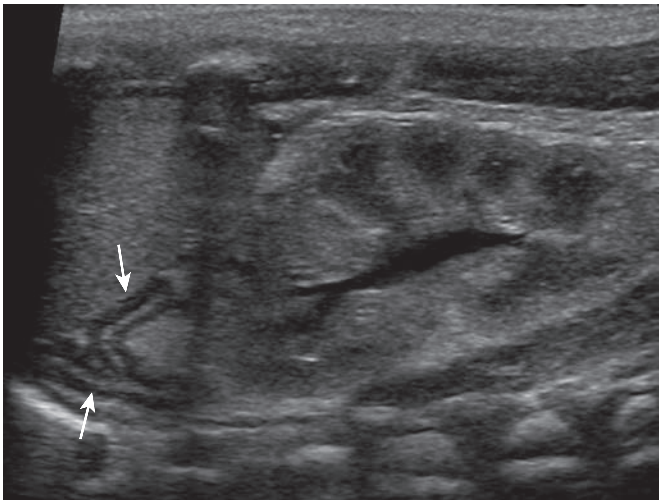


**Figure 121.1. Normal left adrenal in a 1-day-old newborn.** Longitudinal sonogram of the left adrenal gland *(arrows)* shows a central hyperechoic stripe representing the central veins, connective tissue, medullary tissue, and congested sinusoids of the inner part of the fetal cortex. The surrounding hypoechoic zone represents the less congested outer part of the fetal cortex and the thin peripheral definitive cortex. The surface of the gland is smooth.

## Adrenal Hemorrhage

***Overview.*** Adrenal hemorrhage is the most common adrenal gland masslike abnormality in neonates. It often occurs within the first few days of life but can occur prenatally and be seen on antenatal ultrasonography. It is more commonly right sided (70%) and may be bilateral (10%).[7] It usually occurs in situations of perinatal stress, including difficult or traumatic delivery, hypoxia, and sepsis. It may also occur in bleeding diatheses. Large infants and infants of mothers with diabetes are particularly susceptible. Adrenal hemorrhages in neonates may be an incidental finding.

***Imaging.*** Ultrasonography is the modality of choice for documentation of the presence of an adrenal hemorrhage and for follow-up. Ultrasonography shows a suprarenal mass of variable echogenicity (Fig. 121.7) without internal blood flow on color

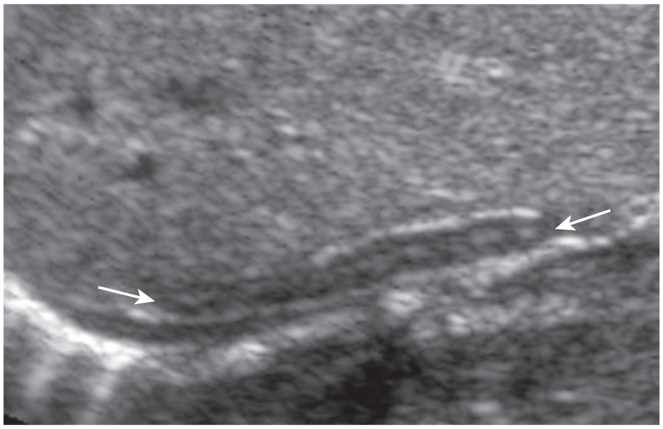

**Figure 121.2. Discoid adrenal gland in a patient with right renal agenesis.** Longitudinal sonogram of the right adrenal gland shows a straight adrenal *(arrows)* that lacks the morphology illustrated in Fig. 121.1. The central hyperechoic stripe, surrounding hypoechoic zone, and smooth surface are preserved.

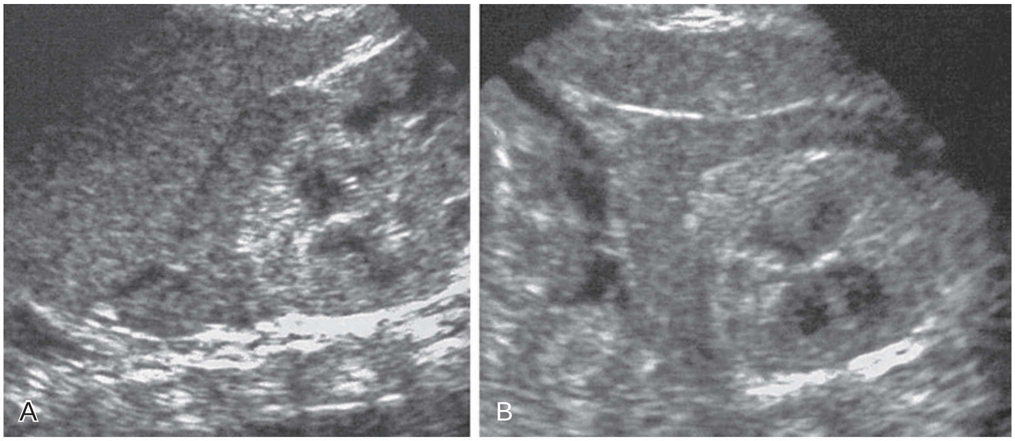

**Figure 121.4. Adrenal congestion in an 8-day-old full-term boy with necrotizing enterocolitis, cardiovascular collapse, and multiorgan failure.** Longitudinal (A) and transverse (B) sonograms reveal marked enlargement of the left adrenal gland. Although it has retained its normal shape and smooth surface, there is loss of the normal central echogenic stripe. The gland has a more homogeneous low-level echogenicity, and in parts, a peripheral anechoic thin rim is seen. A postmortem histologic examination revealed congestion of the fetal cortex. The peripheral thin rim represents the peripheral definitive cortex.

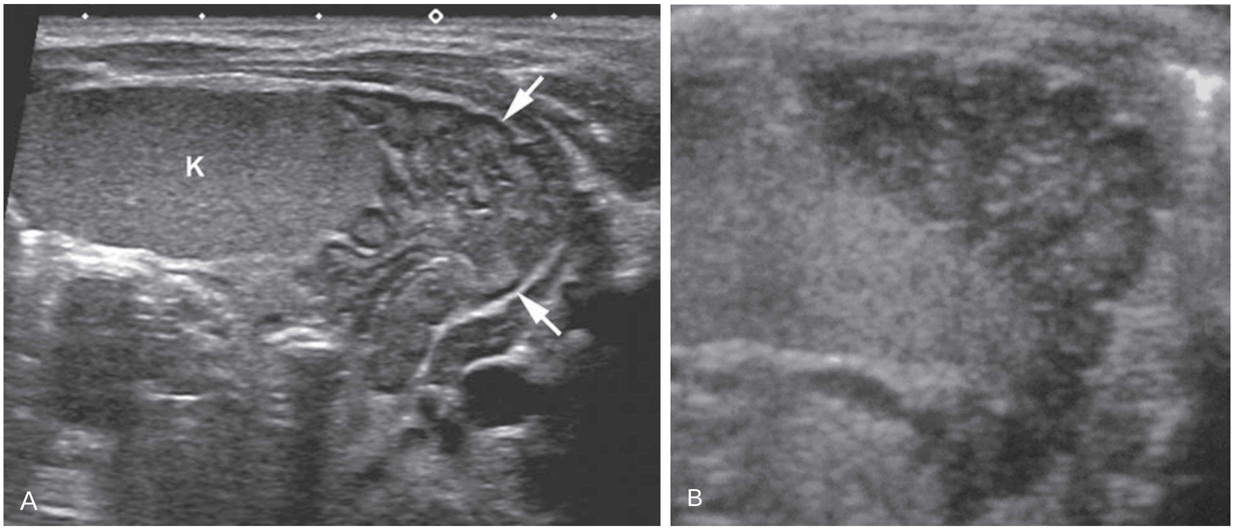

**Figure 121.5. Congenital adrenal hyperplasia.** (A) Transverse sonogram of the left adrenal gland in a newborn shows an enlarged thickened gland *(arrows)* with a cerebriform appearance; *K*, Kidney. (B) Transverse sonogram of the left adrenal gland in another patient shows marked enlargement of the gland, and the central echogenic stripe has been replaced by diffuse stippled echogenicity.

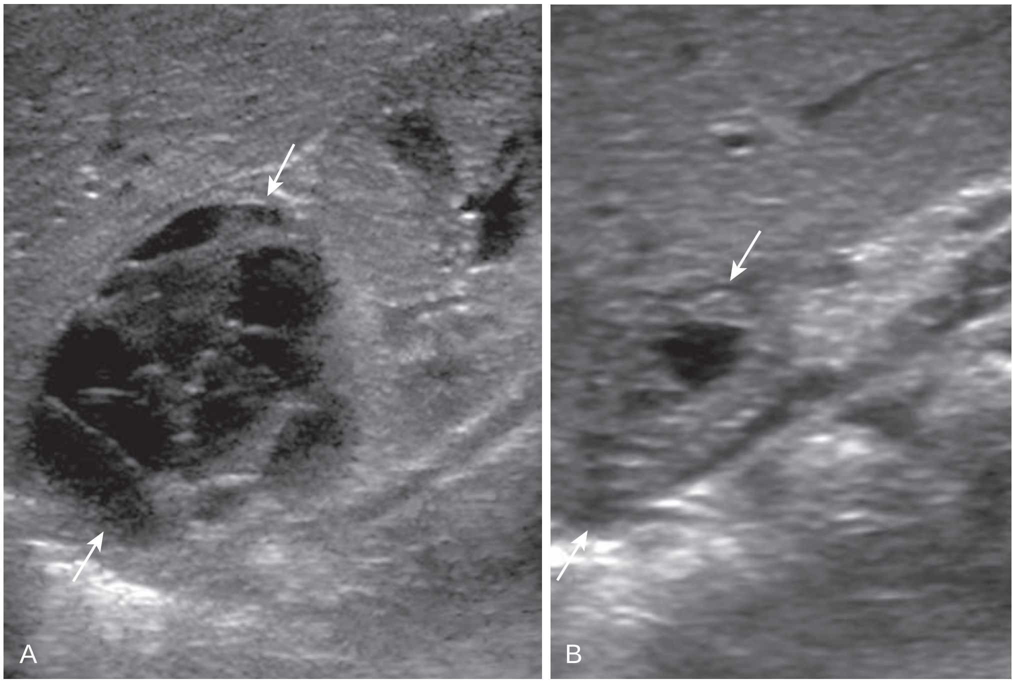

**Figure 121.7. Adrenal gland hemorrhage detected in the third trimester of pregnancy in a neonate.** (A) Longitudinal sonogram of the right upper quadrant at 17 days of age shows a multiseptated predominantly cystic mass *(arrows)* superior to the right kidney. No blood flow in the septa was evident on color Doppler interrogation (not shown). (B) The follow-up sonogram at 38 days of age shows significant decrease in size of the mass *(arrows)* as well as a change in its echogenicity. The pattern of evolution of this lesion is compatible with an adrenal hemorrhage. In addition, urine catecholamines and metaiodobenzylguanidine scan were negative in this patient.

Doppler ultrasonography. These findings may overlap with those of neuroblastoma, and therefore, further confirmation of the diagnosis may be obtained from follow-up ultrasonography.[7] The adrenal hemorrhage decreases in size and changes echogenicity within the first week (see Fig. 121.7), followed by development of peripheral increased echogenicity due to calcification. The calcification becomes more compacted as the mass becomes smaller, and the adrenal gland eventually resumes a more normal shape and size. Rarely, MRI may be used to discriminate adrenal hemorrhage from neuroblastoma, based on the detection of blood products and lack of postcontrast enhancement.

## Neuroblastoma

***Overview and Imaging.*** Neuroblastoma is the most common adrenal gland neoplasm found in the fetus and neonates.[8] When detected antenatally, it is generally diagnosed in the third trimester. It is frequently right-sided, may vary significantly in size (Fig. 121.8), and often has a more cystic appearance than in older infants and children (Fig. 121.9).[8,9] At sonography, the echogenicity varies; some may be homogeneously echogenic (Fig. 121.10), whereas others are highly heterogeneous. Blood flow is often detected on color Doppler ultrasonography aiding in the differentiation from hemorrhage (see Fig. 121.10). However, the absence of flow does not exclude the diagnosis of neuroblastoma.

Perinatal neuroblastoma also may present with metastatic disease, typically in the liver, skin, and bone marrow, corresponding to stage MS (equivalent to stage 4S of the formerly used International Neuroblastoma Staging System) (see Chapter 122). Diffuse infiltration of the liver may result in massive hepatomegaly (e-Fig. 121.11).

In contrast to neuroblastoma in older children, in perinatal neuroblastoma urinary catecholamine metabolites are elevated in only 40% of cases, and metaiodobenzylguanidine (MIBG) avidity exists in only 70% of cases.[8]

## Intraabdominal Pulmonary Sequestration

***Overview and Imaging.*** Intraabdominal extralobar pulmonary sequestration is a mass of pulmonary tissue separate from the lung with systemic arterial supply that can be found in the suprarenal region, usually on the left side. In contrast to adrenal neuroblastoma and hemorrhage, these are commonly diagnosed in the second trimester of pregnancy.[10] In fact, a suprarenal mass diagnosed in the third trimester of pregnancy but with a normal second trimester sonogram goes against a diagnosis of sequestration. On ultrasonography, sequestrations appear homogeneously hyperechoic, although in more than half the cases, small (<5 mm), well-defined intralesional cysts exist because of the presence of associated congenital pulmonary airway malformation (Fig. 121.12).[10,11] The normal adrenal gland is often identified, displaced anteriorly by the sequestration. These sequestrations may decrease in size and even disappear on follow-up ultrasonography.[11]

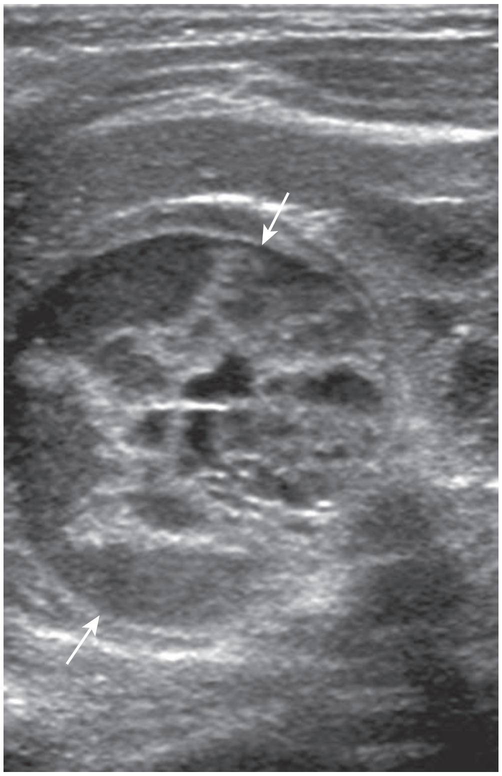

**Figure 121.9. Right adrenal neuroblastoma detected in the third trimester of pregnancy in an 8-day-old girl.** A longitudinal sonogram shows a complex, multiseptated, partly cystic mass *(arrows)* involving the right adrenal. No blood flow in the septa was evident on color Doppler interrogation (not shown). The mass has similar features to the adrenal hemorrhage illustrated in Fig. 121.7, although in this case, urine catecholamines were elevated and the mass was metaiodobenzylguanidine avid.

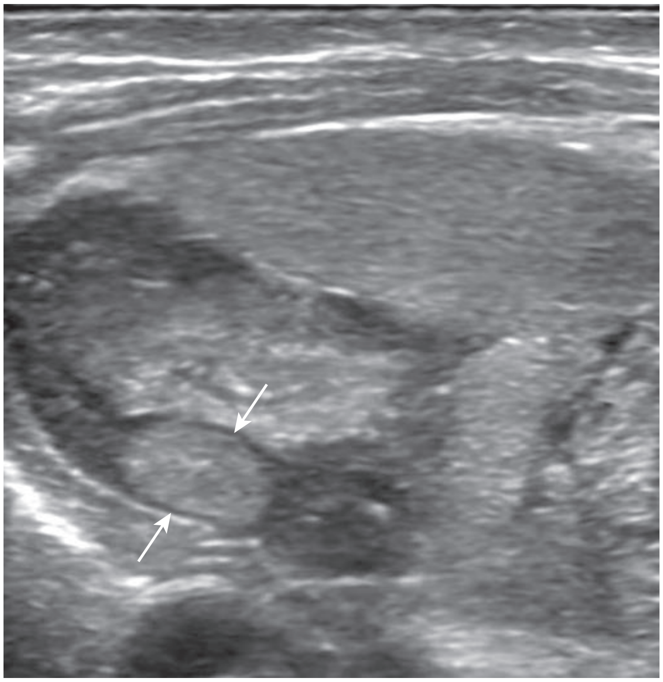

**Figure 121.8. Left adrenal neuroblastoma found incidentally in a 13-day-old boy.** Longitudinal sonogram of the left upper quadrant shows a very small hyperechoic mass *(arrows)* within one of the limbs of the left adrenal gland.

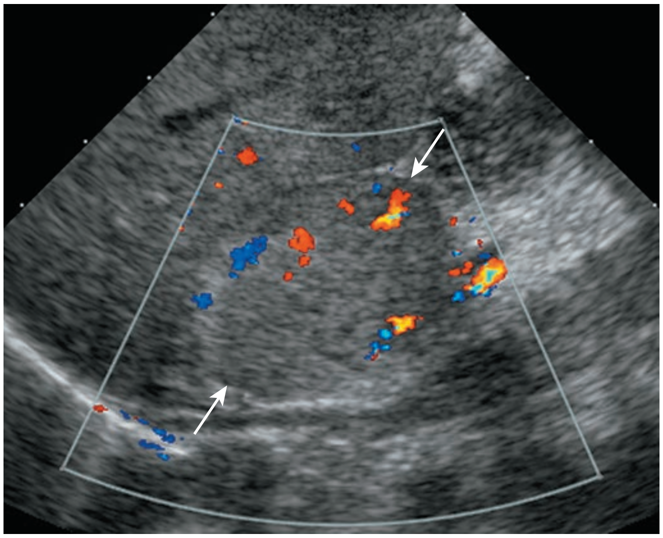

**Figure 121.10. Right adrenal neuroblastoma detected in the third trimester of pregnancy in a 10-day-old boy.** A longitudinal sonogram shows a relatively homogenous hyperechoic mass *(arrows)* arising in a somewhat exophytic fashion from the inferior and anterior aspect of the right adrenal gland. Intralesional blood flow is shown on color Doppler interrogation.

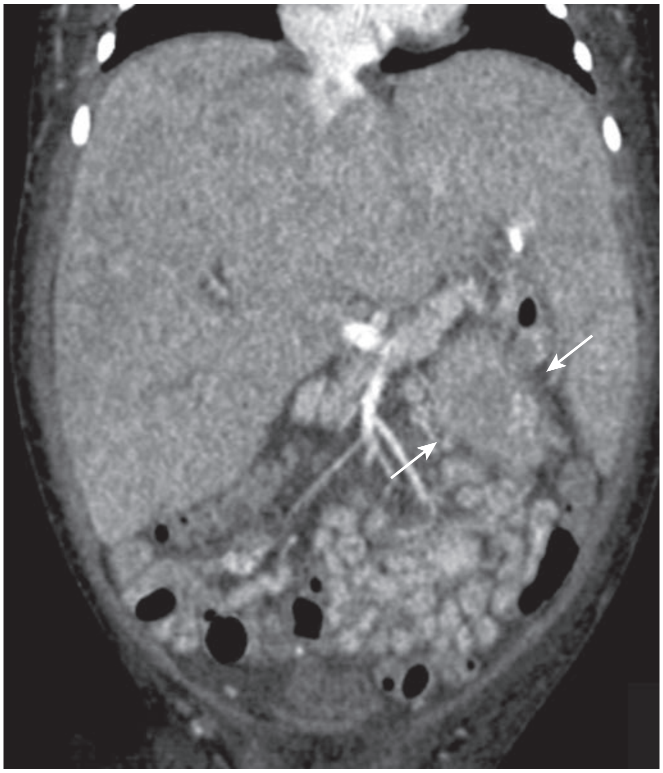

**e-Figure 121.11. Bilateral adrenal neuroblastoma with liver metastatic disease.** Coronal reformatted contrast-enhanced CT image shows marked hepatomegaly with heterogeneous attenuation of the parenchyma due to metastatic infiltration by neuroblastoma. Part of the left adrenal mass is evident *(arrows)*.

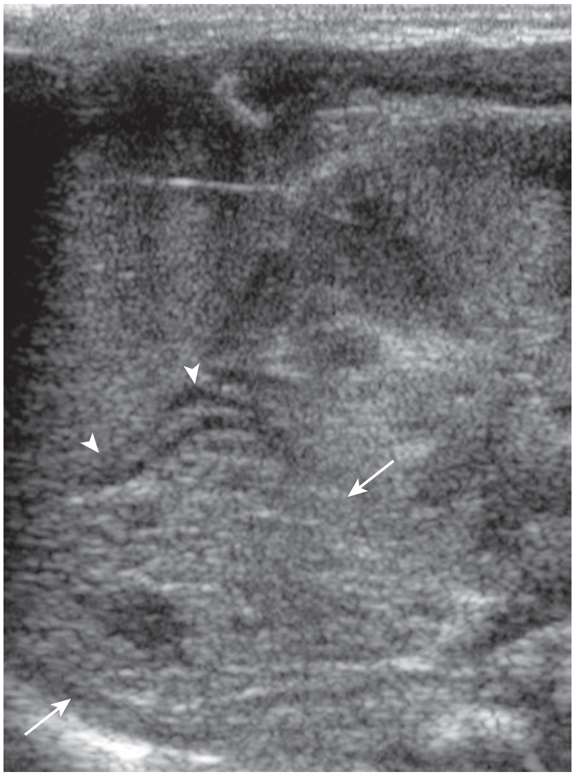

**Figure 121.12. Left-sided intraabdominal pulmonary sequestration detected in the second trimester of pregnancy in a 2-day-old girl.** A relatively echogenic left suprarenal mass *(arrows)* displaces the normal left adrenal anteriorly *(arrowheads)*, characteristic of sequestration. Within the mass, rounded hypoechoic areas represent cysts secondary to a component of congenital pulmonary airway malformation.

## KEY POINTS

- A straight or discoid adrenal gland is a marker for an ipsilateral renal anomaly.
- A horseshoe adrenal gland is associated with nongenitourinary anomalies, including asplenia.
- Ultrasonography can be helpful in the expedient diagnosis of CAH.
- Follow-up ultrasonography is helpful in the differentiation of adrenal gland neuroblastoma from hemorrhage.
- Time of antenatal diagnosis is extremely helpful in the differentiation of adrenal gland neuroblastoma from intraabdominal pulmonary sequestration.

# 122 Acquired Conditions

*Oscar M. Navarro and Alan Daneman*

## NEUROBLASTOMA

***Overview.*** Neuroblastoma is the most common extracranial solid neoplasm in children and accounts for almost 10% of all childhood neoplasms.[1] Neuroblastoma arises in the abdomen in two-thirds of cases; of these, about two-thirds of lesions occur in the adrenal gland, whereas the remainder may arise anywhere along the sympathetic nerve chains.[1]

Neuroblastoma, ganglioneuroblastoma, and ganglioneuroma belong to a group of related neurogenic neoplasms arising from neural crest tissue that are distinguished by their degree of cellular maturation and differentiation. Neuroblastoma accounts for the vast majority and has the most primitive and malignant cells.[2] Ganglioneuroma represents the most differentiated end of the spectrum and is benign. Ganglioneuroblastomas represent an intermediate group with mixed histology and behavior.

Most children with neuroblastoma present between 1 and 5 years of age, with a median age of almost 2 years, although tumors may be uncommonly congenital and present at birth.[2] Neuroblastoma is more common in patients with neurofibromatosis type 1, Beckwith-Wiedemann syndrome, Hirschsprung disease, central hypoventilation syndrome, and DiGeorge syndrome.[2]

Neuroblastomas typically present as palpable masses or with symptoms and signs related to local tumor invasion, metastatic disease, and the effects of hormone production (e.g., catecholamines) or autoimmune response (opsoclonus-myoclonus syndrome). Metastatic disease is seen in up to 70% of patients at presentation.[3] The most common sites include local and distant lymph nodes, bone, bone marrow, liver, and skin.

The diagnosis of neuroblastoma can be made by tissue biopsy, but a combination of positive bone marrow aspirate and increased urinary catecholamine metabolites (vanillylmandelic acid and homovanillic acid) is sufficient to confirm the diagnosis. The urinary level of catecholamine metabolites is increased in almost 90% of cases of neuroblastoma.[4] The International Neuroblastoma Staging System has been the most commonly used worldwide for staging neuroblastoma.[1,2,4] However, its application has encountered many difficulties, as it relies on the extent of tumor resected at surgery. For this reason, the International Neuroblastoma Risk Group Staging System was developed in 2009 and relies on preoperative imaging findings and detection of metastatic disease. Specific involvement of vital structures represent image-defined risk factors (IDRFs) and upstage tumors from L1 to L2 (Box 122.1).[5] In general, IDRFs represent encasement of vessels and nerves, contiguous organ invasion or significant intraspinal extension, airway compression, and tumor in more than one body compartment (Box 122.2).[6]

The prognosis of neuroblastoma depends on stage at presentation, patient's age (children younger than 12 to 18 months have better prognosis), histologic category, grade of tumor differentiation, status of the *MYCN* oncogene, chromosome 11q status, and deoxyribonucleic acid ploidy.[7]

***Imaging.*** Adrenal neuroblastomas and those arising from the adjacent retroperitoneum are usually easily identified with ultrasound (US), computed tomography (CT), or magnetic resonance imaging (MRI) because the mass is generally quite large by the time of presentation (Fig. 122.1). Very small masses are uncommon, and in those cases seen beyond the neonatal age, CT and MRI play a more important role than ultrasonography (Fig. 122.2 and e-Fig. 122.3). The masses have a variety of appearances by US with the most characteristic being that of a solid, heterogeneous, hyperechoic mass, often with small hyperechoic calcifications with or without posterior acoustic shadowing (Fig. 122.4 and e-Fig. 122.5).[1,2,4] Anechoic areas resulting from cystic, hemorrhagic, or necrotic changes may be present (e-Fig. 122.6).

The new International Neuroblastoma Risk Group Staging System requires the use of CT, MRI, or both for staging.[5] On CT, neuroblastomas usually show heterogeneous enhancement, depicting solid areas along with areas of necrosis, hemorrhage, and cystic change (see Fig. 122.1). Calcification is present in more than 90% of cases (see Fig. 122.1 and e-Fig. 122.6).[4] On MRI, the lesions are usually heterogeneous, with predominantly low signal on T1-weighted images and high signal on T2-weighted images, and with variable degrees of enhancement (Fig. 122.7).[2,4]

A characteristic imaging feature of neuroblastoma is the displacement of adjacent organs and the displacement or encasement of adjacent major vessels (see Figs. 122.1 and 122.7).[4] Local spread may be to lymph nodes. Less frequently, direct invasion into the kidneys (Fig. 122.8) or liver may occur, and the tumor may extend into the spinal canal.

Neuroblastoma liver metastases may be single or multiple nodules, or may present with an infiltrative pattern, particularly in neonates (Fig. 122.9) (see Chapter 121). Metastases to bone are best identified with metaiodobenzylguanidine (MIBG) scintigraphy.

If the lesion responds to chemotherapy, the mass regresses and shrinks to a very small amount of soft tissue that often becomes calcified. Certain neuroblastomas in very young children, including individuals with metastatic disease, may undergo spontaneous regression.[8]

## GANGLIONEUROMA

***Overview.*** Ganglioneuroma represents the mature, benign form of neural crest neoplasm. This is far less frequent compared with neuroblastoma; it may develop from the maturation of a known malignant neuroblastoma, or it may be found de novo.[2]

Ganglioneuromas most frequently occur in the posterior mediastinum followed by the extra-adrenal retroperitoneum (e-Fig. 122.10) and the adrenal gland.[2] These tumors usually occur in older children, are frequently asymptomatic, and are often found incidentally on imaging. Occasionally, symptoms may result from tumor growth into the intervertebral foramina, causing spinal cord compression. Urinary catecholamine levels are usually normal.

***Imaging.*** The imaging appearance of ganglioneuroma has been traditionally considered to be indistinguishable from that of neuroblastoma (Figs. 122.11 and 122.12).[2] Therefore definitive diagnosis has usually relied on the histologic examination of tumor tissue. However, more recent studies using diffusion-weighted MRI have shown significantly lower apparent diffusion coefficient (ADC) values in neuroblastoma compared with ganglioneuroma/ganglioneuroblastoma, which may be helpful in tumor differentiation.[9] Ganglioneuromas are also less often calcified as well as generally smaller and more circumscribed than neuroblastoma.

## Abstract:

Acquired conditions of the adrenal glands and retroperitoneum are most commonly neurogenic neoplasms. Neuroblastoma, a malignant tumor, is the most frequent, often presenting in young children. Most arise from the adrenal gland. They usually present as a large, heterogeneous mass with calcifications that can be diagnosed with ultrasound although computed tomography (CT) or magnetic resonance imaging (MRI) are required for staging using the International Risk Group Staging System, which relies on identification of image-defined risk factors. Neuroblastomas often encase major abdominal vessels and may extend into the spinal canal. They can metastasize to the liver and bone. Ganglioneuroma, the benign counterpart, presents more often in older children and occurs most frequently in the retroperitoneum. On imaging ganglioneuroma is indistinguishable from neuroblastoma except for higher apparent diffusion coefficient values on diffusion-weighted MRI in the former. Pheochromocytoma (adrenal) and paraganglioma (extraadrenal) are uncommon, arise from chromaffin cells, are frequently benign and present with symptoms related to catecholamine secretion. CT and MRI are better than ultrasound for diagnosis although imaging features are not specific. Functional imaging with MIBG is more specific for diagnosis. Adrenocortical neoplasms (adenomas and carcinomas) are more commonly seen in girls, in patients with predisposing cancer conditions, particularly Li-Fraumeni syndrome, and are generally hormonally functioning. In children they are often large, heterogeneous masses on all imaging modalities. Other pediatric retroperitoneal masses include lymphadenopathy, vascular malformations, Kaposiform hemangioendothelioma, other neurogenic tumors, adipocytic tumors, germ cell neoplasms (including teratoma), rhabdomyosarcoma, fibromatosis, idiopathic fibrosis, hematoma and abscess.

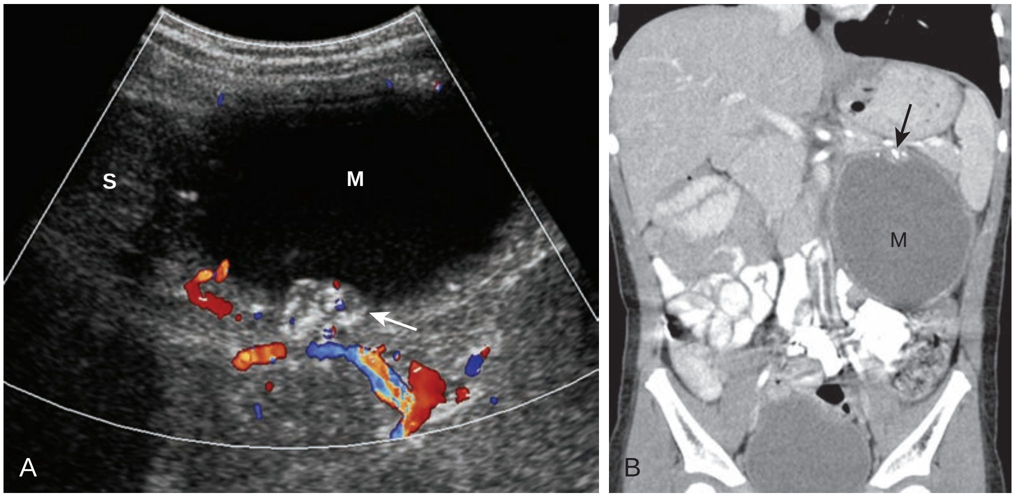
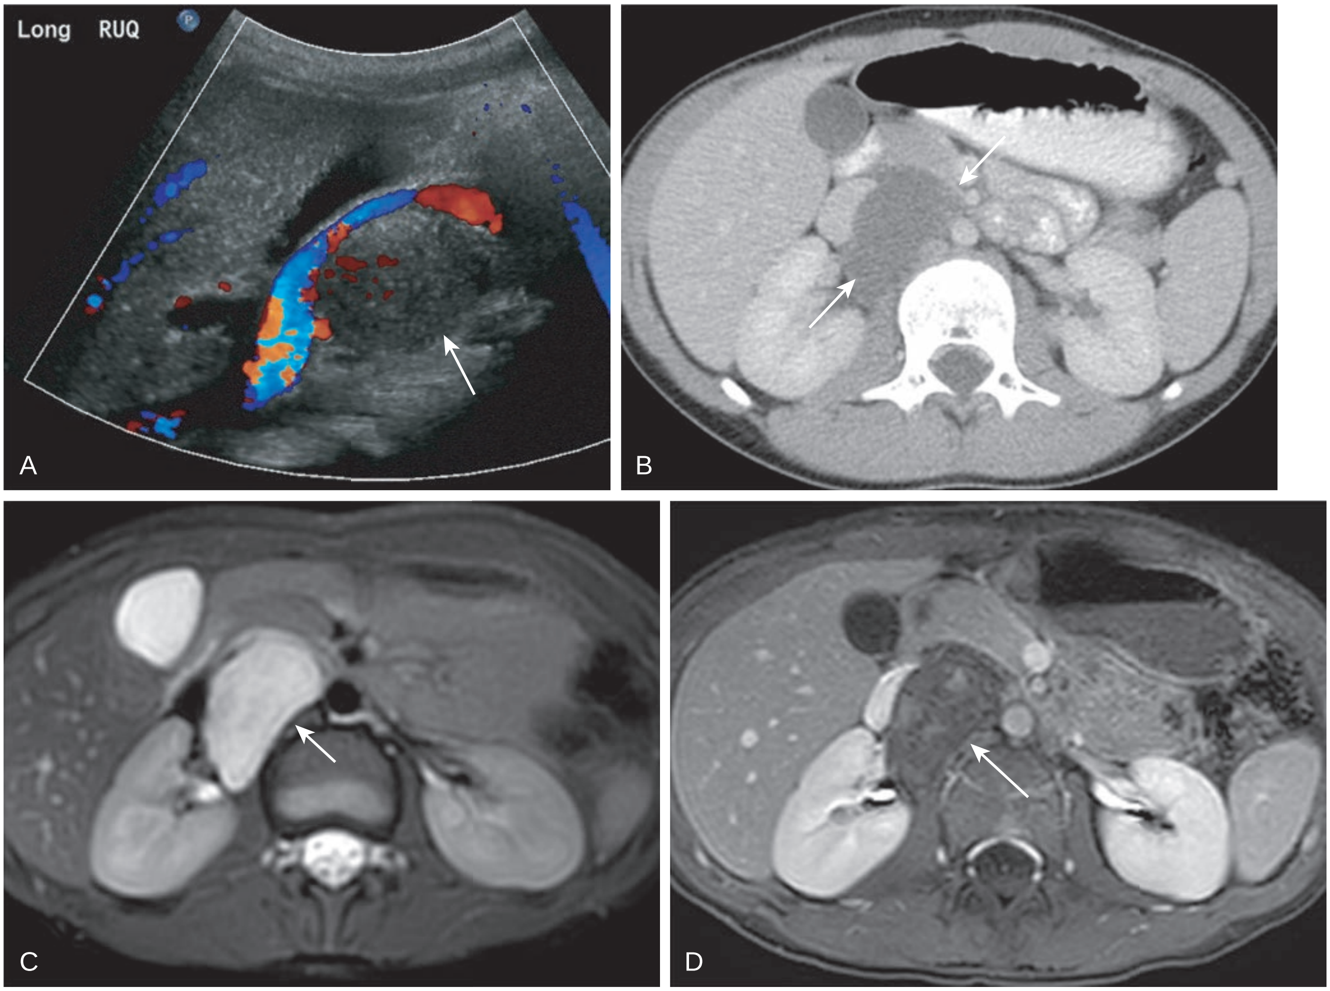
**e-Figure 122.5. Left adrenal neuroblastoma in a 7-year-old girl.** Transverse sonogram shows a round, solid mass (between cursors) posterior to the left lobe of the liver with multiple confluent hyperechoic foci.



**e-Figure 122.6. Left adrenal neuroblastoma in a 3-year-old girl.** (A) Oblique sonogram shows a cystic mass *(M)* anterior and medial to the spleen *(S)* with foci of mural calcification *(arrow)*. (B) Coronal contrast-enhanced computed tomography image shows the left upper quadrant cystic mass *(M)* with mural calcifications *(arrow)*, which on histology proved to be neuroblastoma.



**e-Figure 122.10. Incidentally-detected retroperitoneal ganglioneuroma in a 10-year-old boy.** (A) Longitudinal color Doppler image shows a round, solid retrocaval mass *(arrow)*. (B) Axial contrast-enhanced CT image shows a homogeneous, low attenuation mass *(arrows)* posterior to the inferior vena cava. (C) Axial T2-weighted fat-saturated MR image shows that the mass *(arrow)* is homogeneously hyperintense. (D) Postcontrast T1-weighted fat-suppressed MR image shows only minimal patchy enhancement within the mass *(arrow)*. Surgical pathology confirmed the diagnosis of retroperitoneal ganglioneuroma.

## PHEOCHROMOCYTOMA

***Overview.*** Pheochromocytoma is an uncommon neural crest tumor of the adrenal gland arising from chromaffin cells. If the tumor is extra-adrenal, it is known as a paraganglioma, with most common abdominal locations being in the vicinity of the renal vessels and at the organ of Zuckerkandl near the origin of the inferior mesenteric artery. In children, 70% of pheochromocytomas occur in the adrenal gland, and 19% to 38% have bilateral adrenal gland involvement.[10] Malignancy is present in 12% of lesions in children.[11] The diagnosis of malignancy is often made on the basis of metastases rather than histology.[11]

Pheochromocytoma usually presents in older children (mean age = 11 years). In approximately 40% of cases, it may be part of cancer predisposition syndromes, mainly von Hippel-Lindau disease, multiple endocrine neoplasias (MEN) 2A and 2B, and familial paraganglioma-pheochromocytoma syndromes.[10,11]

The clinical presentation is usually related to the secretion of catecholamines. Patients may present with hypertension, headache, tachycardia, diaphoresis, nervousness, and weight loss.[10]

***Imaging.*** CT and MRI are better imaging modalities than ultrasonography for accurate localization of these tumors. Functional imaging with MIBG is more specific and has been reported to be more sensitive in detecting multifocal disease.[10,11]

Pheochromocytoma may have a solid homogeneous or heterogeneous appearance on US (e-Fig. 122.13 and Fig. 122.14A). Heterogeneity is more commonly seen with larger lesions because of hemorrhage, necrosis, and, less commonly, calcification (see Fig. 122.14).[12] On CT, the lesions show avid enhancement except for areas of necrosis or hemorrhage.[1] The use of nonionic low-osmolar intravenous contrast material for CT is safe in patients with pheochromocytoma.[13] On MRI, pheochromocytoma is hypointense to isointense compared with the liver on T1-weighted images and hyperintense on T2-weighted images (see Figs. 122.14 and 122.15), with a pattern of intense enhancement after the

### BOX 122.1 International Neuroblastoma Risk Group Staging System

**Stage L1:** Localized tumor confined to one body compartment without involvement of vital structures (no image-defined risk factor [IDRF])

**Stage L2:** Locoregional tumor with at least one IDRF

**Stage M:** Distant metastasis (excluding stage MS)

**Stage MS:** Child <18 months of age with metastasis confined to skin, liver, and/or bone marrow

*Modified from Monclair T, Brodeur GM, Ambros PF, et al. The international neuroblastoma risk group (INRG) staging system: an INRG task force report.* J Clin Oncol. *2009;27:298–303.*

### BOX 122.2 Image-Defined Risk Factors in Neuroblastoma

- Ipsilateral tumor extension into another body compartment
  - Neck-chest, chest-abdomen, abdomen-pelvis
- Neck
  - Major artery or vein encasement
  - Skull base extension
  - Tracheal compression
- Thorax
  - Brachial plexus or major vessel encasement
  - Tracheal or principal bronchial compression
  - Costovertebral junction invasion between T9 and T12
- Abdomen and Pelvis
  - Porta hepatis or hepatodeuodenal ligament invasion
  - Superior mesenteric artery origin or proximal branch encasement
  - Aorta, inferior vena cava, celiac axis, or iliac vessel encasement
  - Pelvic tumor crossing sciatic notch
- Intraspinal extension with >⅓ of spinal canal invaded, or perimedullary leptomeningeal spaces effaced, or abnormal spinal cord signal
- Adjacent organ infiltration
  - Including liver, kidney, pancreas, duodenum, diaphragm, mesentery, pericardium

Note: vessel encasement is defined as ≥50% circumference contact or complete compression of venous lumen.

*Modified from Dumba M et al. Neuroblastoma and nephroblastoma: a radiological review.* Cancer Imaging. *2015;15:5.*

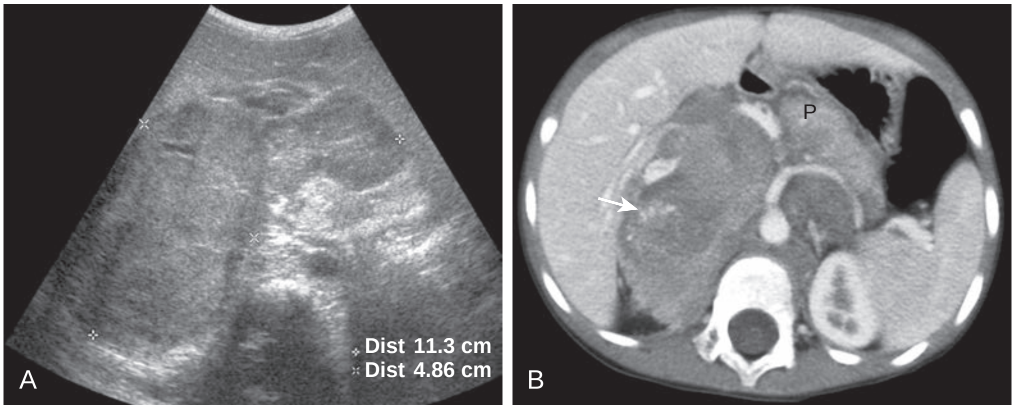


**Figure 122.1. Retroperitoneal neuroblastoma in a 4-year-old boy.** (A) Transverse sonogram and (B) axial contrast-enhanced CT image of the abdomen show a large lobulated, solid mass centered in the right upper quadrant but with a significant component crossing the midline and extending into the left hemiabdomen. At CT, the mass is heterogeneous with hypodense and hyperdense areas as well as foci of calcification *(arrow)*. Note the characteristic encasement of the major vessels by the mass, in this case the aorta, the celiac axis, and its major branches, which are image-defined risk factors. The pancreas *(P)* is displaced anteriorly and to the left by the mass.

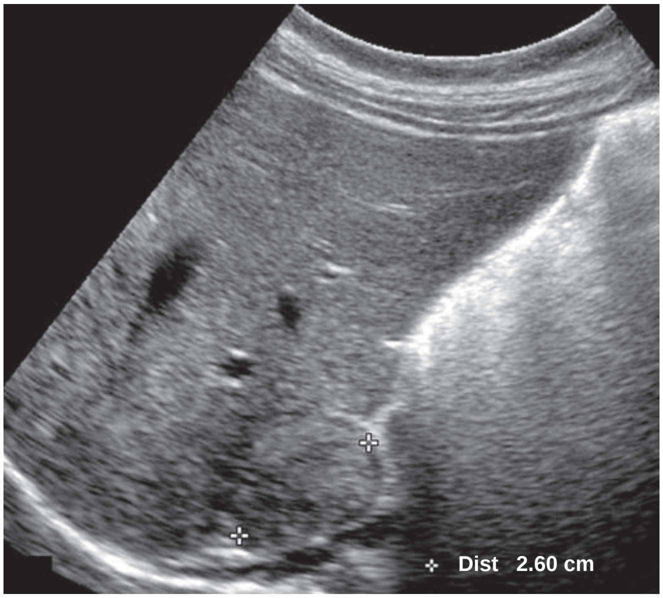

**e-Figure 122.13. Bilateral pheochromocytomas in an 11-year-old boy with von Hippel-Lindau disease and systemic arterial hypertension (same patient as shown in Fig. 122.15).** Longitudinal sonogram of the right upper quadrant shows a well-defined round, solid mass (between cursors) of slightly heterogeneous echogenicity.

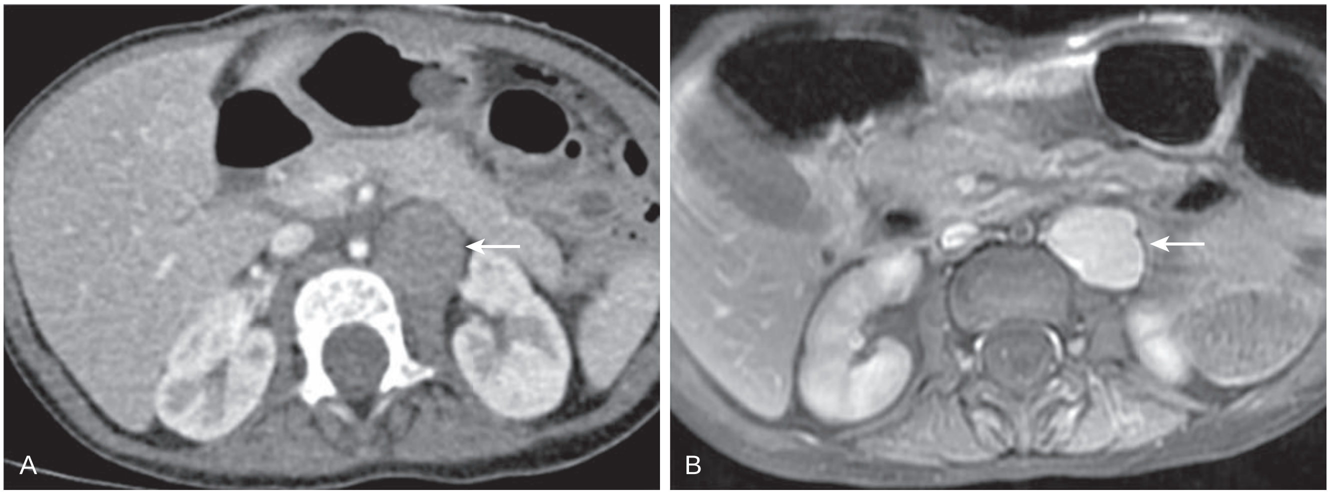

**Figure 122.2. Incidentally detected small neuroblastoma in a 2-year-old boy.** (A) Axial contrast-enhanced CT image shows a small round, enhancing retroperitoneal mass *(arrow)* located between the abdominal aorta and left kidney. (B) Axial postcontrast T1-weighted fat-suppressed MR image confirms the presence of a solid enhancing retroperitoneal mass, proven to be neuroblastoma.

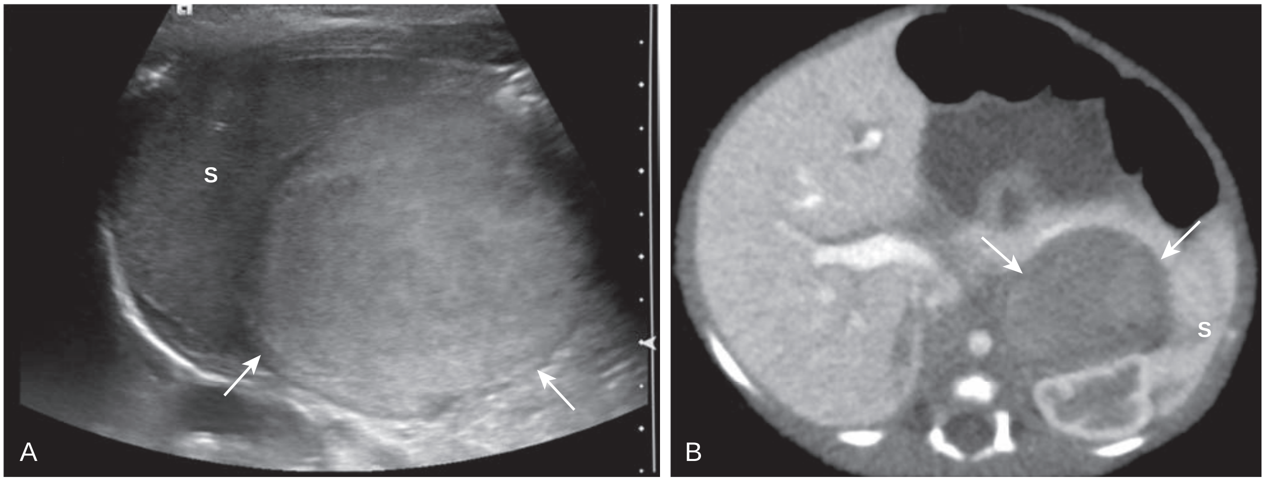

**Figure 122.4. Congenital neuroblastoma in an 8-day-old boy.** (A) Longitudinal sonogram shows a large round, circumscribed, echogenic left upper quadrant solid mass *(arrows)*, with mass-effect upon the spleen *(S)*. (B) Axial contrast-enhanced CT image confirms a mildly heterogenous, enhancing left upper quadrant mass, proven to be a congenital neuroblastoma arising from the left adrenal gland. The mass exerts mass-effect upon the spleen *(S)*, pancreas, and left kidney. Abnormal soft tissue also surrounds the abdominal aorta.

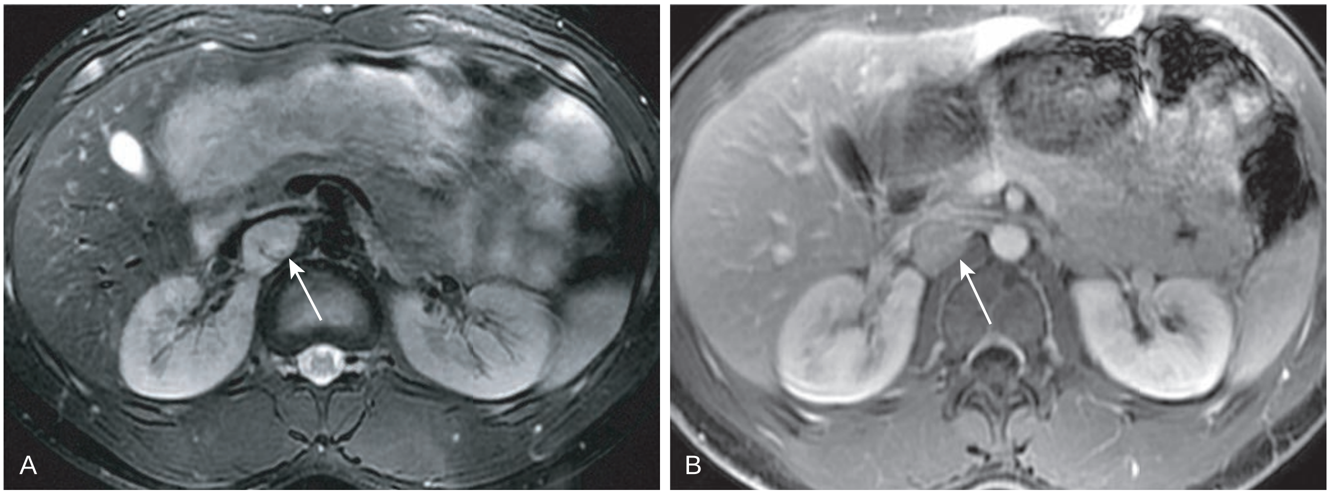
administration of gadolinium chelate.[1] Paragangliomas generally have a similar MRI appearance to adrenal pheochromocytomas (e-Fig. 122.16). Whole body MRI screening has also been shown effective for detecting pheochromocytomas and paragangliomas in patients with syndromes.[14]

***Treatment.*** Surgical removal of all known lesions is usually curative. However, clinical follow-up is essential, along with urinary catecholamine measurement to detect recurrence or the development of new lesions.

## ADRENOCORTICAL NEOPLASMS

***Overview.*** Adrenocortical neoplasms primarily comprise two types of tumor: adenomas and carcinomas. Both are uncommon in children. A higher incidence is seen in children under the age of 4 years.[15] Girls are affected more commonly compared with boys, and carcinomas are more common than adenomas.[16] The majority of these tumors are hormonally functioning, and the most common endocrine abnormality is overproduction of androgens. Girls present with virilization, and boys present with pseudoprecocious puberty. Often, mixed endocrine dysfunction is caused by the overproduction of both glucocorticoids and mineralocorticoids. Two cancer predisposition syndromes, Li-Fraumeni syndrome and Beckwith-Wiedemann syndrome, are associated with adrenocortical neoplasms.[16]

***Imaging.*** At presentation, adrenocortical neoplasms in children are usually larger than 5 cm.[12] Most lesions can be documented with US, but CT and MRI are particularly important for assessing large lesions, and local invasion and spread. On all three modalities, smaller lesions tend to have a fairly homogeneous appearance and may be either an adenoma or carcinoma (Fig. 122.17). Areas of heterogeneity reflecting hemorrhage, necrosis, and calcification are seen more commonly in larger lesions, usually carcinomas (Fig. 122.18).[12] In larger lesions, the characteristic appearance of



**e-Figure 122.16. Retroperitoneal paraganglioma in a 15-year-old boy with a family history of hereditary paraganglioma-pheochromocytoma syndrome.** (A) Axial T2-weighted fat-suppressed MR image shows a predominantly hyperintense, mildly heterogeneous retrocaval mass *(arrow)*. (B) Axial postcontrast, T1-weighted, fat-suppressed MR image shows that the mass mildly homogeneously enhances. Surgical pathology confirmed the diagnosis of paraganglioma.

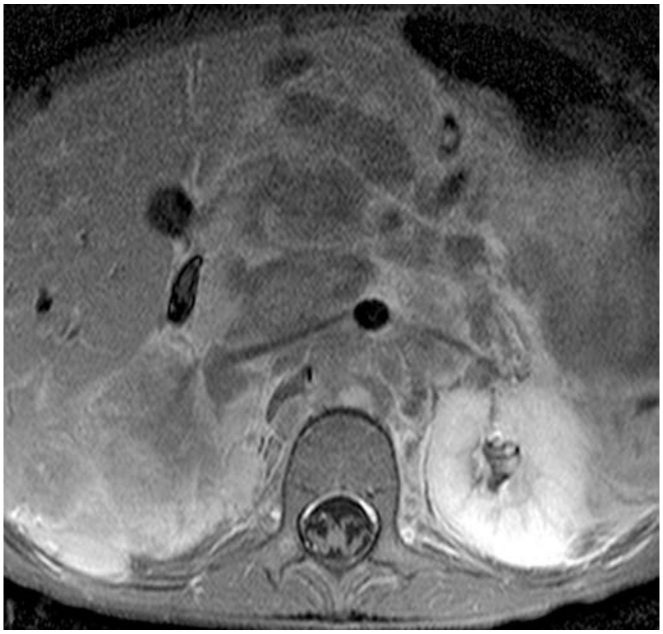


**Figure 122.7. Retroperitoneal neuroblastoma in a 4-year-old girl.** Axial postcontrast, T1-weighted, fat-suppressed MR image shows a large retroperitoneal mass encasing the aorta and renal arteries and displacing the inferior vena cava to the right. The mass shows heterogeneous enhancement.

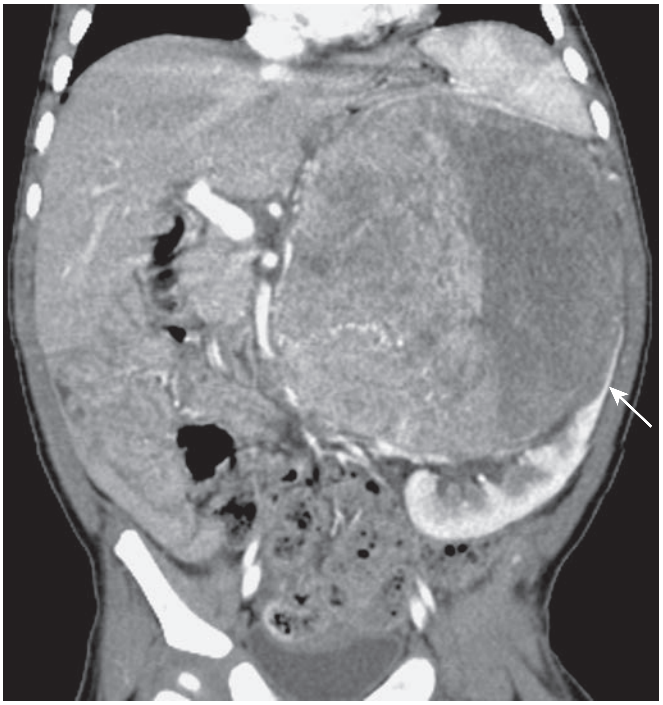

**Figure 122.8. Left adrenal neuroblastoma in a 9-month-old girl.** Coronal contrast-enhanced CT image shows a large heterogeneous retroperitoneal mass invading the left kidney. The left kidney is displaced caudally and laterally with suggestion of a partial “claw sign” *(arrow)*, which may lead to the erroneous interpretation that the mass is arising from the left kidney.

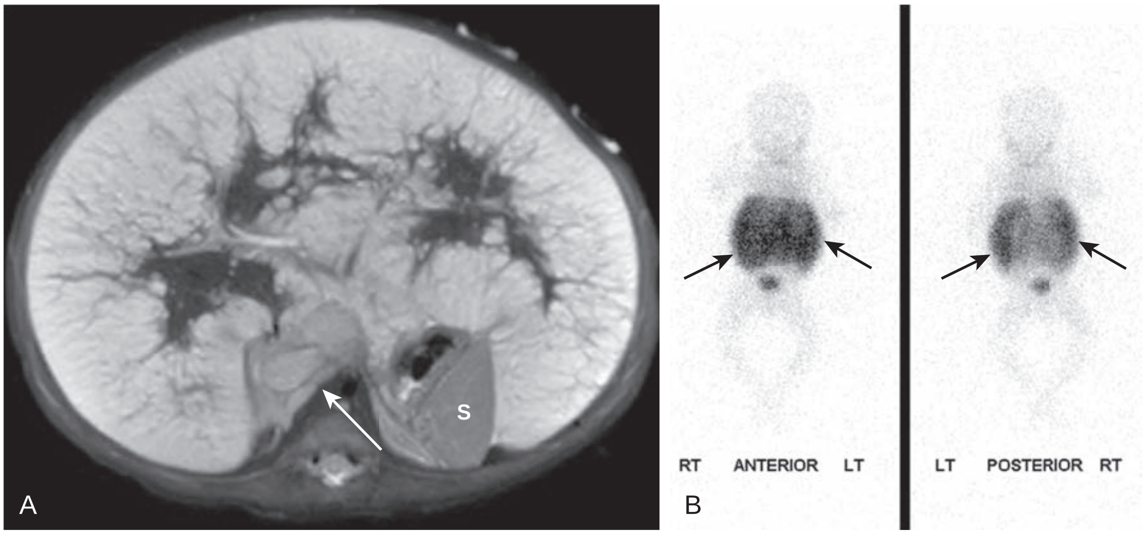

**Figure 122.9. Metastatic liver disease in neuroblastoma in an 8-day-old girl (stage MS [formerly 4S]).** (A) Axial T2-weighted fat-suppressed MR image shows extensive abnormal signal hyperintensity involving the periphery of the liver, proven by biopsy to be infiltrative metastatic neuroblastoma. The primary tumor is partially seen in the right suprarenal fossa *(arrow)*. *S*, Spleen. (B) Anterior and posterior planar MIBG scan images show marked hepatic radiotracer uptake *(arrows)*, indicating metastatic disease.

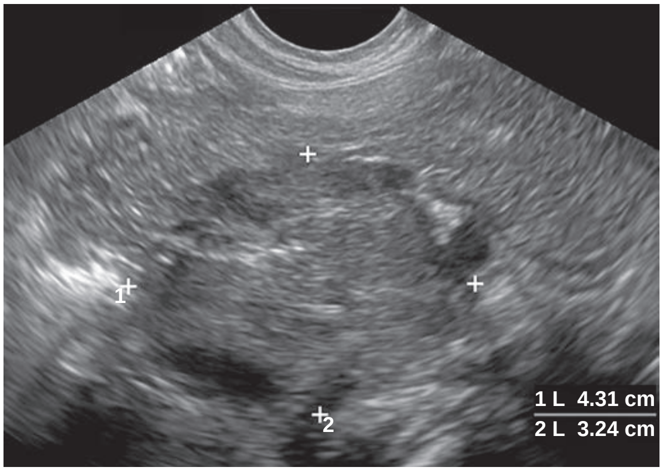

**Figure 122.11. Retroperitoneal ganglioneuroma in a 7-year-old girl.** Transverse sonogram shows a large round, solid mass (between cursors) of intermediate echogenicity with scattered punctate calcifications in the midline retroperitoneum. The sonographic appearance of ganglioneuroma is indistinguishable from neuroblastoma.

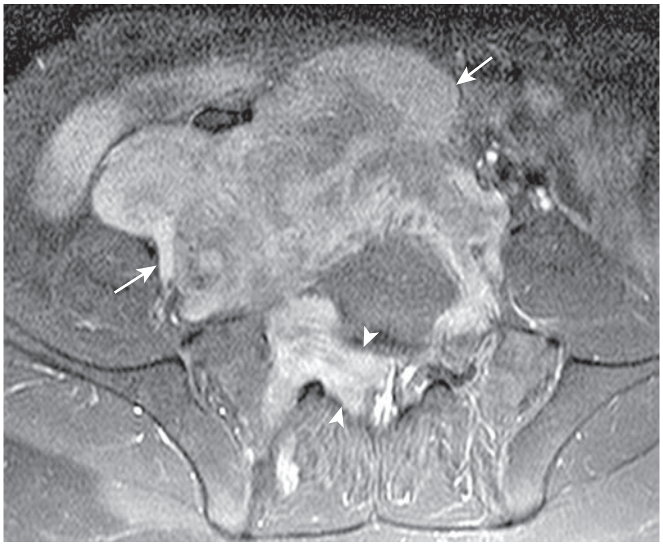

**Figure 122.12. Retroperitoneal ganglioneuroma in a 10-year-old girl.** Axial fat-suppressed, postcontrast, T1-weighted MR image shows a large, heterogeneous, retroperitoneal mass *(arrows)*, which extends into sacral foramina and into the distal spinal canal *(arrowheads)*. The imaging features are similar to those seen in neuroblastoma.

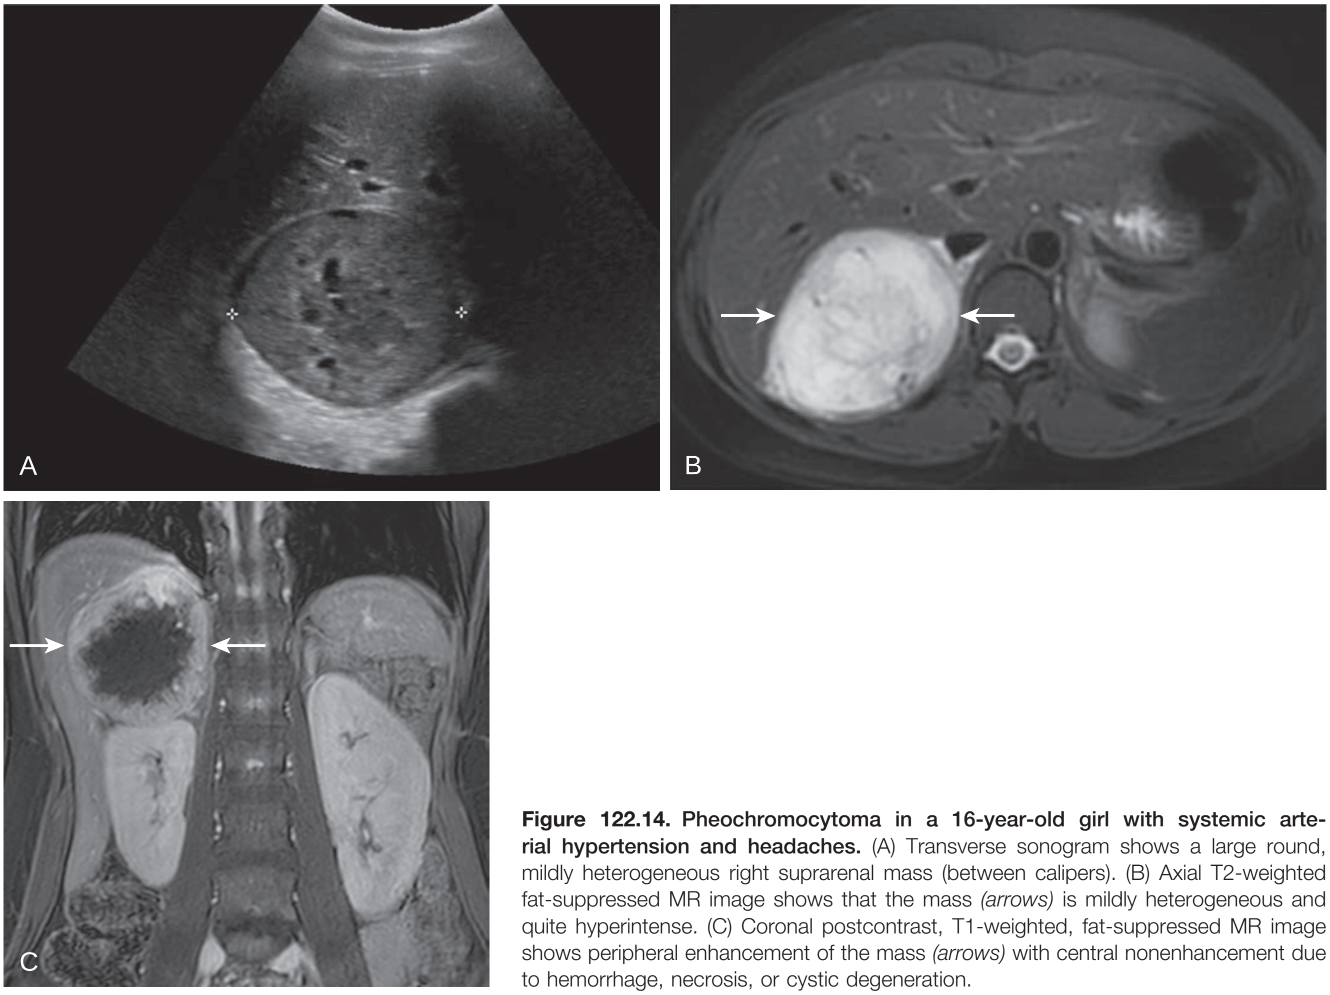

**Figure 122.14. Pheochromocytoma in a 16-year-old girl with systemic arterial hypertension and headaches.** (A) Transverse sonogram shows a large round, mildly heterogeneous right suprarenal mass (between calipers). (B) Axial T2-weighted fat-suppressed MR image shows that the mass *(arrows)* is mildly heterogeneous and quite hyperintense. (C) Coronal postcontrast, T1-weighted, fat-suppressed MR image shows peripheral enhancement of the mass *(arrows)* with central nonenhancement due to hemorrhage, necrosis, or cystic degeneration.

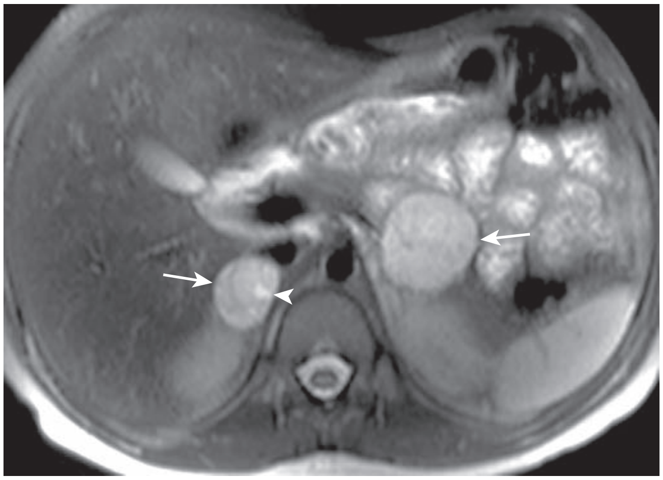

**Figure 122.15. Bilateral pheochromocytomas in an 11-year-old boy with von Hippel-Lindau disease and systemic arterial hypertension.** Axial fat-suppressed T2-weighted magnetic resonance image shows bilateral adrenal masses *(arrows)*, larger on the left. The masses are hyperintense with small cystic change on the right medially *(arrowhead)*. (See e-Fig. 122.13 for US of same patient.)

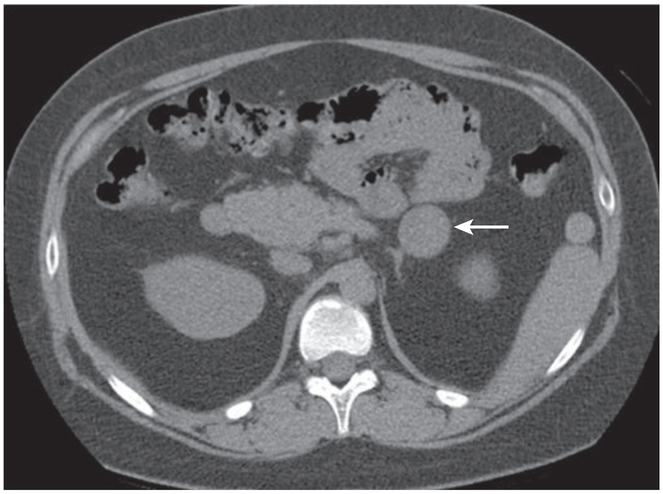

**Figure 122.17. Adrenocortical adenoma in a 2-year-old girl with Cushingoid features.** Axial noncontrast CT image shows a round mass *(arrow)* arising from the left adrenal gland, proven to be a functioning adrenocortical adenoma. There is a large amount of intraabdominal fat for the child's age.

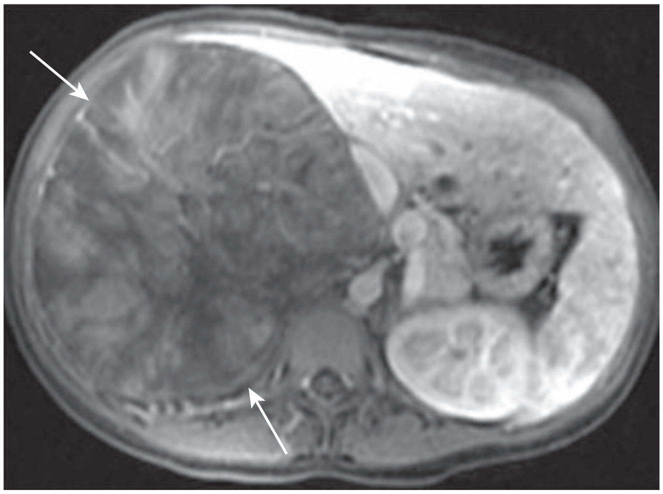

**Figure 122.18. Adrenocortical carcinoma in a 16-year-old girl with abdominal pain and weight loss.** Axial postcontrast, T1-weighted, fat-suppressed MR image shows a very large right suprarenal mass that exerts considerable mass-effect. The mass heterogeneously enhances with areas of alternating relatively increased and decreased signal intensity.

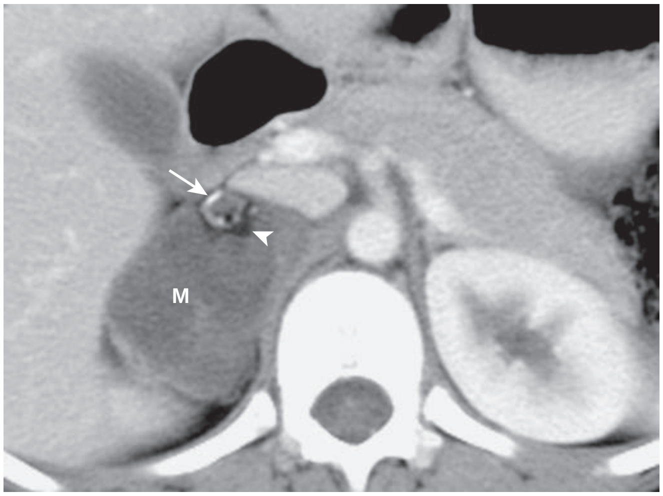

**Figure 122.19. Retroperitoneal teratoma in an 11-year-old girl.** Contrast-enhanced axial CT image shows a well-defined right suprarenal mass *(M)*, with mainly fluid attenuation and some soft tissue septa. Calcification *(arrow)* and fat attenuation *(arrowhead)* are seen anteriorly within the mass.

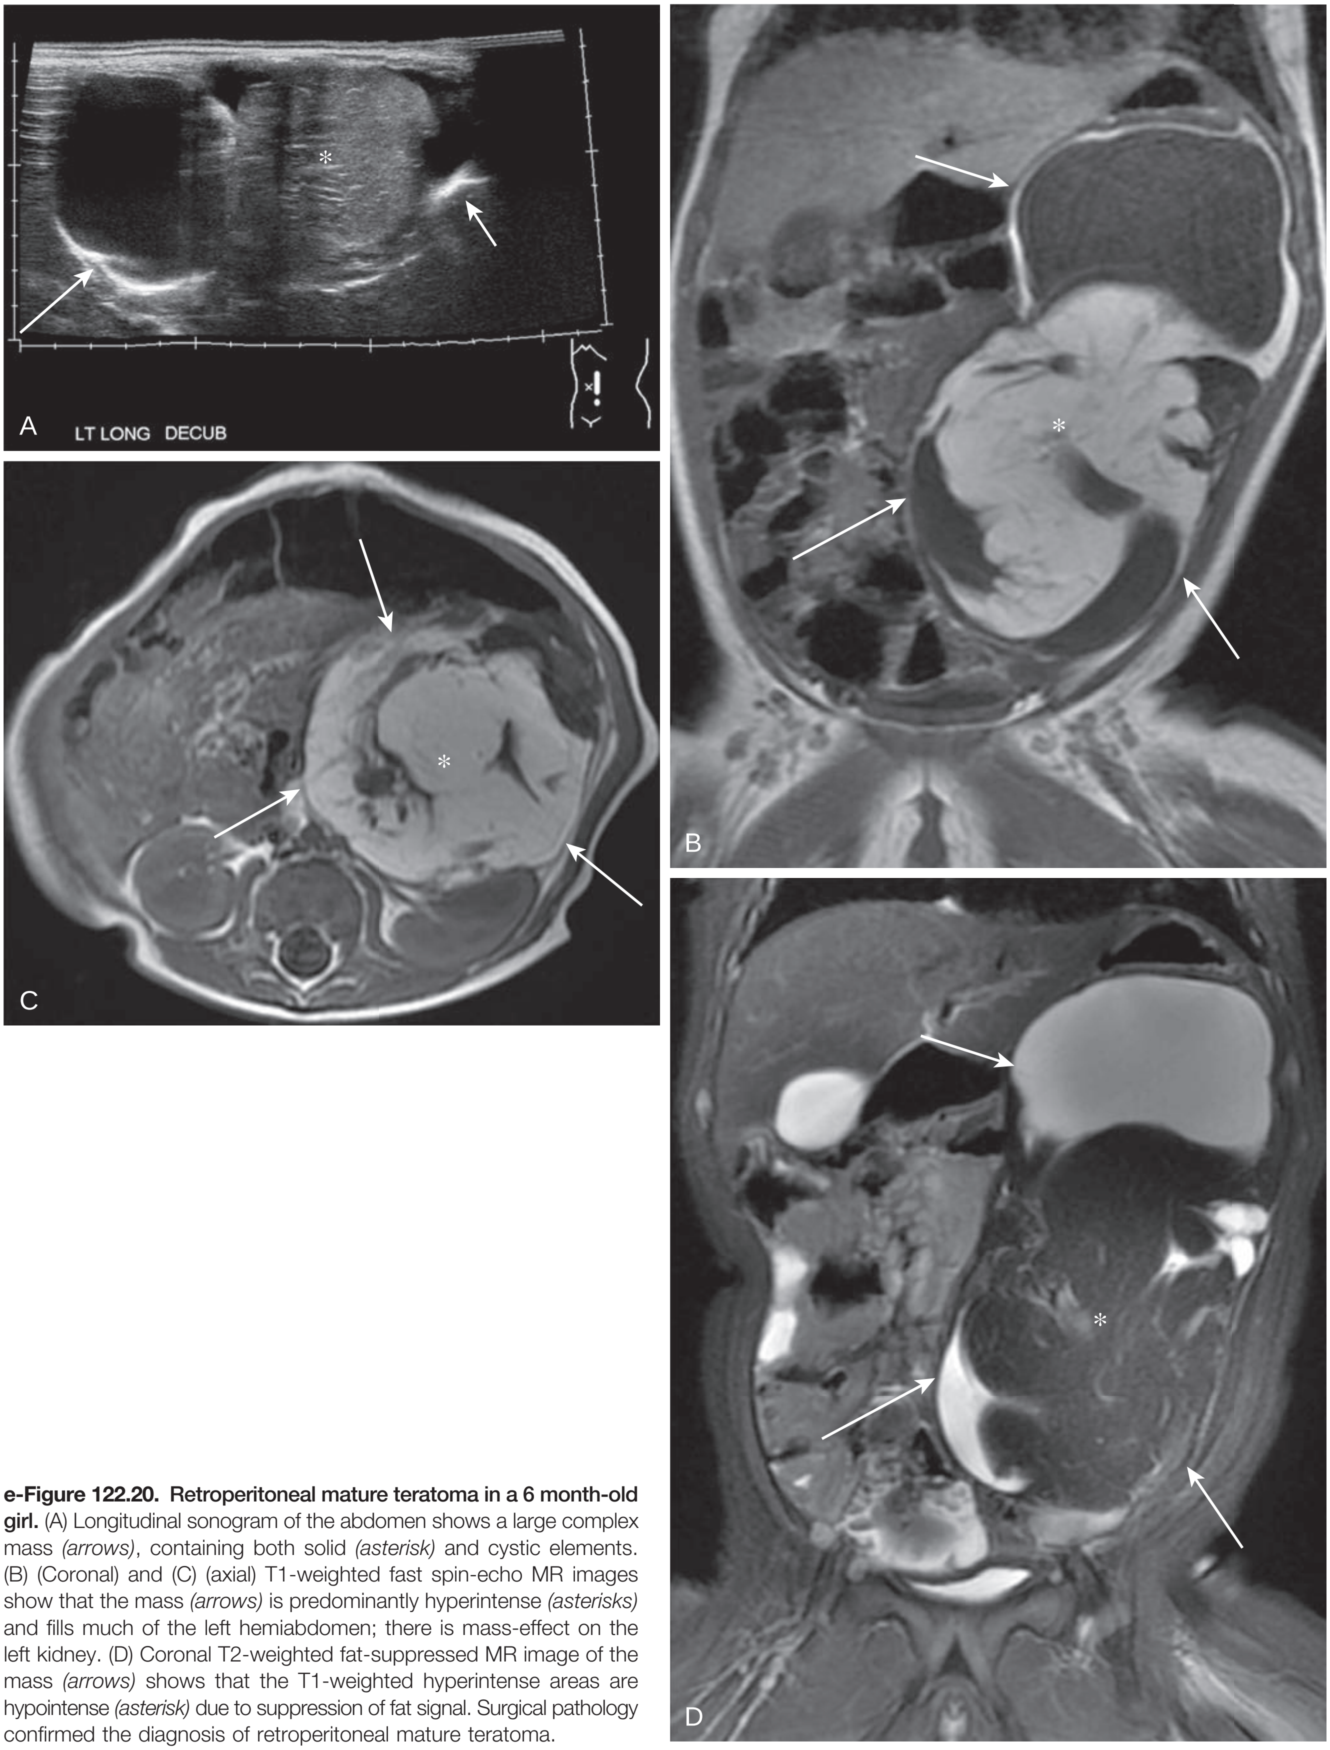
a central scar, with radiating linear bands that represent areas of necrosis and calcification, may be seen.[1] It is not always possible to predict accurately which adrenocortical lesions are malignant by imaging, unless local spread and invasion have occurred or metastatic disease is present. Metastatic disease most commonly occurs to the lungs, liver, and bone.[16]

***Treatment.*** Complete resection of the primary tumor is essential for survival in the setting of malignancy.[16] Adenomas clearly have a good prognosis, but clinical and imaging follow-up are essential because the histologic distinction between adenoma and carcinoma is not possible in all cases.

## OTHER RETROPERITONEAL CONDITIONS

***Overview.*** Apart from pathology arising from the urinary tract and adrenal gland and sympathetic chains, other less common retroperitoneal conditions include lymphadenopathy (mainly lymphoma or metastatic lymphadenopathy), vascular malformations, Kaposiform hemangioendotheliomas, other neurogenic tumors (schwannoma, neurofibroma, malignant peripheral nerve sheath tumor), adipocytic tumors, germ cell neoplasms (including teratomas) (Fig. 122.19 and e-Fig. 122.20), rhabdomyosarcoma, fibromatosis, idiopathic fibrosis, hematoma, and abscess.



**e-Figure 122.20. Retroperitoneal mature teratoma in a 6 month-old girl.** (A) Longitudinal sonogram of the abdomen shows a large complex mass *(arrows)*, containing both solid *(asterisk)* and cystic elements. (B) (Coronal) and (C) (axial) T1-weighted fast spin-echo MR images show that the mass *(arrows)* is predominantly hyperintense *(asterisks)* and fills much of the left hemiabdomen; there is mass-effect on the left kidney. (D) Coronal T2-weighted fat-suppressed MR image of the mass *(arrows)* shows that the T1-weighted hyperintense areas are hypointense *(asterisk)* due to suppression of fat signal. Surgical pathology confirmed the diagnosis of retroperitoneal mature teratoma.

## KEY POINTS

- Neuroblastoma is the most common extracranial solid neoplasm in children and accounts for almost 10% of all childhood neoplasms.
- Metastatic disease in neuroblastoma is present in up to 70% of patients at presentation.
- A characteristic imaging feature of neuroblastoma is the displacement of adjacent organs and the displacement or encasement of adjacent major vessels.
- Ganglioneuroma may be unable to be differentiated from neuroblastoma/ganglioneuroblastoma solely on the basis of conventional imaging appearances.
- Li-Fraumeni and Beckwith-Wiedemann syndromes are associated with adrenocortical neoplasms.
- Adrenocortical tumors most often present with evidence of hormonal overproduction (e.g., precocious puberty, virilization, Cushing syndrome).

# 123 Genitourinary Trauma

George A. Taylor

## RENAL INJURY

***Overview.*** The kidney is the third most frequently injured abdominal viscus in children and accounts for 1.3% to 15% of injuries in children who suffer blunt abdominal trauma. Children are more susceptible to renal injury during blunt trauma compared with adults because of the relatively increased mobility of the pediatric kidney, less perinephric fat, and reduced protection by a more compliant chest wall. Preexisting renal abnormalities such as a horseshoe kidney (Fig. 123.1 and e-Fig. 123.2) or pelvic kidney, hydronephrosis, cystic renal disease, and tumors may increase the size or alter the location of the kidney leading to an increased susceptibility to injury.[1]

Most children with clinically significant renal injury present with hematuria; the risk of underlying renal injury is markedly higher in patients with gross hematuria (22%) compared with those with lesser amounts of urinary blood (8%). However, the presence of asymptomatic microscopic hematuria is a low-yield sign for the presence of underlying renal injury, and the absence of hematuria correlates with a low risk for urinary injury (0.2%).[2,3] Isolated renal injury in children is relatively uncommon, with associated injuries typically present in the lungs (45%), spleen (33%), and liver (29%).

***Imaging.*** Computed tomography (CT) is the preferred modality for initial assessment of hemodynamically stable children with suspected renal injury because of its wide availability, rapid image acquisition, and accuracy. The use of intravenous contrast material is essential for the evaluation of the kidney, and scanning during the portal venous phase of opacification is recommended. A delayed scan may be helpful for the detection of urinary extravasation. Noncontrast scans are not generally helpful, and they unnecessarily increase radiation dose to the patient. Unstable patients who require immediate evaluation may be examined with ultrasonography at the bedside before complete resuscitation or surgery. Routine follow-up imaging can be performed with gray-scale and color Doppler ultrasonography in most patients, and CT can be reserved for selected patients with other associated injury or ambiguous findings on serial ultrasonography.[4]

The most common type of renal injury is parenchymal contusion, which manifests on CT as a focal or diffuse region of absent or delayed contrast enhancement (Fig. 123.3). The contusion is characterized by microscopic areas of hemorrhage and surrounding edema. The involved kidney may also appear larger on CT as a result of the associated edema.

Renal injury may be complicated by perirenal hematoma, which may be subcapsular or perinephric. These two types of hematoma can be differentiated on the basis of CT features. A subcapsular hematoma is limited in its extension by the renal capsule and therefore exerts greater mass effect on the renal parenchyma, whereas a perinephric hematoma is distributed throughout the perirenal space and typically exhibits less mass effect on the renal parenchyma.

Renal collecting system injury results in urinary extravasation of intravenous contrast material (see e-Fig. 123.2, Fig. 123.4, and e-Fig. 123.5). Urine leakage that remains encapsulated in the perirenal space is termed a urinoma. Occasionally, hemorrhage or urinary extravasation may extend into the pelvis owing to direct communication between the perirenal space in the abdomen and the prevesical extraperitoneal space in the pelvis.[1] Grade IV renal injuries with medial contrast material extravasation from the collecting system on CT have been shown to be a high-risk sign for surgical intervention.[3]

The American Association for the Surgery of Trauma has developed an injury scale to categorize the increasing severity of renal injury (Table 123.1). Grade I to grade III injuries are considered low-grade, and account for between 69% to 99% of all renal injuries. Grade IV and V injuries are less common and include the shattered kidney, ureteropelvic junction avulsion, and renal artery transection or thrombosis (Fig. 123.6).

***Treatment.*** The great majority of renal injuries (69%–99%) are treated nonsurgically with great success. Even in high-grade injuries, no surgical intervention is necessary in 60% to 70%. Early ureteral stent placement may be considered in patients with high-grade injuries who do not demonstrate contrast material in the ipsilateral ureter.[5]

## BLADDER INJURY

***Overview.*** Blunt injuries to the bladder typically result from a blow to the lower abdomen when the bladder is distended or when the pelvis is fractured. Fortunately, the incidence of lower urinary tract injury in children is quite low, estimated at 0.2% of pediatric trauma admissions. Although approximately 50% of children with bladder tears have a pelvic fracture, only 0.5% to 3.7% of children with pelvic fractures have associated bladder injuries.[6] High-yield indications for CT cystography include gross hematuria, pelvic fracture, and high-risk mechanisms of injury such as motor vehicle crashes and the presence of a seatbelt ecchymosis. Bladder injuries may be classified as intraperitoneal rupture, extraperitoneal rupture, and combined lesions.

***Imaging.*** Standard abdominal trauma CT scanning protocols may miss important bladder injuries because of incomplete bladder distension. CT cystography is the preferred technique for the detection of bladder tears with a reported sensitivity and specificity of 95% and 100% respectively.[7] The bladder is filled by gravity drip infusion of dilute water-soluble iodinated contrast material using age-based estimates of bladder capacity (e.g., 4.5 × age [0.40] = capacity in ounces).[8]

Extraperitoneal rupture accounts for approximately 83% of all bladder perforations in pediatric patients. They are often associated with pelvic fractures that distort and shear the bladder at its attachments near the trigone, below the peritoneal reflection. On CT cystography, extravasation is usually confined to the perivesical soft tissues (Fig. 123.7, and e-Figs. 123.8 and 123.9) but may extend into the scrotum, superiorly along the anterior abdominal wall, or up through retroperitoneal spaces to the level of the kidney.[1,9]

Intraperitoneal rupture occurs when the bladder is acutely compressed resulting in a sudden increase in pressure and a tear of the dome of the bladder. This results in extravasation of contrast-containing urine into the peritoneal cavity where it fills the cul-de-sac, surrounds the bowel, often extending into the paracolic

## Abstract:

The kidney is the third most frequently injured abdominal viscus in children who suffer blunt abdominal trauma. Children are more susceptible to renal injury during blunt trauma compared with adults because of the relatively increased mobility of the pediatric kidney, less perinephric fat, and reduced protection by a more compliant chest wall. Preexisting renal abnormalities such as a horseshoe kidney or pelvic kidney, hydronephrosis, cystic renal disease, and tumors may increase the size or alter the location of the kidney leading to an increased susceptibility to injury. Most children with clinically significant renal injury present with hematuria. Injuries to the bladder typically result from a blow to the lower abdomen when the bladder is distended or when the pelvis is fractured. Although approximately 50% of children with bladder tears have a pelvic fracture, only 0.5% to 3.7% of children with pelvic fractures have associated bladder injuries. Bladder injuries may be classified as intraperitoneal rupture, extraperitoneal rupture, and combined lesions. The majority of injuries to the scrotum occur in older boys and are the result of a direct blow to the groin during sport activities (50%), motor vehicle crashes (9%–17%), falls, or straddle injuries. Typical indications for imaging include an acute, painful, or ecchymotic scrotum, and a nonpalpable testis. Although common, scrotal injuries rarely need surgical intervention. In this chapter, we will review the various forms of genitourinary tract injury that occur in children as well as discuss strategies for imaging these injuries.

## Keywords:

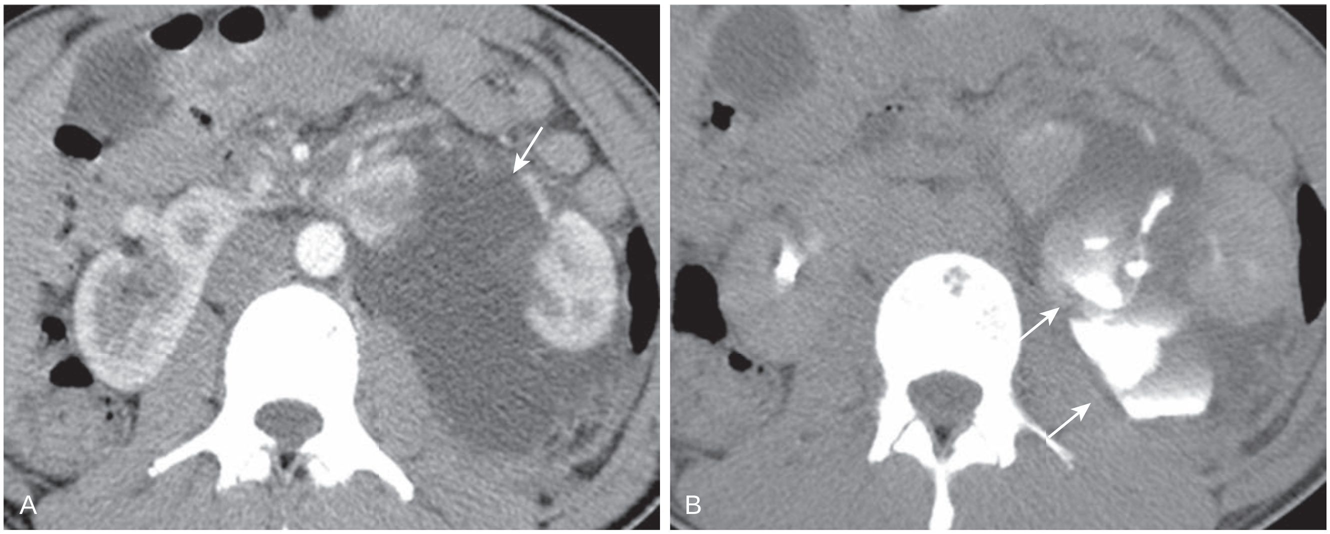
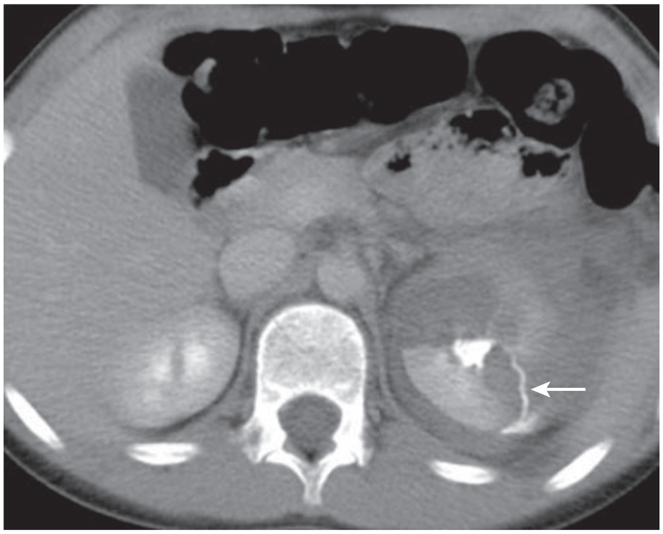
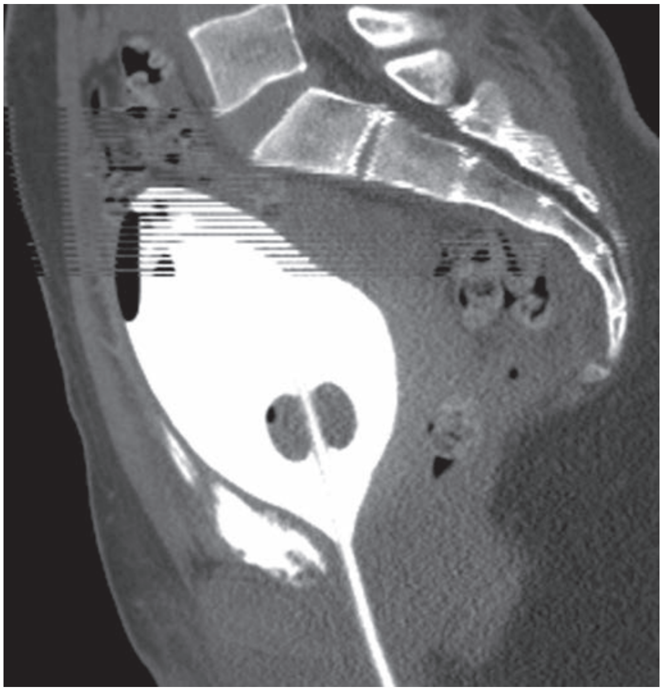
Bladder
Testis



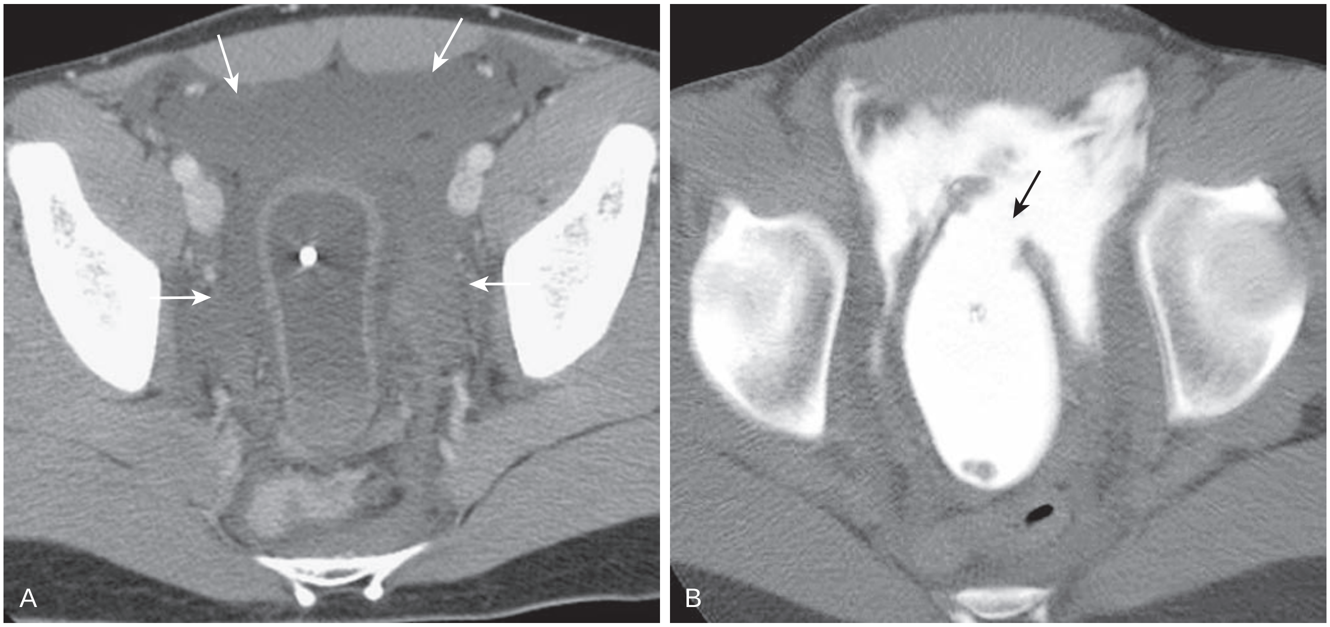
**e-Figure 123.2. Laceration in horseshoe kidney.** (A) Axial contrast-enhanced CT image from an 8-year-old in a motor vehicle accident shows a large laceration involving the left moiety of a horseshoe kidney. (B) Delayed excretory phase image shows urine mixed with contrast material outside of the renal collecting system *(arrows)*, consistent with grade IV injury.



**e-Figure 123.5. Grade IV renal injury.** Axial excretory phase contrast-enhanced CT image from a 10-year-old boy that slipped on a pool deck shows multiple areas of posttraumatic left kidney parenchymal low attenuation. There is contrast material spilling from the left renal collecting system into the left perinephric space *(arrow)*.



**e-Figure 123.8. Extraperitoneal bladder rupture.** A sagittal CT cystogram image shows contained extravasation of contrast-containing urine into the perivesical spaces.



**e-Figure 123.9. Extraperitoneal bladder rupture.** (A) Axial contrast-enhanced CT image from a teenage boy in a motor vehicle accident shows a large amount of extraperitoneal fluid *(arrows)* demonstrating mass-effect upon the urinary bladder. (B) CT cystogram image shows a large defect *(arrow)* involving the anterior inferior wall of the bladder with leakage of contrast material into the prevesical space. Dependent filling defect in the bladder is likely a blood clot.

gutters and subhepatic space (Fig. 123.10 and e-Fig. 123.11). In children, intraperitoneal rupture accounts for up to 17% of all bladder tears.

***Treatment.*** Intraperitoneal ruptures require immediate surgical repair, whereas extraperitoneal ruptures are usually treated by catheter drainage alone. Combined intraperitoneal and extraperitoneal injuries are uncommon in children and are often identified during surgical exploration (Fig. 123.12). Bladder tears generally have a highly favorable outcome, unless the injury extends longitudinally through the bladder base into the proximal urethra. These injuries frequently lead to incontinence and the need for multiple additional surgeries (Fig. 123.13 and e-Fig. 123.14).[10,11]

## URETHRAL INJURY

***Overview.*** Urethral injuries can be divided into posterior and anterior urethral injuries. Most posterior urethral injuries are caused by direct blows to the perineum, falls, or motor vehicle accidents, and occur frequently in the setting of pelvic fractures. These injuries usually involve the membranous urethra and are caused by shearing and rupture of the puboprostatic ligaments. Anterior urethral injuries are usually straddle-type injuries that are rarely associated with pelvic fractures. Although any grade of hematuria may be associated with urethral injury, the strongest clinical sign is the presence of blood at the meatus. No urethral

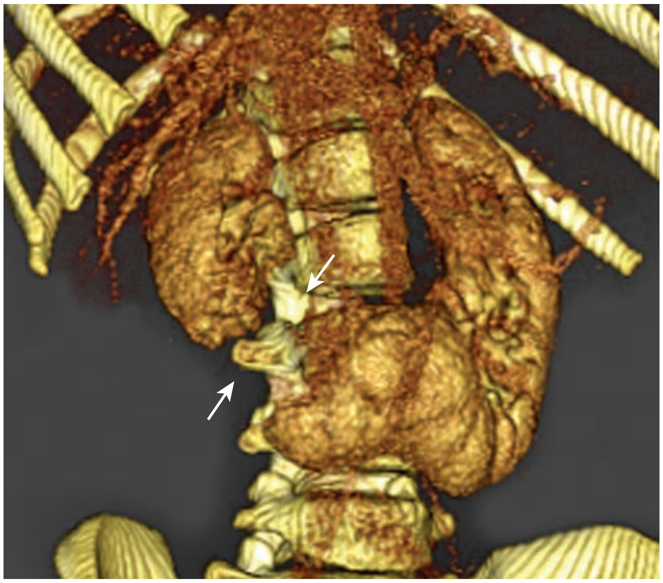


**Figure 123.1. Laceration in horseshoe kidney.** Oblique three-dimensional volume-rendered image from contrast-enhanced CT shows complete transection *(arrows)* of a horseshoe kidney.

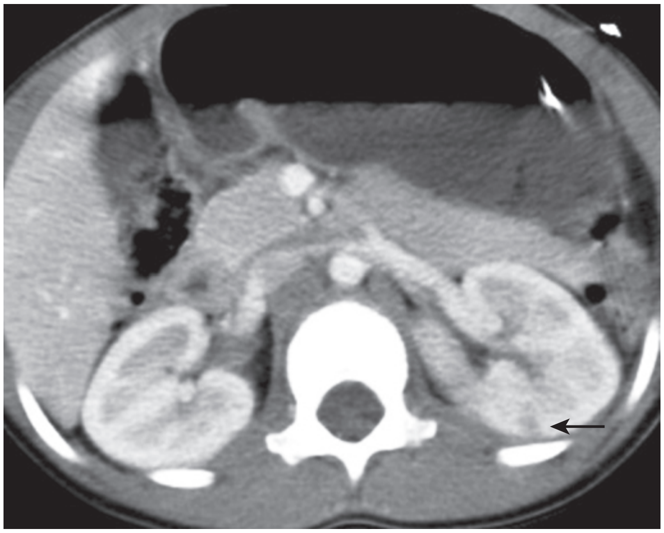

**Figure 123.3. Renal contusion.** A 6-year-old pedestrian hit by a car with multiple liver and splenic lacerations. Axial contrast-enhanced CT image shows a focal area of low attenuation in the left kidney posteriorly *(arrow)*, consistent with contusion (grade 1 injury).

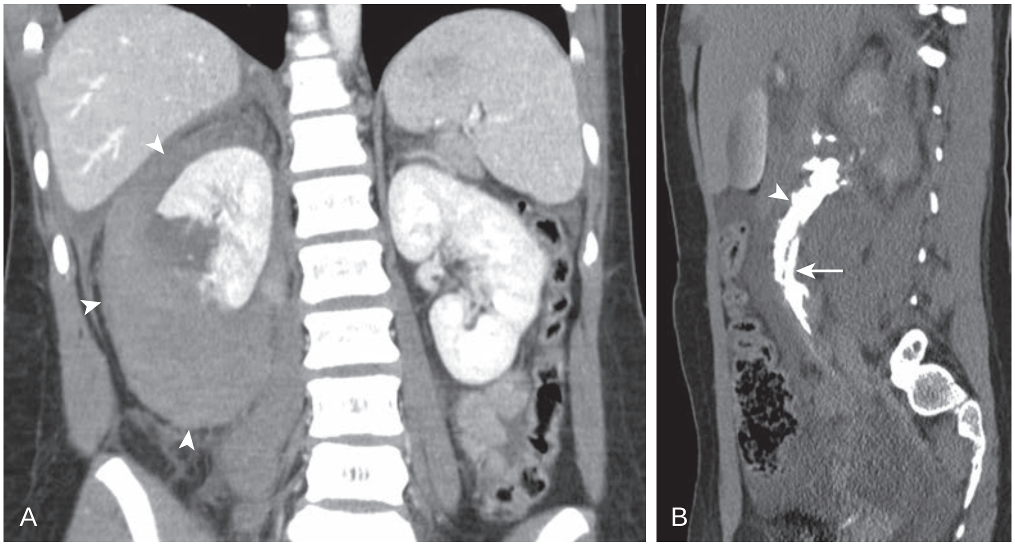

**Figure 123.4. Grade IV renal injury.** (A) Coronal contrast-enhanced CT image shows complete transection of right kidney and large perinephric hematoma *(arrowheads)*. (B) A delayed excretory phase CT image shows extravasation of contrast-containing urine *(arrowhead)* along the right ureter *(arrow)*.

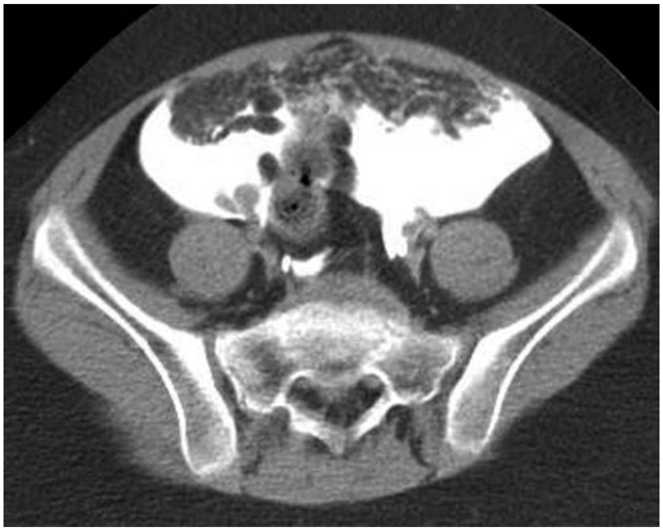
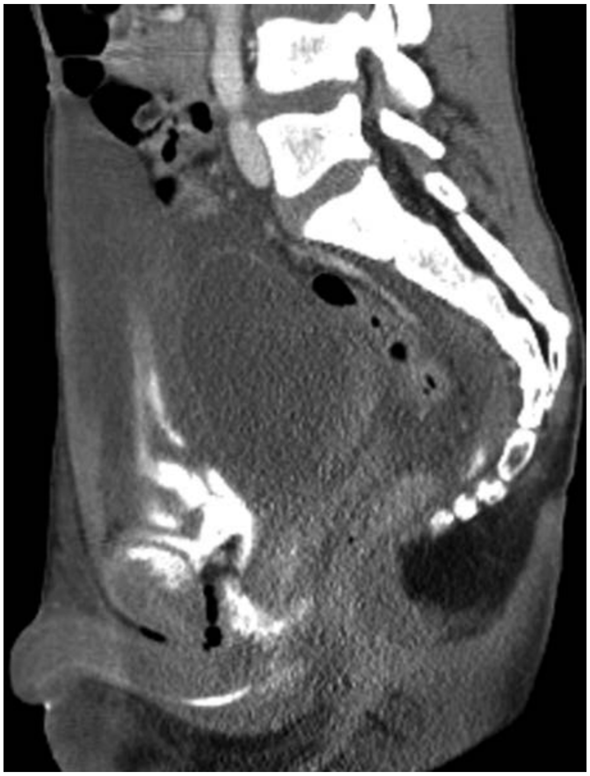


**e-Figure 123.11. Intraperitoneal bladder rupture.** Axial CT cystogram image through the sacral promontory shows extravasated contrast surrounding bowel and mesentery.



**e-Figure 123.14. Bladder neck and urethral tear.** A sagittal contrast-enhanced CT image of the pelvis shows elevated bladder base, perivesical "sentinel" hematoma, and extravasated contrast material.

**TABLE 123.1** American Association for the Surgery of Trauma (AAST) Renal Injury Scale

| Injury Grade | Renal Injury |
|---|---|
| I | Renal contusion, small nonexpanding subcapsular hematoma |
| II | Superficial renal laceration (<1 cm) not involving collecting system or deep medulla, nonexpanding perinephric hematoma |
| III | Deep renal laceration (>1 cm) without involvement of renal collecting system |
| IV | Laceration of renal collecting system, vascular injury with contained hemorrhage, segmental infarction without laceration, expanding subcapsular hematoma compressing the kidney |
| V | Shattered kidney, avulsion of renal hilum, ureteropelvic junction avulsion, complete laceration or thrombosis of main renal artery or vein |

*From http://www.aast.org/Library/TraumaTools/InjuryScoringScales.aspx#kidney.*

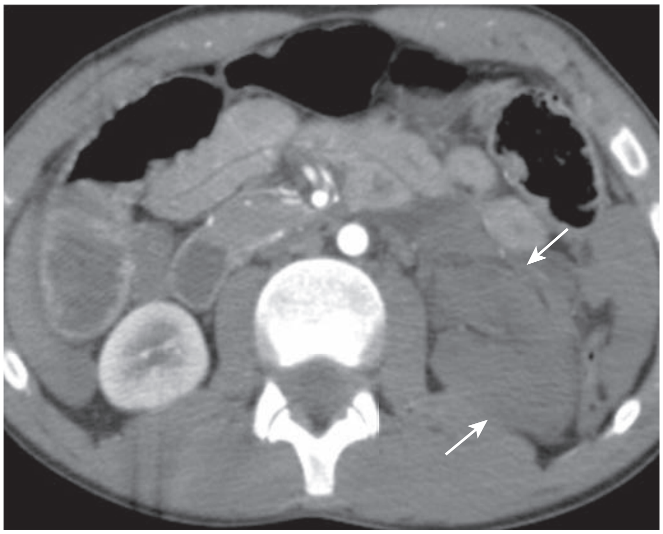


**Figure 123.6. Grade V renal injury.** Teenage boy hit by a truck while driving a snowmobile. Axial contrast-enhanced CT image shows nonenhancement of the left kidney *(arrows)* due to renal artery injury, likely dissection or thrombosis.

instrumentations should be performed in patients with suspected urethral injury until a retrograde urethrogram is performed to evaluate the integrity of the entire urethra. Attempts to catheterize the bladder may convert a partial urethral tear into a complete transection.[12]

***Imaging.*** Retrograde urethrography is performed by inserting the tip of a Foley catheter into the distal urethra. The balloon is slowly inflated in the fossa navicularis, and water-soluble iodinated contrast material is gently hand-injected via a syringe, with the patient positioned in the steep oblique or lateral position. Urethral injuries are manifested by irregular narrowing of the affected urethra and extravasation of contrast material into the surrounding tissues; intraluminal filling defects due to hematoma may be seen (Fig. 123.15 and e-Fig. 123.16).

Although retrograde urethrography is the preferred method of evaluating the urethra, placement of a urinary catheter is common in patients with multiple trauma, and retrograde urethrography may be initially considered only after a CT scan has already been performed. Therefore familiarity with CT findings associated with urethral injuries is important. These include obliteration of the fat plane around the urogenital diaphragm, obscured contours of the prostate, elevation of the bladder base, and blood along the obturator internus muscle (see Fig. 123.13 and e-Fig. 123.14).[13]

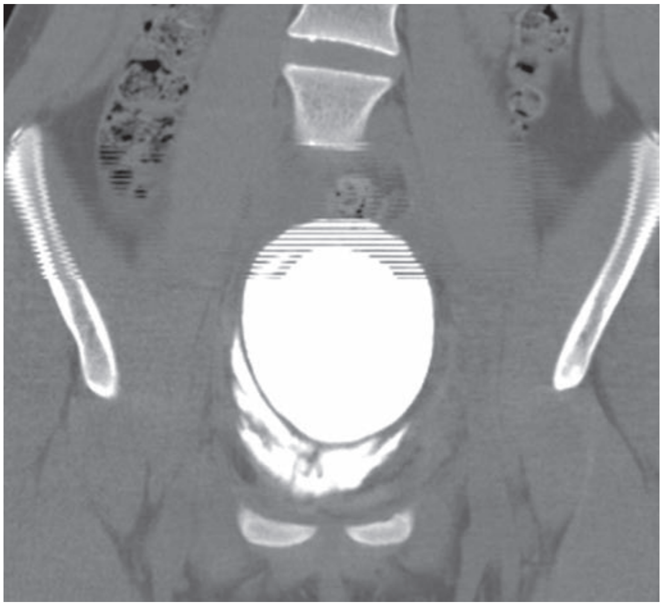

**Figure 123.7. Extraperitoneal bladder rupture.** A coronal reformatted CT cystogram image shows contained extravasation of contrast-containing urine into the perivesical space. A sagittal reformatted image is provided in e-Fig. 123.8.

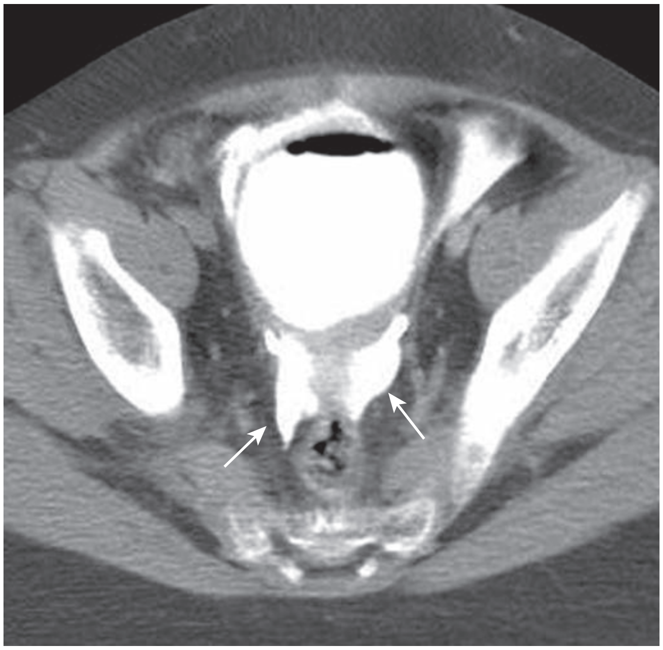

**Figure 123.10. Intraperitoneal bladder rupture.** An axial CT cystogram image through the pelvis shows extravasation of contrast-containing urine into the cul de sac *(arrows)*. A higher axial image showed contrast material surrounding bowel and mesentery (see e-Fig. 123.11).

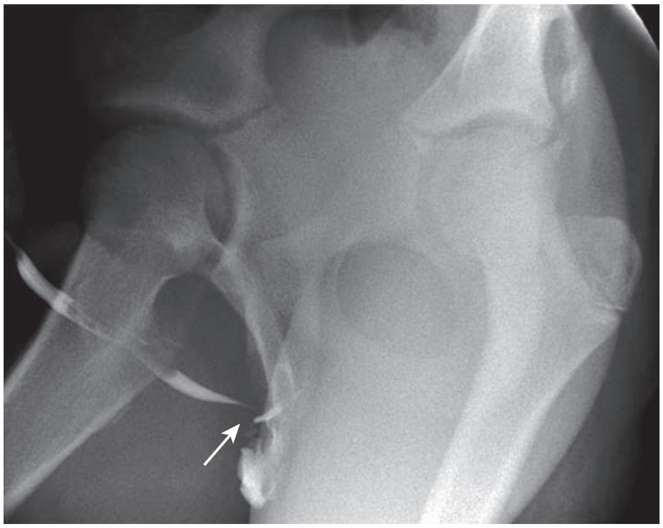
## SCROTAL INJURY

***Overview.*** The majority of blunt injuries to the scrotum occur in older boys and are the result of a direct blow to the groin



**e-Figure 123.16. Straddle injury, bulbous urethra.** Teenage boy with bulbous urethra injury that occurred when attempting to hurdle a chair. Retrograde urethrogram image shows a laceration *(arrow)* of the urethra with extravasation of contrast material into the scrotum.

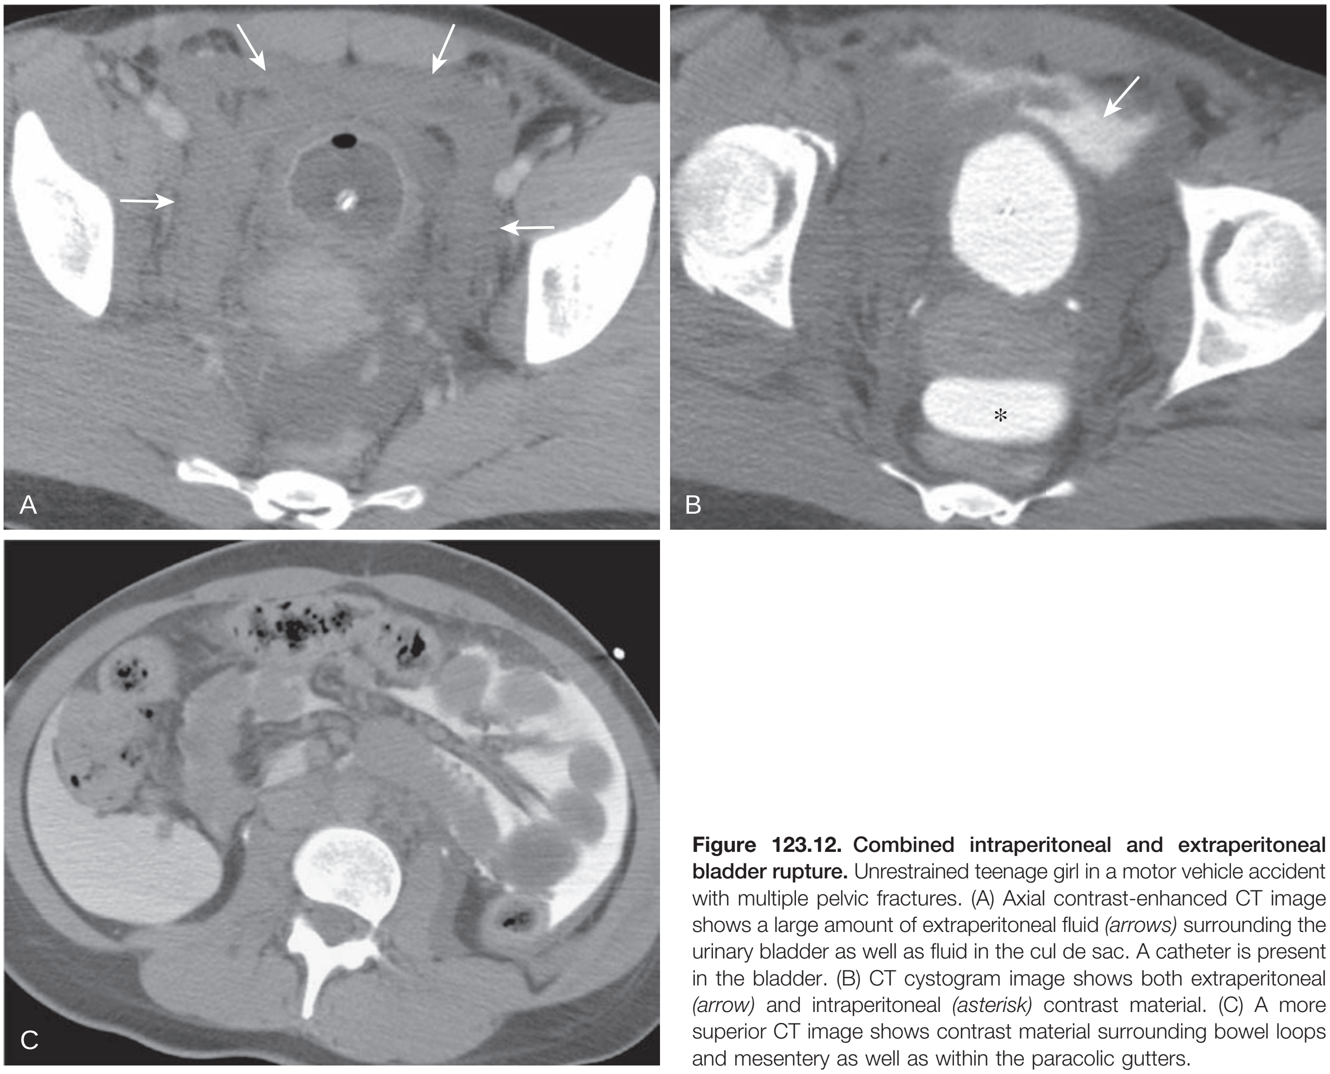


**Figure 123.12. Combined intraperitoneal and extraperitoneal bladder rupture.** Unrestrained teenage girl in a motor vehicle accident with multiple pelvic fractures. (A) Axial contrast-enhanced CT image shows a large amount of extraperitoneal fluid *(arrows)* surrounding the urinary bladder as well as fluid in the cul de sac. A catheter is present in the bladder. (B) CT cystogram image shows both extraperitoneal *(arrow)* and intraperitoneal *(asterisk)* contrast material. (C) A more superior CT image shows contrast material surrounding bowel loops and mesentery as well as within the paracolic gutters.

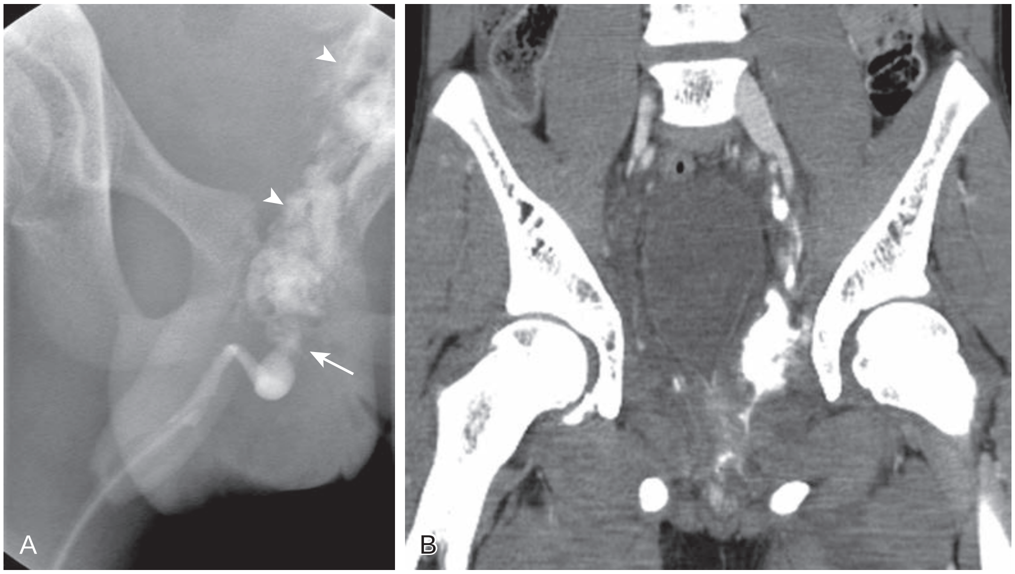

**Figure 123.13. Bladder neck and urethral tear.** (A) An oblique retrograde urethrogram image shows complete transection *(arrow)* of posterior urethra and bladder neck with extraperitoneal extravasation of contrast material *(arrowheads)*. (B) A coronal reformatted contrast-enhanced CT image of the pelvis shows elevated bladder base, perivesical “sentinel” hematoma, and extravasated contrast material. A sagittal reformatted image is provided in e-Fig. 123.14.

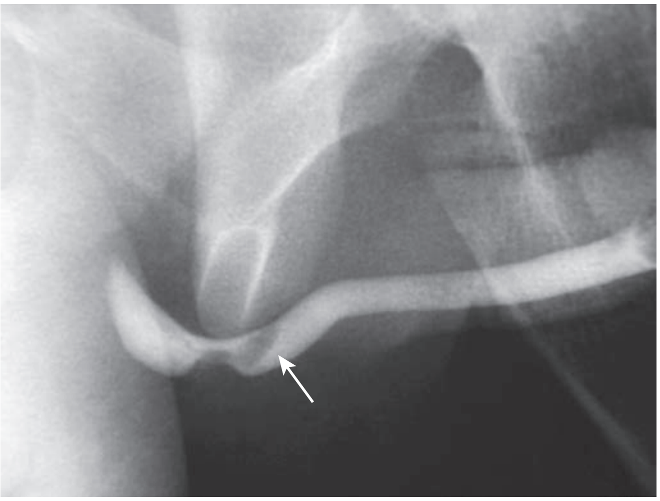

**Figure 123.15. Straddle injury, bulbous urethra.** An oblique retrograde urethrogram shows focal urethral narrowing and intraluminal hematoma *(arrow)*.

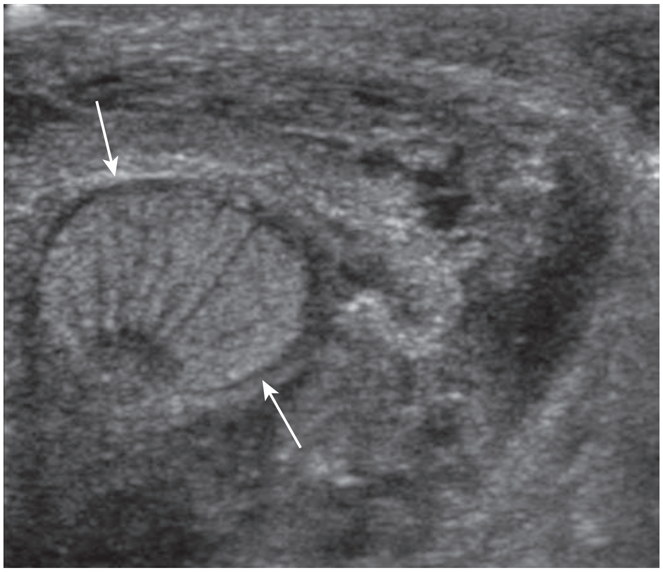

**Figure 123.17. Scrotal hematoma.** Transverse ultrasonogram of the right scrotum shows an intact testis *(arrows)* surrounded by heterogeneous peritesticular hematoma (hematocele). See e-Fig. 123.18 for the longitudinal view.

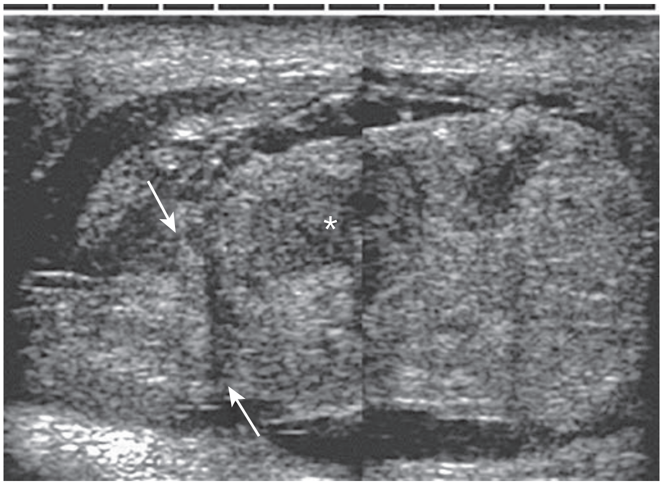

**Figure 123.19. Testicular rupture.** A longitudinal composite scrotal ultrasound image shows a heterogeneous testis with intratesticular hematoma *(asterisk)* and extrusion of testicular contents through a tear in the tunica albuginea *(arrows)*. See e-Fig. 123.20 for power Doppler image of the same testicle.

during sport activities (50%), motor vehicle crashes (9%–17%), falls, or straddle injuries. Typical indications for imaging include an acute, painful, or ecchymotic scrotum, and a nonpalpable testis. Although common, scrotal injuries rarely need surgical intervention. Fortunately, more than 80% of ruptured testes can be successfully salvaged if surgical repair is performed within 72 hours of injury.[12]

***Imaging.*** Sonography is the most effective method of assessing the injured scrotum. High-frequency (7–20 megahertz) linear array transducers should be used to evaluate both testes with gray-scale and color or power Doppler to determine the location and extent of injury. Ultrasonography plays a key role in the identification of testicular rupture allowing for immediate surgical exploration and repair.

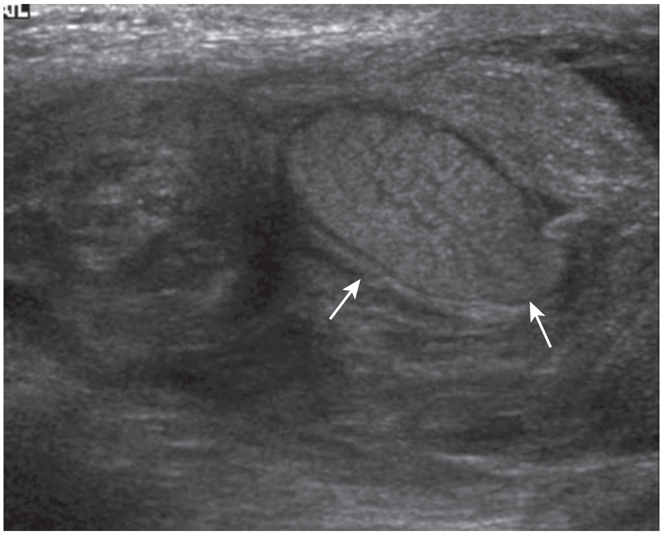
Hematomas and hematoceles are the most common findings after scrotal injury. They may be single or multiple and may have a wide range of echogenicities, depending on the time interval between injury and imaging (Fig. 123.17 and e-Fig. 123.18). With time, the contained hemorrhage becomes less echogenic, and the fluid may become more typical of hydrocele.

Testicular fractures occur when a break occurs in the testicular parenchyma alone or is associated with a tear in the tunica albuginea (testicular rupture). Sonography demonstrates heterogeneous echogenicity of the testicular parenchyma, caused by infarction and hemorrhage. Irregularity of the normally smooth testicular border and, occasionally, nonvisualization of any normal testicular parenchyma are also encountered. Ultra-sonographic findings of an abnormal testicular contour and heterogeneous echotexture caused by hemorrhage and extrusion of seminiferous tubules have a high sensitivity and specificity for the diagnosis of testicular rupture (Fig. 123.19 and e-Fig. 123.20).[12–14]

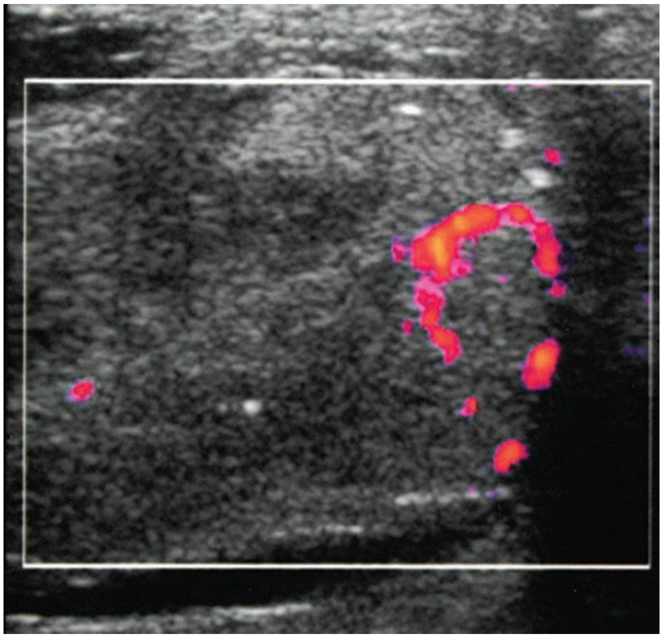
One must be wary of the possibility that bizarre heterogeneous echogenicity in a traumatized scrotum may actually be a hematoma that has superiorly displaced a normal testis into the inguinal canal. Other extratesticular findings include reactive hydroceles, posttraumatic epididymitis, and testicular torsion.

## KEY POINTS

- Asymptomatic microscopic hematuria is a low-risk indicator of renal injury.
- Delayed CT imaging through an injured kidney should be considered to identify urinary extravasation.
- High-risk indicators of bladder injury include the combination of gross hematuria, pelvic fracture, and high-risk mechanism of injury.
- Fifty percent of children with bladder injury have a fracture of the bony pelvis.
- A retrograde urethrogram is essential in boys with suspected urethral injury.
- Ultrasonographic findings are both sensitive and specific for testicular rupture.
- Most genitourinary injuries can be treated nonsurgically. Exceptions include intraperitoneal bladder rupture, urethral transection, and testicular rupture.



**e-Figure 123.18. Scrotal hematoma.** A longitudinal ultrasound image of the right scrotum shows an intact testis *(arrows)* surrounded by heterogeneous peritesticular hematoma (hematocele).



**e-Figure 123.20. Testicular rupture.** A power Doppler ultrasound image of the same patient shown in Fig. 123.19 shows only minimal flow in the remaining viable testis.

# Disorders of Sex Development

Harris L. Cohen and Stephen F. Miller

## EMBRYOLOGY, SEX DIFFERENTIATION, AND GONAD DIFFERENTIATION

***Overview.*** The three important precursor components needed for genital system development are the genital ridge and the two sets of internal sex ducts, the Müllerian-paramesonephric and the Wolffian-mesonephric. Around 7 weeks' gestation, the embryologic genital ridge becomes either an ovary or a testis. The development of the male genital system is an "active" process requiring testes and Müllerian inhibiting substance (MIS). The sex-determining region (*SRY* gene) on the short arm of the Y chromosome encodes a testis-determining factor. Under this factor's influence (and in the presence of H-Y antigens found in the cell membranes of normal XY males), there is normal testis development with germ cells in the genital ridge differentiating into Sertoli cells and Leydig cells. Sertoli cells secrete MIS, which causes complete Müllerian duct system involution. Leydig cells produce testosterone. The enzyme 5a-reductase converts testosterone intracellularly within the target tissues into the powerful androgen dihydrotestosterone (DHT). DHT allows the Wolffian duct system to develop into the epididymis, vas deferens, ejaculatory duct, and seminal vesicles.

If no Y chromosome exists or if abnormal encoding of testes-determining factor is present, the gonad will passively differentiate into an ovary between 11 weeks' to 17 weeks' gestation (typically in the presence of two X chromosomes). Absence of two X chromosomes may lead to abnormal or "streak" ovaries. The ovaries and their hormones, however, are thought to have no apparent role in sex differentiation of the female genital tract. The absence of MIS leads to persistence of Müllerian structures, which develop into the fallopian tubes, uterus, cervix, and upper two-thirds of the vagina. The Wolffian ducts involute in the absence of testosterone.

The undifferentiated external genitalia include the urogenital tubercle, urogenital swelling, and urogenital folds. DHT stimulation in males causes these structures to develop into the glans penis, scrotum, and penile shaft, respectively. In females, they develop into the clitoris, labia majora, and labia minora, respectively. The prostate gland develops from the urogenital sinus.[1–6] Disorders of Sexual Development (DSD) are diagnosed when there is discordance between chromosomal (genetic), gonadal, and anatomical sex.

## DISORDERS OF SEX DEVELOPMENT WITHOUT AMBIGUITY OF EXTERNAL GENITALIA (Box 124.1)

### Phenotypic Females

### Turner Syndrome (XO Gonadal Dysgenesis)

***Overview.*** Classic Turner syndrome (isochromatous 45,XO karyotype pattern) is the most common gonadal dysgenesis associated with an abnormal karyotype in girls and is nonfamilial. A single X chromosome is the probable cause for the presence of streak ovaries (streaks or ridges of connective tissue in the mesosalpinges parallel to the fallopian tubes), rather than normal ovaries. Some functional ovarian elements are present in a few cases. Fallopian tubes, a uterus, and a vagina are present, and no Wolffian duct derivatives are found.[1,5,6]

Patients with classic Turner syndrome have several somatic findings. Affected patients are short in stature with a distinctive facies that includes low-set ears, a low hairline, and a high-arched palate. They have a short, broad, and webbed neck; widely spaced nipples; and a shield chest. Classically, there is shortening of the fourth and/or fifth metacarpal bones. Cervical lymphatic malformations can be noted in fetal life, and the webbed neck is thought to be a residuum. Other variably seen findings include a bicuspid aortic valve, enlarged aortic root, coarctation of the aorta, renal anomalies (e.g., horseshoe kidney), and Hashimoto thyroiditis. Patients with Turner syndrome have delayed onset of puberty, no breast development or vaginal mucosal estrogenization (but presence of pubic and axillary hair), infantile internal and external genitalia, and primary amenorrhea.[1,7,8]

***Imaging.*** The prepubertal uterus (Fig. 124.1) and vagina are normally formed and will respond to exogenous hormone stimulation. The dysgenetic or streak gonads are difficult to image. When the adnexa are measurable, they are typically less than 1 mL in volume.

### Mosaic Turner Syndrome

Approximately 25% of patients with 45,XO Turner syndrome have a so-called chromatin-positive pattern. Their mosaic karyotype is most often of a mixture of 45,XO and 46,XX chromosomes. Less often, other mosaic patterns (e.g., XO/XXX or XO/XX/XXX) or 46,XX with an abnormal X chromosome are present. In such cases, the gonads may consist of a streak ovary on one side and a hypoplastic or normal ovary on the other side, bilateral hypoplastic ovaries, or essentially normal ovaries. External and internal genitalia are entirely female, without Wolffian duct remnants. These patients usually do not have the somatic abnormalities typically attributed to classic Turner syndrome, but many are short.[1] Patients with mosaic Turner syndrome may develop secondary sex characteristics at puberty (found to occur in about 50%), and some may menstruate regularly.[1,9]

### Amenorrhea Caused by Hypergonadotropic Hypogonadism

Primary amenorrhea (defined as a lack of menses by age 16 years), with high levels of circulating follicle-stimulating hormone and luteinizing hormone by serum assays, occurs because of ovarian failure; gonadal tissues fail to respond to endogenous gonadotropins. Patients included in this category may have classic Turner syndrome, gonadal dysgenesis (including 46,XY and familial 46,XX), secondary ovarian failure as a result of radiation or chemotherapy, or on an autoimmune basis (autoimmune oophoritis).[1,5,6,8]

### 46,XY Gonadal Dysgenesis

Patients with 46,XY gonadal dysgenesis (X-linked recessive or sex-limited autosomal dominant) are phenotypically female, with streak gonads and infantile internal and external female genitalia. Patients are usually first diagnosed as having an abnormality in adolescence. As with other forms of gonadal dysgenesis, in such patients, the sex chromosome may not be absent but is abnormal. A deletion of the small arm of the Y chromosome (responsible

## Abstract:

This chapter reviews disorders of sexual development (DSD) by noting normal embryology, sex differentiation and gonadal differentiation of the genital system and then reviewing disorders of these processes. Discussed disorders include: DSDs without external genital ambiguity such as Turner syndrome XO (gonadal dysgenesis) with its classic streak ovaries but present fallopian tubes, uterus and vagina as well as 46XY gonadal dysgenesis and familial 46XX gonadal dysgenesis. DSDs in phenotypic males including Klinefelter's syndrome and persistent Mullerian duct syndrome are discussed. DSDs with ambiguous external genitalia including patients with pseudohermaphroditism i.e. female intersex (46,XX DSD) and male intersex (46,XY DSD) patients and those with androgen insensitivity syndrome are reviewed. Various forms of complete and partial gonadal dysgenesis are discussed along with the association of gonadal dysgenesis and gonadoblastomas. The diagnostic imaging evaluation of the ambiguous genitalia patient is reviewed.

## Keywords:

**BOX 124.1** Disorders of Sex Differentiation Without Ambiguous External Genitalia

- Turner syndrome
- Mosaic Turner syndrome
- Gonadal dysgenesis, various forms
- Klinefelter syndrome
- Persistent Müllerian duct syndrome

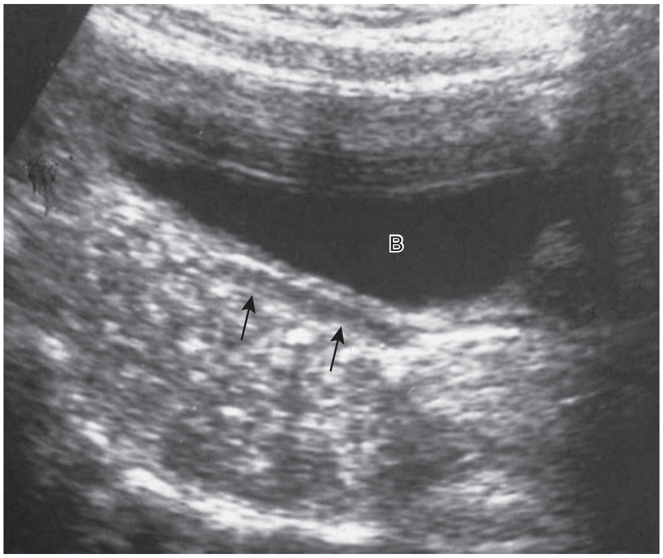

**Figure 124.1. Turner syndrome.** A longitudinal sonogram of the pelvis shows a small tubular uterus *(arrows)* in this 16-year-old with primary amenorrhea and 45,XO Turner syndrome. Her ovaries could not be identified. *B,* Bladder.

for production of testis-determining factor or MIS) may be present. Mosaicism may lead to the development of ovaries rather than streak gonads. If a Y chromosome is a component of the karyotype of a patient with gonadal dysgenesis and ovaries, the patient has an increased risk of developing a gonadoblastoma within a dysgenetic ovary. Seminomas also may occur in these patients.[1,2]

### Familial 46,XX Gonadal Dysgenesis

Patients with familial 46,XX gonadal (sporadic or autosomal recessive) dysgenesis have gonads that consist of bilateral streaks in some cases or hypoplastic ovaries in others. A hypoplastic ovary may present on one side with a streak gonad on the other. The internal and external genitalia are entirely female, without Wolffian duct derivatives. Incomplete puberty may be observed in patients with residual ovarian tissue. Sexual infantilism and primary amenorrhea are typical findings in those patients with bilateral streak gonads.[1,2]

## Phenotypic Males

### Klinefelter Syndrome (47,XXY Seminiferous Tubular Dysgenesis)

Seminiferous tubular dysgenesis (Klinefelter syndrome) is the most common aberration of the human sex chromosome. The typical 47,XXY karyotype is found in phenotypic males with primary hypogonadism. It is nonfamilial, occurring in 1 in every 750 to 1,000 males. Variants have been described with less common chromosomal abnormalities, including XX/XXY or XY/XXY mosaicism, as well as XXXY, XXXXY, XXYY, or XXXYY sex chromosomal karyotypes. The external genitalia, especially the testes, are small. The testes are usually less than 3 cm in length and are firm. Cryptorchidism and hypospadias are common, with most patients developing azoospermia and sterility. The diagnosis is usually not made until after puberty. Gynecomastia develops in almost half of the older patients, and affected patients (particularly those with the classic 47,XXY karyotype) are at an increased risk for breast cancer. Rare cases of testicular and extragonadal germ cell neoplasms have been reported.[1,5,6]

**BOX 124.2** Disorders of Sex Differentiation With Ambiguous External Genitalia

- 46,XX DSD, preferred term for female intersex (pseudohermaphroditism)
- 46,XY DSD, preferred term for male intersex (pseudohermaphroditism)
- Gonadal dysgenesis, various forms
- 46,XX/46,XY ovotesticular DSD (preferred term for true hermaphroditism)
- 46,XX testicular DSD

*DSD*, Disorders of sexual differentiation.

### Persistent Müllerian Duct Syndrome (46,XY PMDS)

Persistent Müllerian duct syndrome is a rare type of sexual differentiation abnormality in males caused by a deficiency of Müllerian inhibiting factor (MIF). These patients usually have a normal 46,XY karyotype and are phenotypically male, but they have a small uterus and fallopian tubes and a small vagina connected to the posterior urethra at the level of the verumontanum. Unilateral or bilateral cryptorchidism is common, as are unilateral or bilateral inguinal hernias. A uterus (uteri hernia syndrome), fallopian tubes, or sometimes a testis may be found in the hernia. The disorder, typically sporadic, has been reported in siblings.[1,2,10,11]

## DISORDERS OF SEX DEVELOPMENT WITH AMBIGUOUS EXTERNAL GENITALIA (Box 124.2)

## Pseudohermaphroditism (Intersex)

Disorders of sex differentiation formerly referred to as intersex, pseudohermaphroditism, or hermaphroditism are abnormalities in which nonaccord of chromosomal, gonadal, and genital sex is present. Unlike true hermaphroditism, in which two types of gonadal tissue are present, pseudohermaphroditism shows nonaccord but with only one gender's gonads present. By definition, male intersex patients have testes and female intersex patients have ovaries or ovarian tissue.[1]

## Female Intersex (46,XX DSD)

***Overview.*** 46,XX DSD or female intersex is usually diagnosed in neonatal life in chromosomally normal females with masculinized external genitalia. The cause is usually increased fetal adrenal androgen production, most commonly from congenital adrenal hyperplasia or adrenogenital syndrome. Congenital adrenal hyperplasia (Fig. 124.2) is the most common cause of abnormal sex differentiation in females, causes adrenal gland enlargement ("cerebriform" appearance), and occurs in 1 in 15,000 live births worldwide. It is caused by an inherited deficiency of enzymes involved in adrenocortical hormone biosynthesis. Affected patients have normal ovaries, a uterus, and fallopian tubes, and no testicular tissue or internal Wolffian duct derivatives. In most cases, the external genitalia are ambiguous (Fig. 124.3), with a prominent phallus/clitoris or partially fused labioscrotal folds.

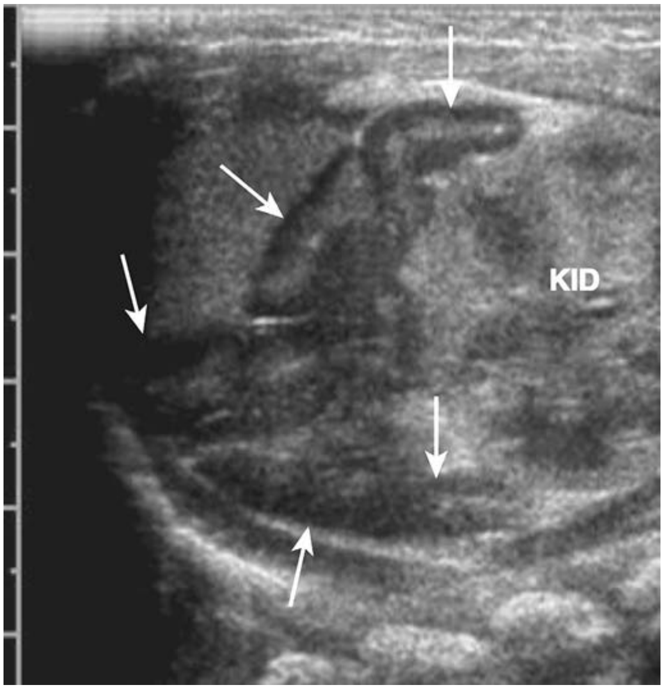

**Figure 124.2. Congenital adrenal hyperplasia.** A longitudinal gray-scale sonogram of the left adrenal gland and superior left kidney shows an enlarged, redundant adrenal gland *(arrows)*. The patient was a newborn with ambiguous genitalia and had three times the normal level of 17-hydroxyprogesterone. Her karyotype proved to be 46,XX. She was diagnosed with salt-wasting 21-hydroxylase deficiency as the cause of her congenital adrenal hyperplasia.

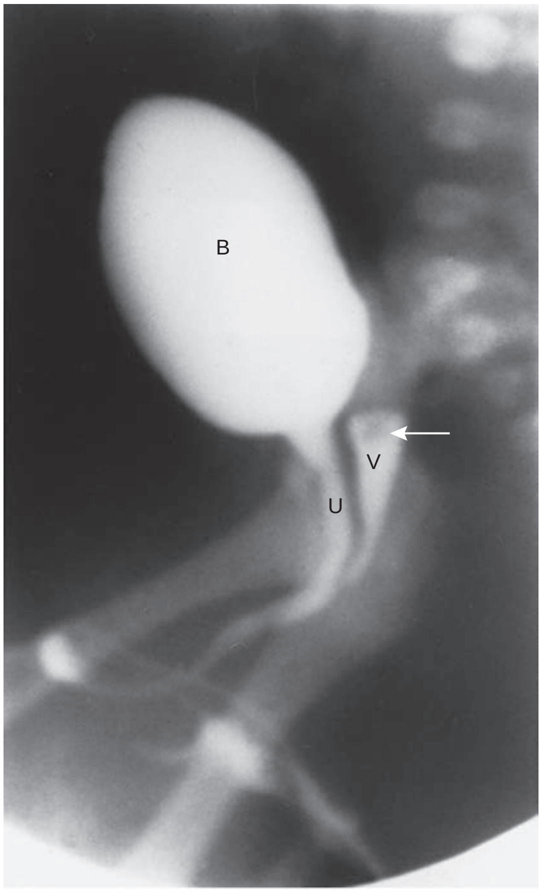

**Figure 124.4. Congenital adrenal hyperplasia.** Lateral voiding cystourethrogram shows a bladder *(B)* with an elongated male-type urethra *(U)*. Posterior to it is a vagina *(V)* with a subtle impression *(arrow)* of a cervix superiorly. The patient was a 46,XX neonate from an area in Puerto Rico, where congenital adrenal hyperplasia is common. *(From Cohen HL, Haller J. Pediatric and adolescent genital abnormalities.* Clin Diagn Ultrasound*. 1988;24:187–216. With permission. Copyright Elsevier Science USA.)*

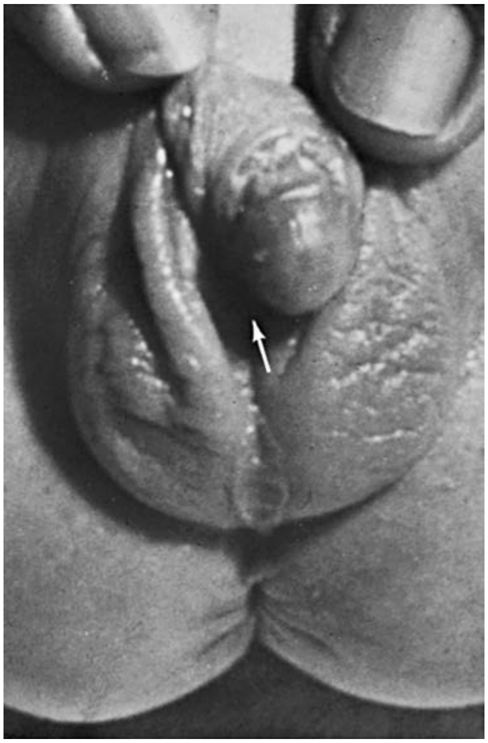

**Figure 124.3. Ambiguous external genitalia in a 1-month-old infant.** A penis and scrotum are present, but no gonads are palpable. A single perineal opening was found at the base of the penis *(arrow)*.

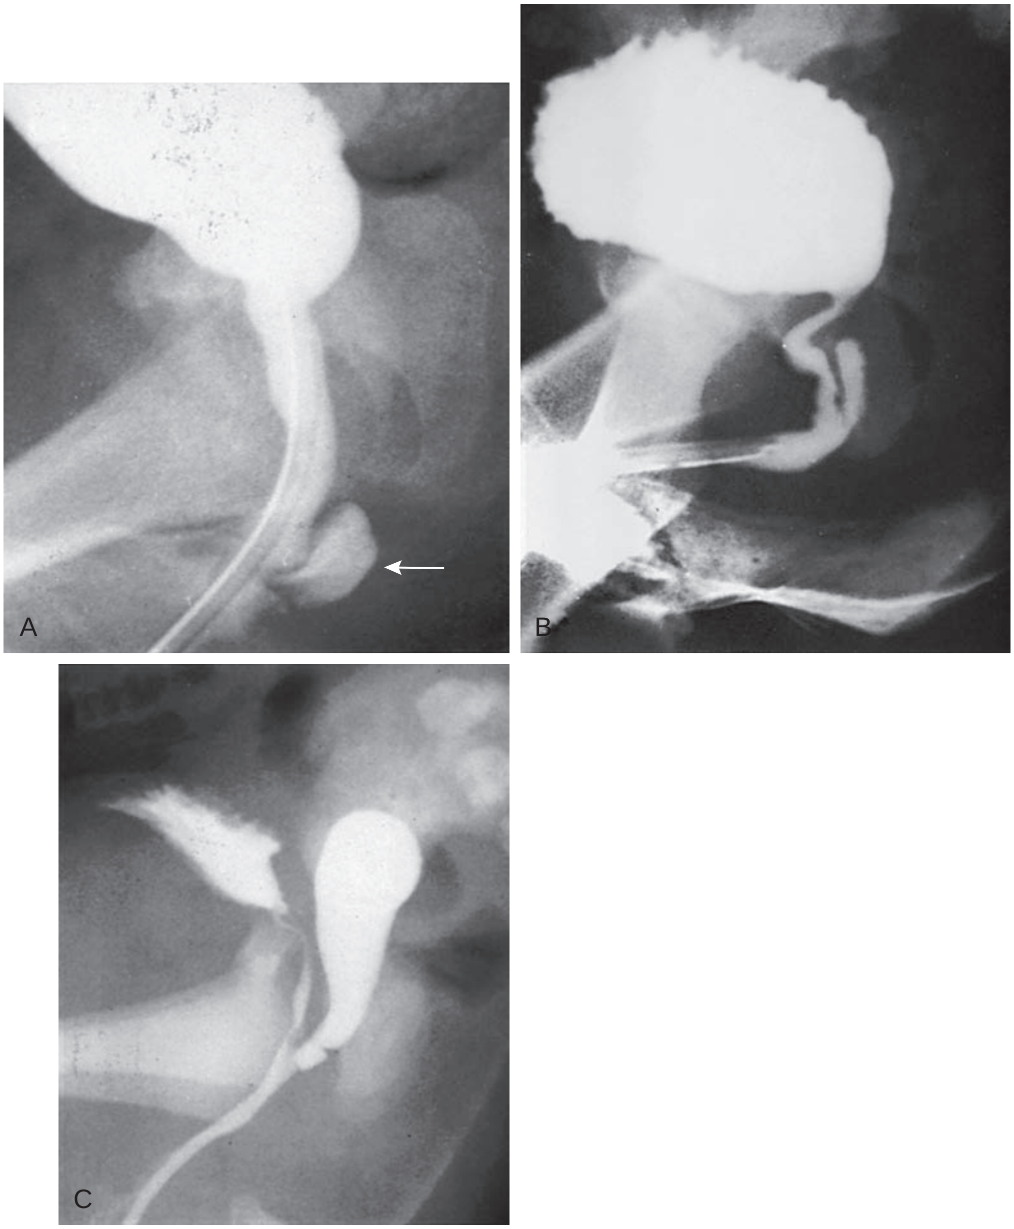
***Imaging.*** A variably-sized vagina is connected with the posterior urethra, forming a urogenital sinus, which commonly empties at the base of the penis. No gonads can be palpated in the labioscrotal folds or in the inguinal canal because they are located within the pelvis. Voiding cystourethrography (VCUG) often shows a male-type elongated urethra (Fig. 124.4). These patients are potentially fertile with external genital reconstruction and correct sex assignment.[1,2]

## Male Intersex (46,XY DSD)

46,XY DSD or male intersex patients are true males with a normal 46,XY male karyotype, present H-Y antigens, normal or mildly defective (and usually undescended) testes, but incomplete masculinization or frank ambiguity of their external genitalia. Decreased testosterone production and a lack of MIF production results in a karyotypically normal male with a female phenotype (except for partial masculinization of the external genitalia), and incomplete inhibition of the development of Müllerian-derived structures, such as the uterus, vagina, and fallopian tubes (Fig. 124.5 and e-Fig. 124.6). Such patients usually have no secondary sexual development at puberty and may have an infantile uterus



**e-Figure 124.6. 46,XY DSD (male pseudohermaphroditism).** (A) Incomplete testicular feminization syndrome in a patient with a predominantly female phenotype. Voiding cystourethrography shows a mildly elongated urethra and retrograde opacification of a short, blind-ending vaginal pouch *(arrow)* in the perineum behind the urethra. Seminal ducts may end in a vaginal pouch such as this. A similar configuration can be seen in patients with complete testicular feminization syndrome and in patients with 5-alpha-reductase deficiency. (B) Three-year-old child with ambiguous external genitalia and 5-alpha-reductase deficiency. A retrograde urethrogram shows a urogenital sinus and a small vagina without a cervical imprint. A more common pattern in 5-alpha-reductase deficiency is that shown in A. (C) Infant with severe hypospadias. A retrograde urethrogram shows a somewhat longer utricle connected with the distal end of the posterior urethra. The male urethra is somewhat short.

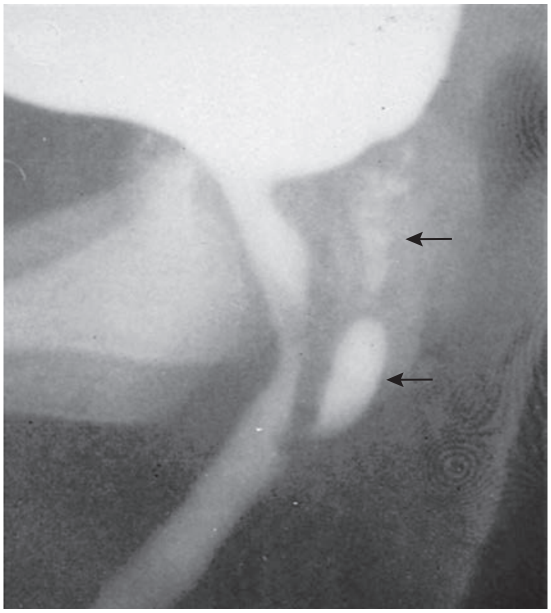


**Figure 124.5. A male infant with severe hypospadias (perineal and scrotoperineal), bilateral cryptorchidism, small penis, and unfused scrotal folds.** The image shows a utricle or blind vaginal pouch *(lower arrow)* that is very short and extending off the distal aspect of the posterior urethra. *Upper arrow* shows seminal ducts emptying into the utricle. The male urethra is somewhat short. See e-Fig. 124.6.

on ultrasonography. If the production of MIF by the testes is not affected, no internal Müllerian system structures (uterus and fallopian tubes) will develop. The biochemical defect may be decreased androgen synthesis, decreased DHT production as a result of 5-alpha-reductase deficiency, or a defect in androgen receptors. In many cases, the exact etiology remains unknown.[1,2,5,6,12,13]

### Androgen Insensitivity Syndrome

Androgen insensitivity syndrome (AIS; X-linked recessive), formerly known as testicular feminization syndrome, is a form of intersex in which patients with 46,XY karyotype have well-formed testes (usually undescended within the abdomen or inguinal region) that produce androgens and MIF. However, lack of end-organ response to androgens is caused by a defect in a specific cytoplasmic receptor protein that normally binds DHT to the plasma membrane and transports it to the nuclear chromatin. Müllerian system development is inhibited, and patients do not develop a uterus, fallopian tubes, or the upper two-thirds of the vagina. They do develop secondary female sexual characteristics via circulating estrogens (produced from the breakdown of testosterone and adrenal steroids as well as from direct production by the testes).

Patients with the complete form of the abnormality appear as phenotypically normal females, although they may have inguinal or labial masses resulting from the undescended testes (Fig. 124.7). They have normal breast development and may or may not have a short, blind-ending vagina behind the urethral opening. They usually present with amenorrhea and may respond to substitutional estrogen therapy. In the incomplete form (10%–20% of cases), patients present earlier in life because of ambiguous genitalia, not usually noted with the complete form of the disorder. Affected patients may have a predominantly female phenotype (incomplete testicular feminization) or a predominantly male phenotype (Reifenstein syndrome).[1,2]

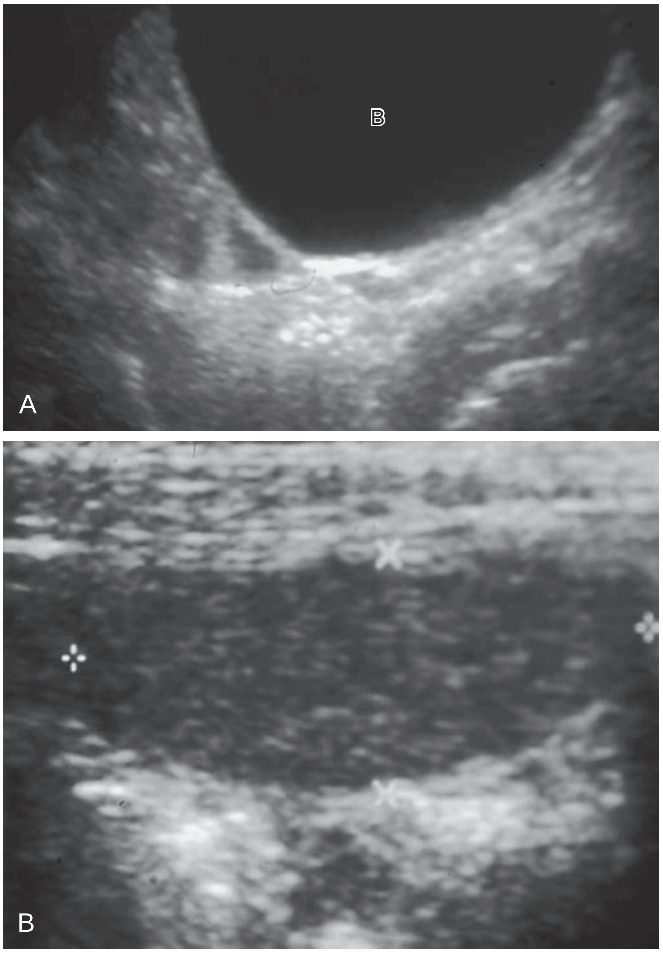

**Figure 124.7. Androgen insensitivity syndrome.** (A) Phenotypically normal 16-year-old girl, who presented with primary amenorrhea. Longitudinal midline gray-scale sonogram showed no uterus posterior to the bladder *(B)*. Ovaries were not seen. Karyotyping showed 46,XY, and the patient was proven to have androgen insensitivity syndrome. (B) This patient was noted to have bilateral inguinal masses. An oval structure *(cursors)* without cysts was found in the patient's left inguinal region on ultrasonography and proved to be an undescended testis. *(Courtesy of Joseph Yee, MD.)*

## Gonadal Dysgenesis

### Mixed Gonadal Dysgenesis (45,XO/46,XY MGD)

Mixed or asymmetric gonadal dysgenesis (also known as XO/XY gonadal dysgenesis) is a relatively common form of abnormal sexual differentiation, usually occurring sporadically. Affected patient karyotypes are most often a mosaic of 45,XO and 46,XY. At times, XO/XYY or other mosaicisms are seen. These patients often have a streak gonad similar to that seen in Turner syndrome on one side and a usually dysgenetic (but occasionally normal) testis on the other. A fallopian tube is often present on the side of the streak gonad, and a vas deferens may be present on the side of the testis. The testis is usually intraabdominal, but can be partially or completely descended. The external genitalia cover a wide spectrum of appearances from that of an almost normal female to that of an essentially normal male with hypospadias. Most patients have ambiguous external genitalia (as seen in other intersex situations), with a penis or clitoris of variable size, unfused labioscrotal folds, and a variably sized vagina connected with the

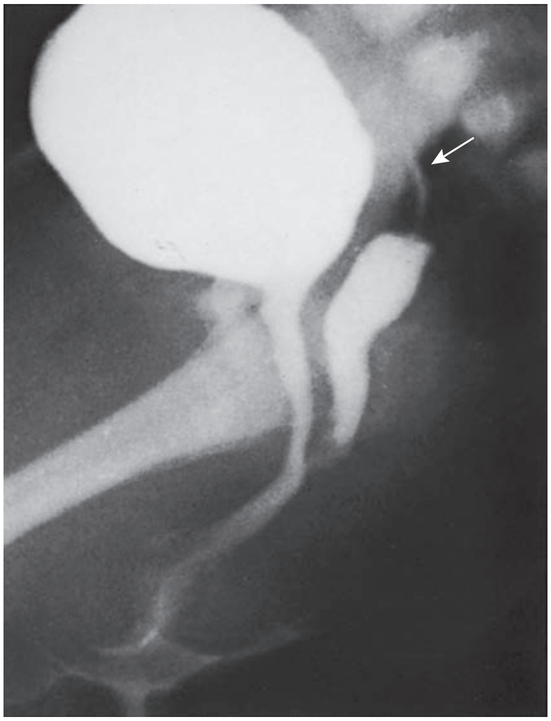

**Figure 124.8. Mixed gonadal dysgenesis.** Lateral voiding cystourethrography image shows a urogenital sinus with a well-developed vagina in an 11-day-old with ambiguous external genitalia. A cervical imprint is seen, and contrast material opacifies the uterine canal *(arrow)*.

urethra (urogenital sinus) that commonly empties at the base of the penis (Fig. 124.8). A uterus, said to be present in all cases, is usually small or rudimentary. Most patients are raised as females, but at puberty, some virilization may take place (usually without gynecomastia).[1,2]

## Familial Gonadal Dysgenesis

### 46,XY Complete Gonadal Dysgenesis

Familial 46,XY gonadal dysgenesis is typically an X-linked dominant abnormality (but can have Y-linked, autosomal dominant, or recessive inheritance patterns) that may be nonsyndromic or associated with several syndromes. The gonads are variable, and there may be bilateral streaks, bilateral dysgenetic testes, or a streak on one side and a dysgenetic testis on the other (mixed gonadal dysgenesis). Patients with bilateral streak gonads have a female phenotype with normal fallopian tubes, uterus, and vagina, usually clitoromegaly, and absence of Wolffian duct derivatives. Sexual infantilism and amenorrhea are expected at puberty. Patients with bilateral dysgenetic testes or with a mixed form of gonadal dysgenesis typically have ambiguous or incompletely masculinized external genitalia. Müllerian and Wolffian duct derivatives are present but may be hypoplastic or rudimentary. Swyer syndrome is a constitutional syndrome associated with CGD. [1,5,6]

### 46,XY Partial Gonadal Dysgenesis

There are several syndromes associated with Partial Gonadal Dysgenesis (PGD). Denys-Drash syndrome is an uncommon form of PGD and male intersex. Patients most often have a 46,XY karyotype, bilateral gonadal dysgenesis with a variable histologic pattern, ambiguous external genitalia, and intraabdominal testes. They have chronic glomerulonephritis with histologic features similar to those of congenital nephrosis, and they develop end-stage renal disease in early life. More than half of these patients develop a Wilms tumor at a young age, with the tumor purportedly occurring only in those patients with a female phenotype. Between 20% and 30% of Denys-Drash patients develop gonadal neoplasia. Camptomelic dysplasia as well as WAGR syndrome (*W*ilms tumor, *A*niridia, *G*enitourinary anomalies, and mental *R*etardation) are two other PGD syndromes.[1,5,6,14,15]

### 46,XY Gonadal Agenesis (Vanishing Testes Syndrome)

Patients with this condition are males with a 46,XY karyotype. No gonads are present, and male sex differentiation is absent or incomplete as a result of idiopathic testicular resorption of unknown cause in early fetal life (approximately 13–14 weeks' gestation). The external genitalia are ambiguous, and usually both Müllerian and Wolffian duct derivatives are completely absent. Vanishing testes syndrome is differentiated from cases of bilateral anorchia (congenital absence of the testes), which are presumably caused by resorption of the testes beyond 13 to 14 weeks' gestational age. Patients with bilateral anorchia have normal male sex development and no residual Müllerian structures.[1,16]

## 46, XX Testicular DSD

46,XX DSD (de la Chapelle syndrome), formerly known as XX maleness, is a very unusual cause of ambiguous genitalia occurring in 4 to 5 cases per 100,000 individuals. Because of errors in meiosis, an unequal interchange of sex chromosomes occurs, such that individuals may have one or two X chromosomes containing the male *SRY* gene. Patients are sterile but usually have two small testes, usually descended. Gynecomastia may be present, but more often the individuals are phenotypically male and have no intraabdominal Müllerian tissue despite being genetically female.[1,17]

## 46,XX/46,XY Ovotesticular DSD

46,XX/46,XY ovotesticular DSD, formerly known as true hermaphroditism, is a rare sporadic disorder in which the affected patient has both testicular and ovarian tissues in the same or contralateral gonads. More than half such patients have the 46,XX karyotype. Mosaic karyotype patterns with at least one line with a Y chromosome do exist, including XO/XY, XX/XXY, or XX/XY chimerism. Fifteen percent of patients have the 46,XY karyotype. All true hermaphrodites are H-Y antigen positive regardless of karyotype. In patients with the 45,XX karyotype, undetected Y chromosomal material is probably present and transferred to another chromosome. The testes or ovotestes may be intraabdominal, in the inguinal region, in the scrotal area, or in the labia majora. The ovaries are almost always intraabdominal. Internal gonadal ducts are usually consistent with the ipsilateral gonad (i.e., a vas on the side of a testis and a fallopian tube on the side of an ovary). In the case of ovotestes, the associated internal gonadal duct is usually a fallopian tube. A uterus is found in almost all cases but is most often hypoplastic.[1]

A wide spectrum of external genitalia exists ranging from normal male to ambiguous to female. Cryptorchidism and inguinal hernias are common. Hernias can contain a gonad with its internal gonadal duct or even a uterus. About 75% of affected patients are raised as males. At puberty, some virilization as well as gynecomastia usually occurs.[1,2]

## GONADAL NEOPLASIA OF PATIENTS WITH DISORDERS OF SEXUAL DEVELOPMENT

The gonads in several disorders of sexual development (with or without ambiguous genitalia) are at an increased risk for developing neoplasms. Patients with the highest risk of developing gonadal neoplasia are those with XO/XY mixed gonadal dysgenesis and those with 46,XY gonadal dysgenesis. The incidence of a gonadal tumor in these conditions increases from 3% to 4% in the first decade, from 10% to 20% by age 20, and from 15% to 40% or more in older patients. Neoplasms are almost always germ cell in type, including seminoma or dysgerminoma and gonadoblastoma. Less commonly, patients may develop a gonadal teratoma, teratocarcinoma, yolk sac tumor, embryonal carcinoma of the adult type, or choriocarcinoma. These neoplasms are rare in patients who do not have a Y chromosome as part of their karyotype. The risk is apparently related to the H-Y antigen.[1,2]

## DIAGNOSTIC EVALUATION OF PATIENTS WITH AMBIGUOUS GENITALIA

***Overview.*** The discovery of anomalous or ambiguous genitalia in a newborn has been described as an emergency from a social perspective. Optimal care should be provided by an experienced multidisciplinary team. The identification of the uterus, vagina, or urogenital sinus using ultrasonography and contrast genitogram aids in the decision on how to rear the child. These findings can then be correlated and sexual identification aided by karyotyping, including fluorescent studies for Y chromosomes, specific analysis of the Y chromosome for the testis-determining gene, culture of genital skin fibroblasts for androgen receptor binding, and tests for androgen responsiveness. The appearance of the external genitalia is seldom diagnostic of a specific disorder, but palpable gonads in the inguinal canal, labioscrotal folds, or scrotum can exclude female 46,XX DSD in most cases. Sometimes, the definitive anatomic diagnosis is made only at laparoscopy or laparotomy and on the basis of gonadal biopsy. The main role of ultrasonography is identification of the uterus, a relatively easy task in the newborn female.[1,2,18]

***Imaging.*** A detailed radiographic study of the lower genitourinary tract (genitography or vaginography) is important for diagnosis and as a guide in surgical reconstructive procedures. Patients commonly have a urogenital sinus, a common terminal channel for the anterior urethra and posterior vaginal pouch. This sinus usually empties at the base of the phallus. VCUG, particularly on lateral view, may outline the entire anatomy needed for evaluation. If the urethral catheter can be advanced only into the vagina, an injection with the catheter in that position may opacify the vagina, the urogenital sinus, and often the proximal urethra. If confusion about the anatomy persists during the VCUG examination, a retrograde injection of contrast material may be attempted through a catheter with the tip placed just inside the "urethral" meatus. At times, a coude catheter (with a curved tip) manipulated under fluoroscopic control into the urethra and bladder or into the vagina may improve contrast study of the area. An effort should be made on the VCUG or vaginogram to determine if a uterine cervix is present (see Fig. 124.4). A cervical impression at vaginography, however, may not be apparent if the vagina is not sufficiently distended or if the uterus is hypoplastic. A uterine cervix is present in all female intersex patients and is a common finding among many patients with mixed gonadal dysgenesis or ovotesticular DSD (true hermaphroditism) as well. All members of these groups may have a hypoplastic or rudimentary uterus that may not be noted radiographically. Cervical imprints are not seen in 46,XY DSD (male pseudohermaphrodites) or males with hypospadias.[1,2]

In some patients evaluated by VCUG or genitography, the urogenital sinus is quite short and joined by the vagina very close to the perineal surface (Fig. 124.9). In other patients, it is a much longer channel, joined by the vagina at a much higher level, occasionally near the bladder neck. A very high insertion of the vagina in the urogenital sinus may pose a problem at the time of vaginal reconstruction because of the danger of injuring the external urethral sphincter. In patients evaluated for disorders of sex development or ambiguous genitalia, the vagina may vary in size from a small cavity to an organ of normal size for the patient's age. Occasionally, its distal end is stenosed or is completely obliterated, resulting in hydrocolpos at birth or hematocolpos at puberty (Fig. 124.10).[1]

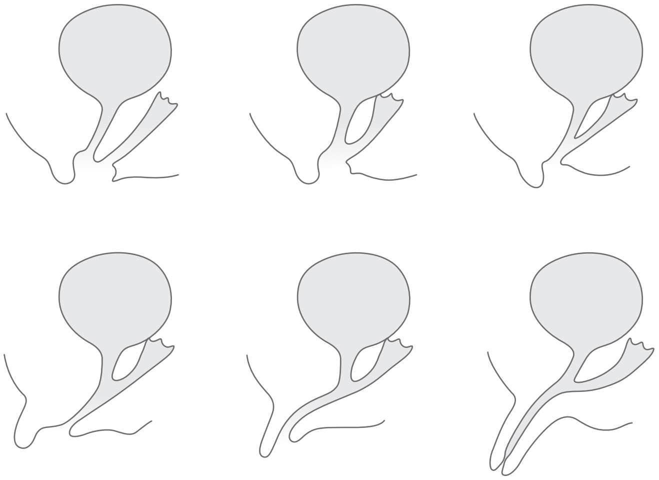

**Figure 124.9. Different types of urogenital sinus are arranged in order of increasing masculinization, from an almost normal female pattern to a penile urethra.** The urogenital sinus is of variable length, and the vagina may enter the urogenital sinus at various levels.

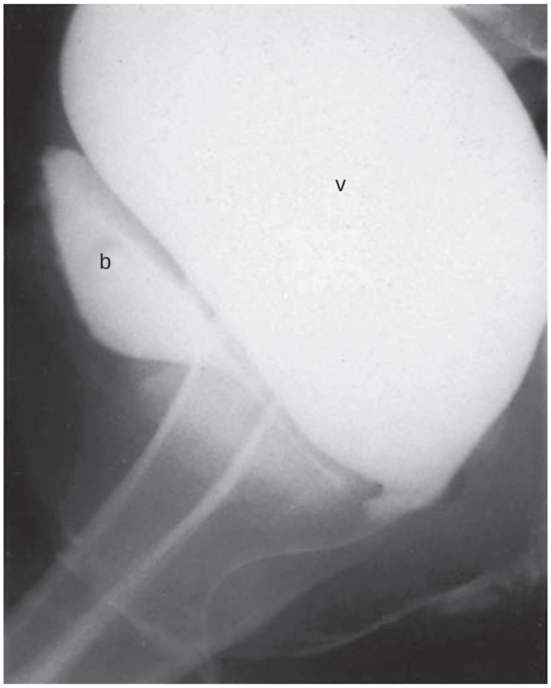

**Figure 124.10. Hydrocolpos in congenital adrenal hyperplasia syndrome.** Lateral view from a vaginogram of a 14-year-old girl with a urogenital sinus shows a catheter within a large obstructed vagina. She had presented with abdominal pain and a pelvic mass. *v*, Vagina; *b*, bladder.

Pelvic ultrasonography is valuable in evaluating infants and children with ambiguous genitalia. Ultrasonography is an excellent imaging tool for identification of uterine tissue (Fig. 124.11), although it may be difficult with hypoplastic uteri. The proximal vagina may also be demonstrated, particularly if it contains urine, but the urethra and urogenital sinus cannot be studied by this method. Ultrasonography does not replace genitography, but it is of particular value when genitography is unsuccessful. Ovaries are often seen, but fallopian tubes, unless obstructed, are more difficult to image. Ultrasonography is an excellent tool for the assessment of the adrenal gland in the newborn. Pelvic magnetic resonance imaging is of value in evaluating Müllerian duct system structures when ultrasonography and genitography do not provide sufficient information (Fig. 124.12).[1,19–21]

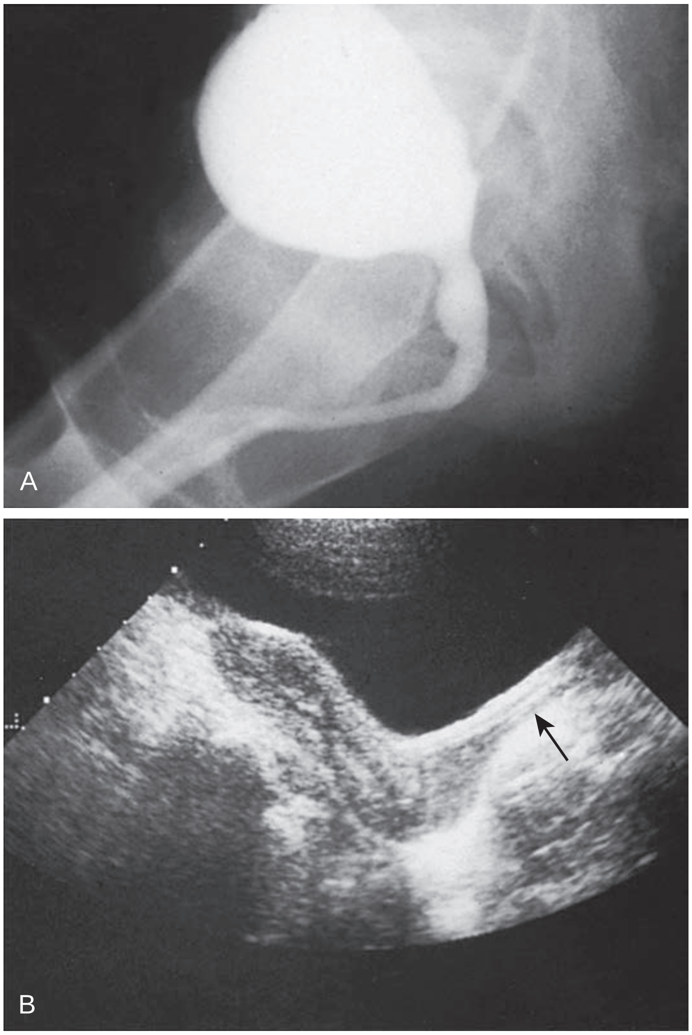

**Figure 124.11. Anatomic evaluation of a 13-year-old with known congenital adrenal hyperplasia being evaluated before surgical vaginoplasty.** (A) Voiding cystourethrography shows a phallic urethra. (B) Sagittal gray-scale sonogram shows a normal adult uterus. The proximal two-thirds of the vagina *(arrow)* are noted and appear normal.

## KEY POINTS

- DSD are abnormalities that have nonaccord of chromosomal, gonadal, and genital sex. 46,XY DSD (male intersex) patients have testes, and 46,XX DSD (female intersex) patients have ovarian tissue.
- DSD may be caused by abnormalities of hormone production, end-organ response, chromosomes, or gonads.
- The development of a male genital system requires the presence of testes and their production of MIS.
- Turner syndrome is the most common gonadal dysgenesis associated with an abnormal karyotype in girls.
- Primary amenorrhea is defined as a lack of menses by age 16 years. Many of the causes may also be linked to causes of delayed sexual development.
- 46,XX/46,XY ovotesticular DSD, once known a true hermaphroditism, is a rare sporadic disorder in which the affected patient has both testicular and ovarian tissues in the same or contralateral gonads.
- Patients with several of the DSD disorders are at an increased risk for developing gonadal neoplasms.
- The length of the urogenital sinus and the level of insertion of the vagina are indicators of the degree of virilization, but are nonspecific regarding the type of underlying disorder. Noting the presence or absence of a cervical imprint on the vaginogram is more important. A uterine cervix is present in all 46,XX DSD (female intersex) patients. Ultrasound, particularly in the young infant, can readily denote the presence of a normal uterus.

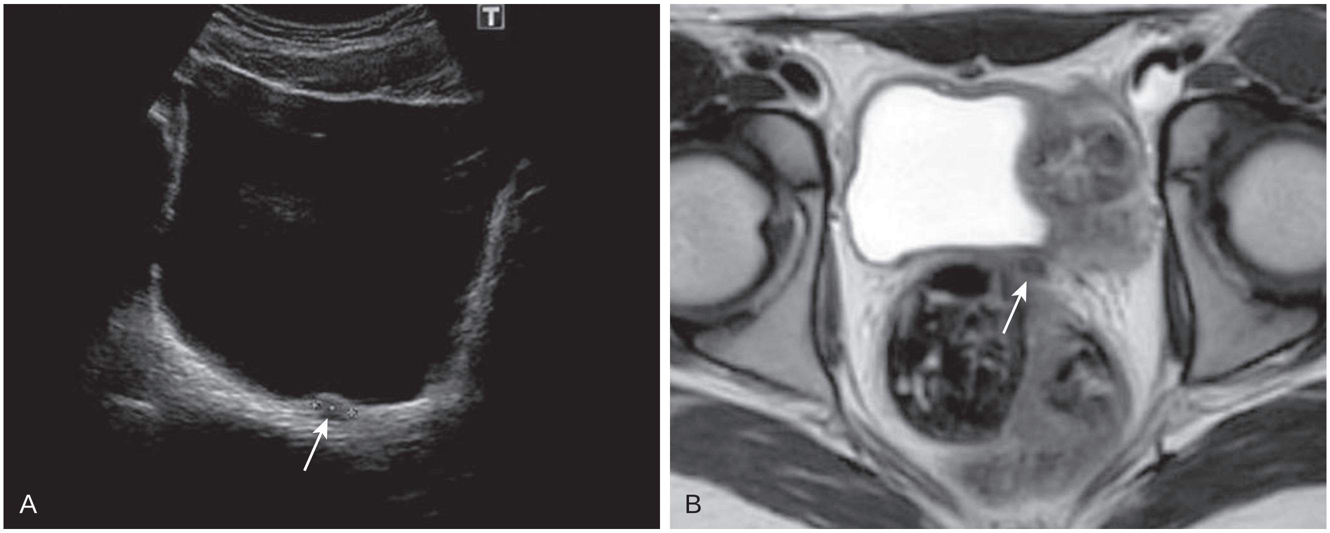

**Figure 124.12. Anatomic evaluation of a 12-year-old with known mixed gonadal dysgenesis.** (A) Transverse gray-scale sonogram through the pelvis shows a small, round, hypoechoic structure *(arrow)* posterior to the urinary bladder, thought to possibly represent a prepubertal uterus. (B) Axial T2-weighted MR image confirmed the presence of a tiny uterus *(arrow)*. The gonads had been previously removed.

# 125 Abnormalities of the Male Genital Tract

Harris L. Cohen and Stephen F. Miller

## OVERVIEW

Ultrasound (US), including Doppler imaging in all its forms, is the main diagnostic imaging tool for evaluating the scrotum. Computed tomography (CT) is used predominantly to evaluate metastatic spread of testicular or other intrascrotal tumors. Magnetic resonance imaging (MRI) has been used in the search for undescended testes that remain in an intraabdominal position. MRI, like CT, also can be used to analyze metastatic spread of testicular tumor. Its uses in evaluating the male genital tract are evolving.

### Ultrasound Technique

Scrotal US is performed using a high-frequency transducer. The superficial position of testes in the normally thin-walled scrotum allows excellent imaging with a transducer of 7.5 MHz or higher. Longitudinal and transverse views are taken of each hemiscrotum. Transverse views, sometimes using a convex array transducer (e-Fig. 125.1), allow the best side-by-side comparison of both testes and their adnexa, especially when checking for differences in size, echogenicity, and vascularity.[1–5] Spectral Doppler ultrasound can be used to further characterize testicular blood flow and demonstrate both arterial and venous waveforms (e-Fig. 125.2).

### Normal Findings

The testes should be ovoid, nearly symmetric, and homogeneously echogenic. There is some discrepancy with regard to normal testicular volumes (Box 125.1). A highly echogenic linear focus (seen posteriorly and superiorly) represents the mediastinum testis (Fig. 125.3), which is the inward extension of the tightly adherent covering of the testis, the tunica albuginea. Fibrous septa extending from the mediastinum testes divide the testes into more than 250 lobules, each drained by one or more seminiferous tubules that merge into the rete testes. The rete testes, draining veins, lymphatics, nerves, and testicular artery course within the mediastinum testis.[5–8]

The head of the epididymis (e-Fig. 125.4) sits atop the superior pole of each testis. The head is continuous with the epididymal body and tail, which travel inferiorly along the posterolateral margin of the testis. The echotexture of the epididymis is normally homogeneous. It may be of equal or of slightly greater or lesser echogenicity than that of the testes.[5–8]

The scrotal wall should be between 3 and 6 mm thick. Beneath the scrotal wall are the two layers of the tunica vaginalis (Fig. 125.5), the outer (parietal) and the inner (visceral) layers, which are the residua of the processus vaginalis (i.e., peritoneum that descended with the testis from the abdomen). The visceral layer covers the testis on its anterior border and is attached to the tunica albuginea. Between the tunica's two layers is a potential space that normally may contain 1 to 2 mL of fluid. It is here that the fluid of a hydrocele may accumulate.[5–8]

**BOX 125.1** Normal Scrotal Volumes

0–9 months: 0.27–0.44 mL
1 year: 0.31 mL
6–12 years: 2–5 mL
13–15 years: 5–10 mL
16.5–18 years: 6–22 mL

Several small, persistent, vestigial remnants of the mesonephric (wolffian) and Müllerian duct systems may be found within the scrotum. Of these, usually only three may be seen on US examination, usually only if fluid (e.g., from a hydrocele) surrounds one of them. These remnants are the appendix testis (e-Fig. 125.6) (a remnant of the Müllerian duct), which is attached to the upper pole of the testis (and the most common appendix to potentially undergo torsion); the appendix epididymis (a remnant of the

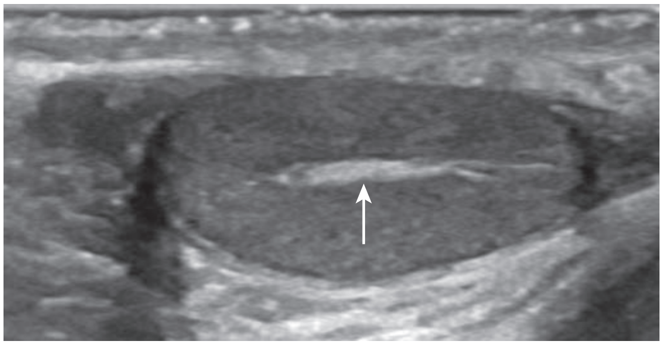

**Figure 125.3. Mediastinum testis.** A transverse sonogram shows a linear echogenic structure *(arrow)* within a normal testis, which is the mediastinum testis.

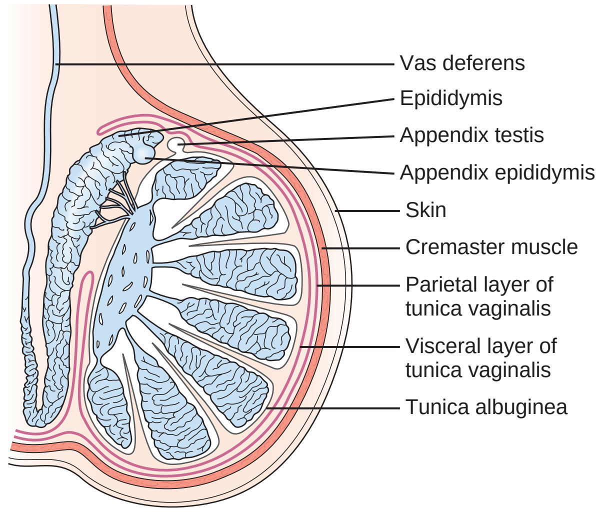

**Figure 125.5. A schematic drawing of the scrotum and its contents as seen in the longitudinal plane through a single testis.** Note the tunica albuginea surrounding the lobules of the testes. The tunica albuginea, in turn, is surrounded by the visceral layer of the tunica vaginalis and the more superficial parietal layer of the tunica vaginalis. *(From Cohen HL, Sivit C, eds.* Fetal and pediatric ultrasound: a casebook approach. *New York: McGraw-Hill; 2001. ## Abstract:

This chapter discusses imaging of the normal and abnormal male genital tract. Ultrasound techniques and normal imaging findings of scrotal contents are presented. Current evaluation of cryptorchidism, causes of testicular and scrotal enlargement and/or pain (e.g., hydrocele, varicocele, trauma, testicular torsion, torsion of testicular and epididymal appendages, epididymitis or epididymo-orchitis, and neoplasm), and testicular microlithaisis are discussed.

## Keywords:

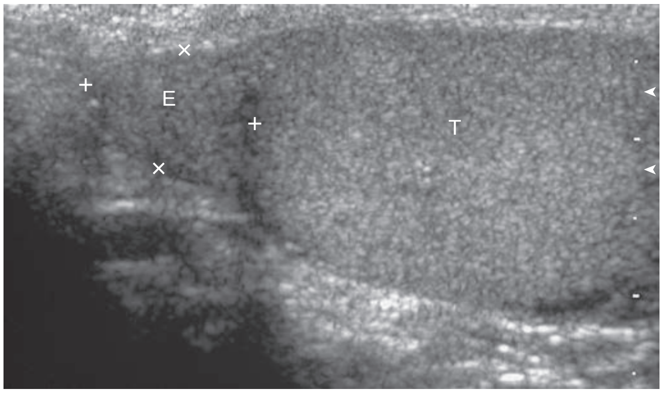
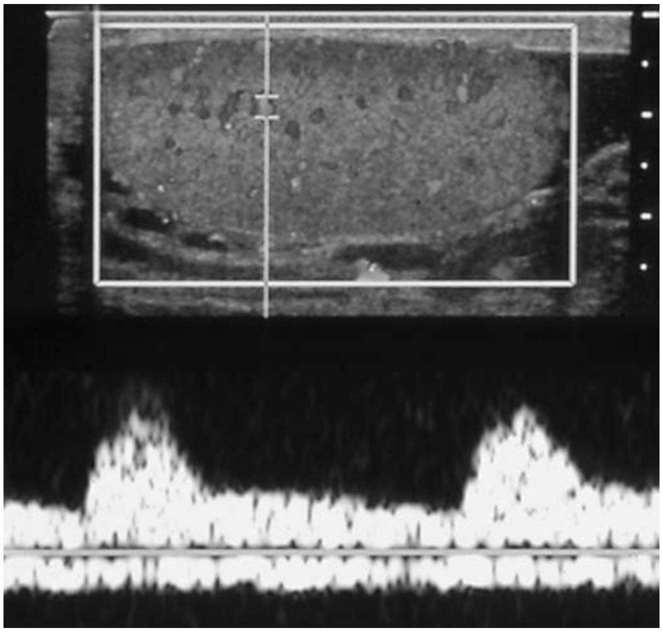
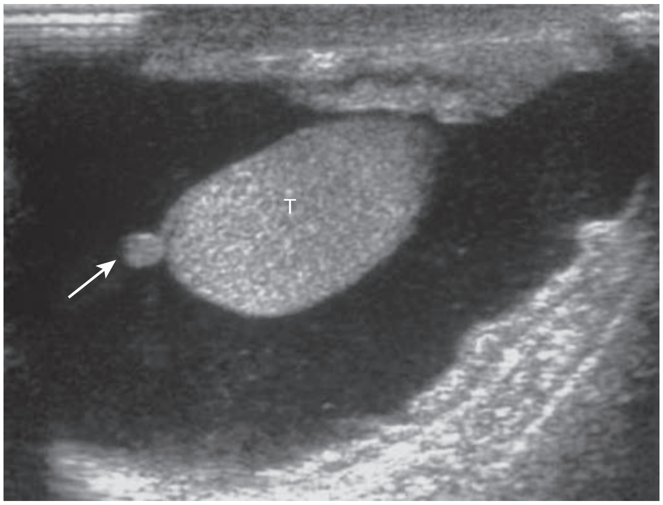
**e-Figure 125.1. Normal testes.** The testes of a teenager appear homogeneously echogenic on ultrasound in the transverse plane. This image was obtained using a convex linear array transducer that allowed imaging of most of both testes. These transducers can show both testes in their entirety in most cases and therefore are an improvement over linear array transducers (which are limited by the size of their footprint) for side-by-side comparisons of testes.



**e-Figure 125.4. Normal epididymis.** In this longitudinal sonogram, cursors mark off the head of the epididymis *(E)*, which sits atop the superior testis *(T)*. The normal epididymal body and tail, which travel along the side of the testis, are more difficult to separate from normal testis.



**e-Figure 125.2. Normal Doppler flow in a testis.** The upper half of the image shows the normal testis, with color signal filling vessels with moving blood. Insonation of a point in the upper third of the testis provides a spectral pattern that shows a classic arterial signal with its systolic and diastolic components above the baseline and a relatively unchanging and continuous venous signal below it.



**e-Figure 125.6. Appendix testis.** Longitudinal sonogram shows a small circular structure *(arrow)* extending off the testis *(T)* that is a normal appendix testis. It was readily seen on this image because of the presence of a large hydrocele.

mesonephron), which is attached to the head of the epididymis; and the vas aberrans (a remnant of the mesonephron), which is attached to the epididymis at the junction of its body and tail.[5–8]

## CRYPTORCHIDISM

***Overview.*** By 32 weeks' gestational age, the testes have descended into the scrotum via the inguinal canal in 93% of all male fetuses. By 6 weeks of age, only 4% of term infants have a nonpalpable testis. Of these infants, 20% have true cryptorchidism (undescended testis). Cryptorchidism is more common on the right (70%) and is bilateral in 10% to 33% of cases. Beyond the age of 1 year, the prevalence of true cryptorchidism is approximately 1%. The etiology of cryptorchidism is not clear; it may be hormonal or mechanical (e.g., lack of proper fixation of the testis or an abnormal gubernaculum), or a combination of the two.

***Imaging.*** US is the initial procedure for localization of a testis that is not palpable within the scrotum (e-Fig. 125.7). The undescended testis may be smaller and hypoplastic, although usually is of equal echogenicity to the contralateral normal testis. T2-weighted MRI with fat-suppression generally is more effective than CT for finding an intraabdominal testes. Normal testes have a homogeneous high signal on T2-weighted images.[5,9] Alternatively, exploratory laparoscopy can be performed to identify a suspected intraabdominal testis that cannot be palpated by a pediatric urologist.

***Treatment.*** Surgical treatment for undescended testes is orchiopexy, fixation of the testes within the scrotum. It is performed, especially in cases of intraabdominal testes, because of the increased risk for the development of testicular neoplasia (a 10–40 times greater risk, with seminoma being the most common neoplasm).[10] Spontaneous descent during the first year of life may occur from an endogenous surge of luteinizing hormone, and thus surgical correction typically is delayed until 18 to 24 months.[5,11] After orchiopexy, 53% of the originally undescended testes are reported to be abnormal by either position, volume, structure, or perfusion.[12–15]

## HYDROCELE

***Overview.*** Hydrocele, the most common scrotal mass in a child (Fig. 125.8), results from fluid accumulated between the layers of the tunica vaginalis. Several types of hydroceles are identified (Fig. 125.9). The processus vaginalis is closed in 50% to 75% of children at birth and in most of the remainder by the end of the first year of life. Residual fluid from testicular descent is responsible for the noncommunicating hydroceles reported in at least 15% of male fetuses beyond 28 weeks of life. If the processus vaginalis fails to close, a communicating hydrocele can develop.

In a hydrocele of the spermatic cord (a funicular hydrocele), the processus vaginalis is obliterated in its proximal and distal end, and the hydrocele is contained in the patent space between these two points. In an inguinoscrotal hydrocele, the processus vaginalis is obliterated only at the internal inguinal ring, and the hydrocele extends cephalad from the scrotum into the inguinal canal. In an abdominoscrotal hydrocele (e-Fig. 125.10), the funicular process at the internal inguinal ring remains patent, allowing a dumbbell-shaped cystic mass to protrude into the extraperitoneal space above the inguinal area.[16]

In most cases, the etiology of a hydrocele found in the child or adolescent is idiopathic. Acquired (commonly reactive) hydroceles can develop after scrotal trauma or as a complication of epididymitis-orchitis, testicular torsion, or in the presence of an intrascrotal neoplasm. A hydrocele that increases in size without an intrascrotal cause suggests the presence of a patent processus vaginalis and the possibility of an associated inguinal hernia.

***Imaging.*** Scrotal US shows the cystic (fluid) nature of the hydrocele as it appears to surround the normal homogeneously echogenic testis. Septations and debris may be present, particularly if the hydrocele is infected (i.e., a pyocele) or hemorrhagic (i.e., a hematocele) (e-Fig. 125.11). Echogenic debris (e.g., cholesterol crystals) may be seen in the fluid of chronic hydroceles (e-Fig. 125.12), along with occasional calcifications.

***Treatment.*** After the age of 2 years, a hydrocele is unlikely to resolve, and surgery is required. This consists of a high ligation of the patent processus vaginalis and emptying of the distal fluid collection.[17,18]

## TESTICULAR TORSION

***Overview.*** Torsion may occur at any age but is seen most often in adolescent boys between 11 and 18 years of age, perhaps because of the increase in testicular growth and weight during this time.

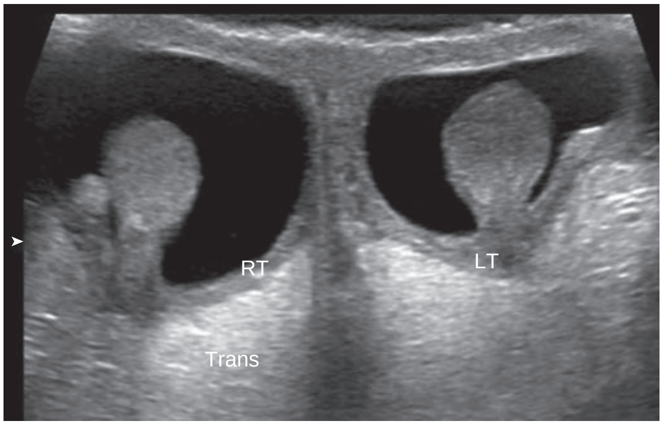


**Figure 125.8. Hydroceles.** Transverse gray-scale sonogram shows two normal testes appearing as echogenic structures within an enlarged fluid-filled scrotum of a young child due to large hydroceles. Note that the testes are normally affixed to the posterior scrotal wall.

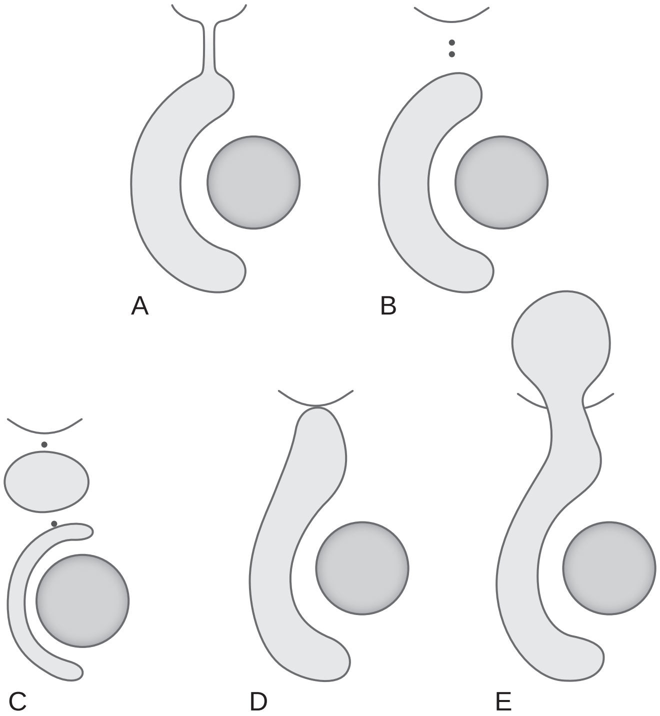

**Figure 125.9. Hydrocele types.** (A) Congenital or intermittent hydrocele. (B) Scrotal hydrocele. (C) Hydrocele of the cord. (D) Inguinoscrotal hydrocele. (E) Abdominoscrotal hydrocele.

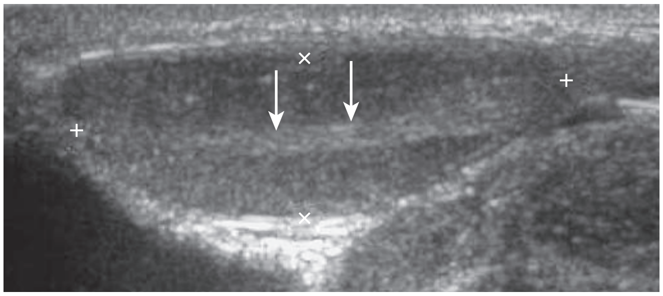
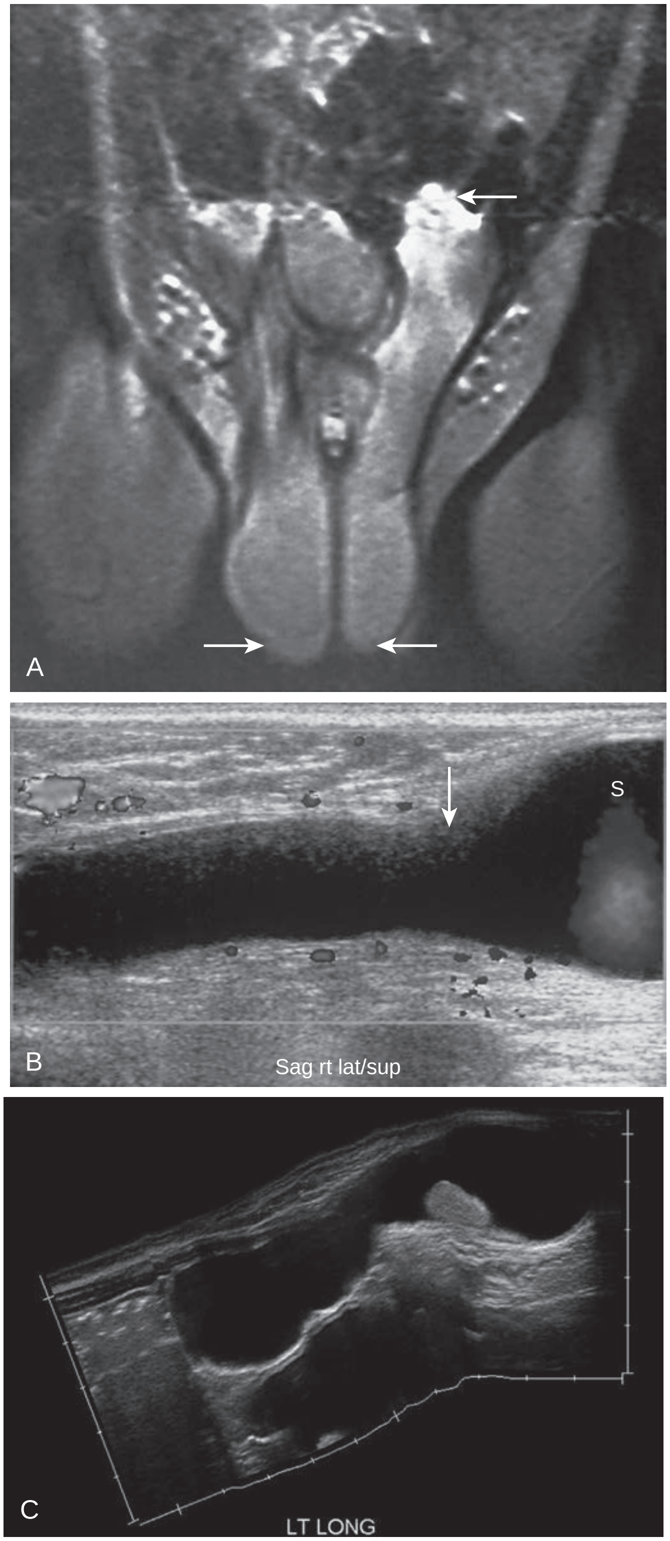
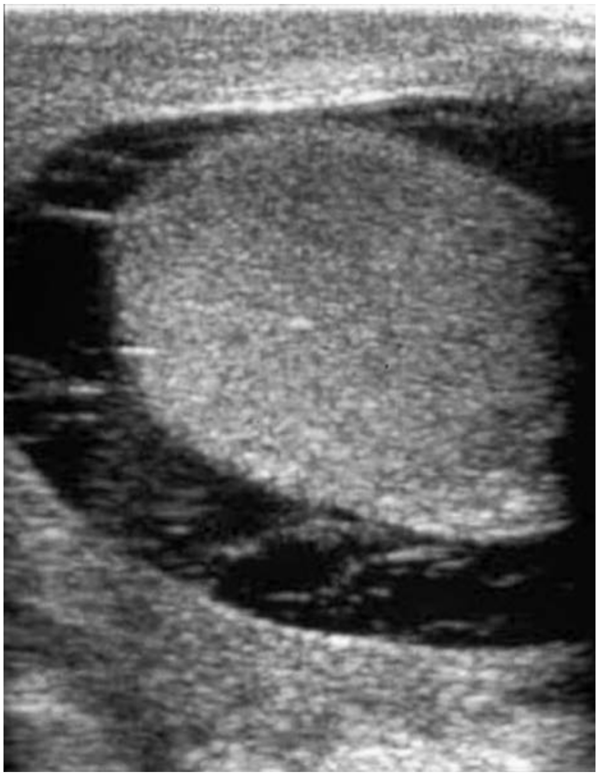


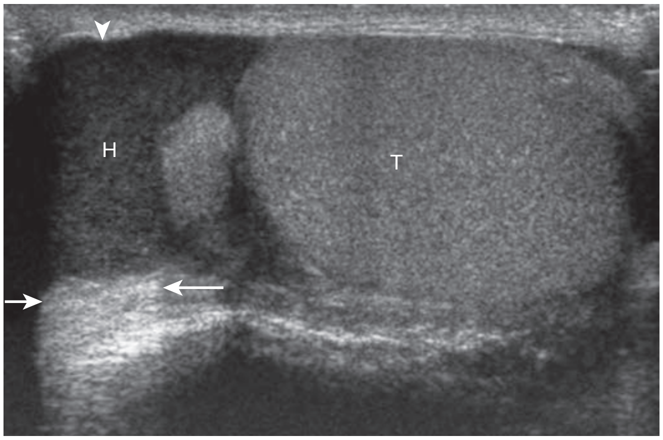
**e-Figure 125.7. Analysis of the inguinal region for undescended testis.** Longitudinal sonogram shows cursors *(graticules and x's)* marking off the borders of a normal undescended testis found in the right groin of a child. *Arrows* point to the mediastinum of the testis.



**e-Figure 125.10. Abdominoscrotal hydrocele.** (A) Tubular structures *(arrows)* are seen extending from each side of the scrotum superiorly into the abdominal cavity on a coronal T1-weighted magnetic resonance (MR) image. This child had bilateral abdominoscrotal hydroceles; the superior extent on the right is not well visualized on this image. He presented with an enlarged scrotum and palpable inguinal masses, the sizes of which changed with scrotal compression. (B) Longitudinal sonogram in another patient shows a right-sided tubular, fluid-filled structure extended from the scrotum *(S)* to above the inguinal area *(arrow)*. (C), Abdominoscrotal hydrocele in 6-month-old boy with scrotal swelling. *(A, from Cohen HL, Sivit C, eds.* Fetal and pediatric ultrasound: a casebook approach. *New York: McGraw-Hill; 2001. Reproduced with*



**e-Figure 125.11. Hematocele.** Longitudinal sonogram shows fluid containing echogenic material that surrounds the normal testis of a 14-year-old who was kicked in the scrotum several days before imaging.



**e-Figure 125.12. Chronic hydrocele.** Longitudinal sonogram shows echogenic debris-filled fluid due to a chronic hydrocele *(H)* in the scrotum of a teenager. Excellent through transmission of sound *(arrows)* helps indicate that the echogenic material is complicated fluid rather than solid material. *T,* Testicle.

The normal testis is strongly attached to the epididymis, which in turn is applied to the posterior scrotal wall. If these attachments fail to develop properly (the "clapper-in-a-bell" phenomenon), the testis, suspended within the tunica vaginalis, may rotate and the spermatic cord undergoes torsion. A male with acute testicular torsion experiences sudden acute scrotal pain, often accompanied by nausea and vomiting. An important finding on physical examination is a change in testicular axis from the normal vertical positioning of the testis in the scrotum to a more horizontal positioning (Fig. 125.13). Within hours of torsion, a reddened scrotum develops, with or without enlargement.

***Imaging.*** Ultrasonography is the only diagnostic tool necessary to make the diagnosis of torsion and suggest surgical exploration. The testis is normal sized to enlarged, with normal to decreased echogenicity (see Fig. 125.13). Enlargement and hypoechogenicity are thought to be due to venous congestion. The echotexture pattern is usually homogeneous early with heterogeneity increasing over time. Epididymal enlargement may be an early finding in some cases of torsion. At least 10% of cases of torsion have associated reactive hydroceles. US performed more than 24 to 48 hours after symptomatology may show a heterogeneous or hyperechoic testis from hemorrhage or hemorrhagic necrosis (Fig. 125.14).

State-of-the-art color or power Doppler imaging methods have made US the reference standard for the imaging and preoperative diagnosis of testicular torsion. Venous flow is lost before arterial flow ceases. Color flow comparison to the contralateral testis is helpful and necessary, particularly when torsion is incomplete. Such a partial torsion is suggested not by absence of arterial flow but by blood flow asymmetry. The spermatic cord should always be imaged and, when seen, should be straight. When torsion is present, a spiral twist (whirlpool sign or knot) can be seen. Flow may be normal or increased in a torsed testis that spontaneously detorses.[19–22]

***Treatment.*** Torsion must be corrected in a timely manner to preserve testicular viability. Surgery within 24 hours leads to 60% to 70% testicular salvage, but after 24 hours salvage is only 20%. Because abnormal testicular fixation to the scrotum is usually bilateral, preventive orchiopexy often is performed on the contralateral testis.[15]

## Testicular Torsion in the Fetus and Newborn

***Overview.*** Testicular torsion that occurs in the newborn period usually presents as a painless, firm scrotal mass often associated with bluish-red scrotal discoloration. The affected testis is generally nonviable. If the torsion occurred in intrauterine life, one is imaging the neonatal equivalent of delayed torsion. This form of torsion is considered extravaginal and is not associated with the "clapper-in-a-bell" deformity. Such torsions may be bilateral.

***Imaging.*** Antenatal torsion may be diagnosed on fetal US examination. Antenatal torsion must be considered if the fetal testis or testes are heterogeneous in echogenicity or of asymmetric size (Fig. 125.15). Diagnosis in the newborn is made by similar imaging findings.[23–26] Infarcted testes due to intrauterine torsion may be small and may be located in the inguinal canal. They may have an echogenic rim due to calcification or infarction of the more central testicular parenchyma (see Fig. 125.15).

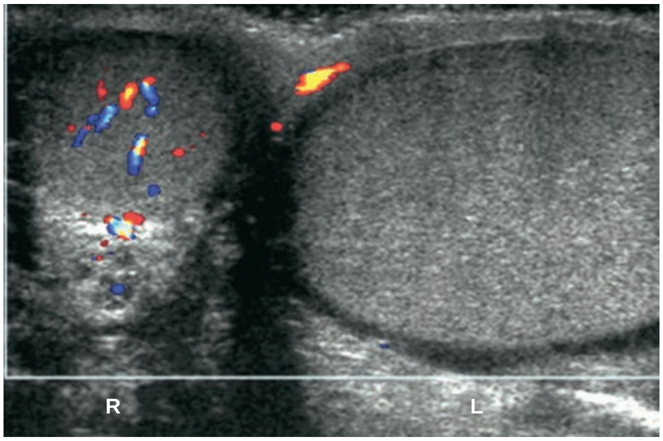


**Figure 125.13. Testicular torsion and axis change.** Color Doppler sonogram in the transverse plane shows flow in the right testicle. The right testicle is oval to circular, because it has been evaluated in the transverse plane. The left testicle is elongated as if it is in longitudinal plane, indicating an abnormal lie within the scrotum worrisome for torsion. Lack of color Doppler flow confirms left testicular torsion.

## Torsion of Testicular and Epididymal Appendages

***Overview.*** Testicular and epididymal appendage torsion occurs most often in the 6- to 12-year-old age group. Patients present with localized pain, a pea-sized mass in the area of the upper pole of the testis, and at times, a pinpoint discoloration (the "blue dot" sign) seen through the overlying scrotal skin. The clinical picture may be indistinguishable from that of testicular torsion, albeit in a somewhat younger age group.

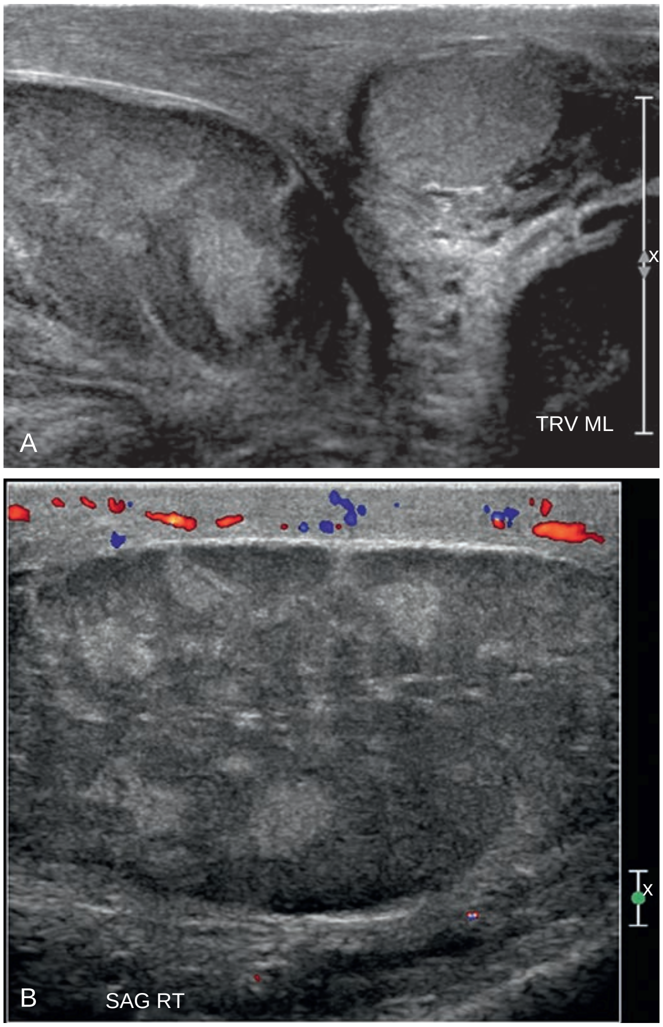

**Figure 125.14. Delayed diagnosis of testicular torsion in a boy with scrotal pain greater than 24 hours.** (A) Transverse sonogram shows an enlarged, heterogeneous right testis when compared with the left testis. (B) Longitudinal color Doppler image shows no blood flow within the right testis.

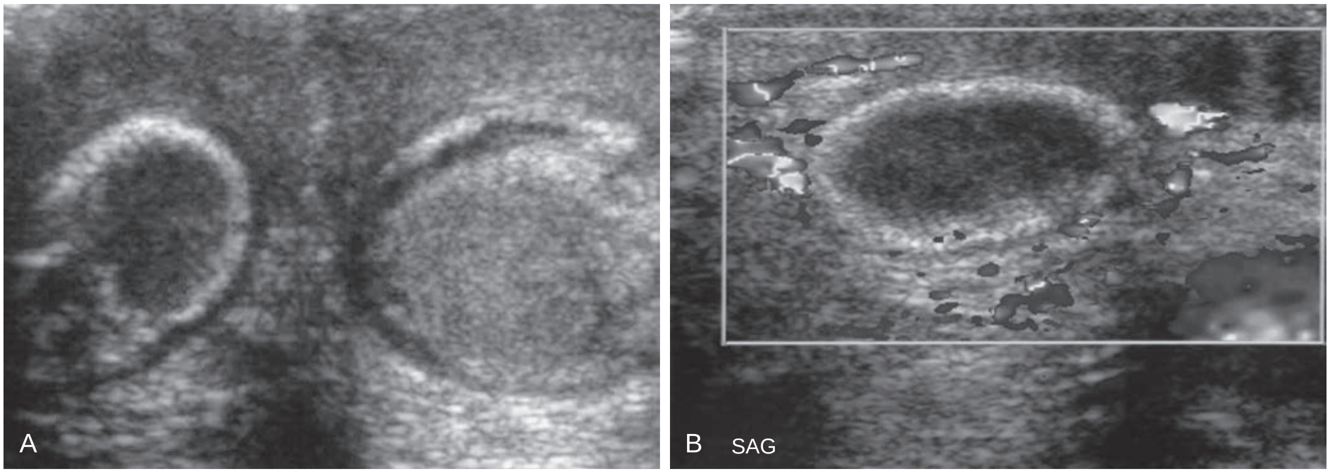

**Figure 125.15. Bilateral antenatal testicular torsion.** (A) Transverse sonogram shows two testes with torsion of different ages in a newborn with scrotal swelling. The testes are seen deep to a more superficial thickened scrotal wall. The right testis is hypoechoic with an echogenic rim, suggesting remote torsion. The more echogenic left testis does not appear particularly abnormal on this image, although its periphery is more echogenic than the remainder of its parenchyma. Color Doppler imaging showed no flow in either testis. Upon surgery, both testes proved to have undergone torsion. The torsion of the left testis probably occurred later in fetal life. Tiny hydroceles are present bilaterally. (B) Longitudinal color Doppler sonogram of the torsed right testis shows no color Doppler flow within the hypoechoic parenchyma.

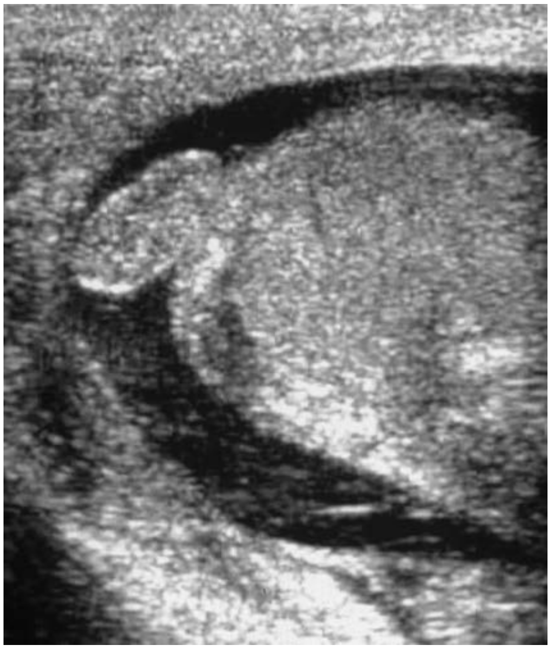

**Figure 125.16. Torsed appendix testis.** Longitudinal sonogram of the superior portion of the scrotum shows a prominent oval structure superior to the testis of a child who presented with sudden testicular pain. Some debris is present in a small surrounding hydrocele. Color Doppler imaging of the testis was normal, proving that no testicular torsion was present.

***Imaging.*** The US appearance of a torsed appendage shows it not to have its typical small comma-like shape but rather a larger circular or ovoid shape (Fig. 125.16). The torsed appendage can vary in echogenicity and is associated with the testis or epididymis on the affected side. Reactive epididymal swelling and hyperemia often are present. Usually the testicular echogenicity and vascular flow are normal.[23,27] Infarcted appendages may eventually calcify, appearing echogenic with posterior acoustic shadowing.

***Treatment.*** Appendage torsion generally is a self-limited disorder that responds to nonsteroidal antiinflammatory medications and comfort measures, such as limited activity and a warm compress. As the appendage infarcts and undergoes necrosis, the pain resolves. Surgical intervention is indicated when the symptoms are prolonged and spontaneous resolution does not occur.[28]

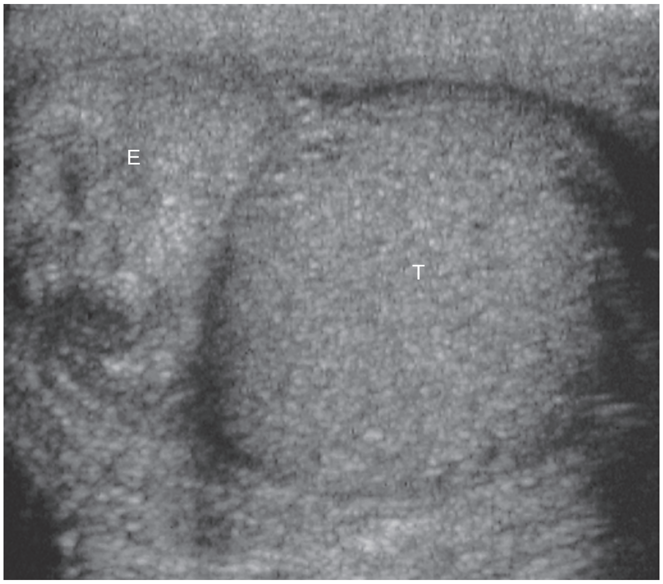
## EPIDIDYMITIS

***Overview.*** Epididymitis is the most common cause of an acute painful scrotum in the postpubescent male. The cause is usually bacterial, although in pediatric and some adolescent patients, epididymitis may be viral (e.g., as a result of the mumps virus). Patients with epididymitis often are febrile, and at least half report dysuria. Pyuria is common, and nausea, vomiting, and leukocytosis may be present. An enlarged epididymis may be palpated, and scrotal edema and tenderness often are present.

The infection usually reaches the epididymis through the spermatic ducts. Causative factors include urinary tract infections, urethral instrumentation and indwelling catheters, distal urethral obstruction, and reflux of urine from the urethra into the seminal ducts as a result of a congenitally patulous orifice, an ectopic ureter draining into the vas deferens, and an ectopic vas deferens draining into the bladder or ureter.

Complications of epididymitis include direct spread of the infection to the testis (i.e., epididymo-orchitis), which can be seen in as many as 20% of cases. Although it is an uncommon complication, an abscess may develop and require drainage. In unusual cases, acute epididymitis may impede testicular blood flow, resulting in focal or diffuse infarction of the testis or epididymis even in the absence of torsion.

***Imaging.*** US shows enlargement of the epididymis (e-Fig. 125.17) and commonly a reactive hydrocele or pyocele. Overlying scrotal wall thickening may be present. The echogenicity of the enlarged epididymis may be normal, slightly decreased, or slightly increased. The affected area of epididymis, although enlarged, usually maintains its normal shape. The diagnosis is supported by color Doppler imaging showing increased flow (Fig. 125.18). With epididymo-orchitis, a hypoechoic area of involvement is



**e-Figure 125.17. Epididymitis.** A longitudinal gray-scale sonogram shows that the left epididymis *(E)* of this teenager is very large and heterogeneous compared with the normal testis *(T)*.

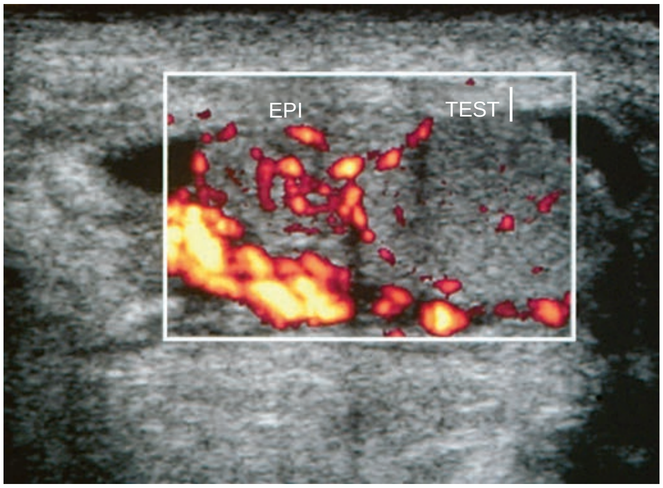


**Figure 125.18. Epididymitis in a child.** Longitudinal power Doppler sonogram shows that flow to the prominent right epididymis *(EPI)* of this 10-year-old child is greater than that to the testis *(TEST)*.

seen within the testis directly adjacent to the area of involved epididymis (e-Fig. 125.19). Color Doppler imaging usually shows increased flow to the involved portion of adjacent testis and the epididymis. In the prepubescent male, when epididymitis is the result of a congenital anomaly, a voiding cystourethrogram may be performed to detect abnormalities such as reflux of contrast agent into a vas deferens.[29–31]

***Treatment.*** Urine cultures should be obtained for all pediatric patients with epididymitis. Antibiotic therapy is reserved for young infants and those with pyuria and positive urine cultures.[32]

## HENOCH-SCHÖNLEIN PURPURA

***Overview and Imaging.*** Henoch-Schönlein purpura is a generalized vasculitis of unknown cause characterized clinically by a purpuric rash, abdominal pain, joint manifestations, and often hematuria secondary to glomerulonephritis. Involvement of the epididymis and less commonly the testis may result in scrotal swelling and tenderness. More often, however, the scrotum alone is involved by severe purpura and swelling. Imaging may be indicated to exclude testicular torsion. Imaging normal testes with normal flow despite marked edema of the scrotal wall helps suggest the diagnosis and can prevent the need to explore the scrotum surgically.[33,34]

## TESTICULAR AND PARATESTICULAR NEOPLASMS

### Primary Testicular Neoplasms

***Overview.*** Testicular neoplasms are uncommon in infants and children, representing only 1% to 1.5% of all childhood malignancies. When present, they tend to occur in very young children, with a peak incidence at 2 years of age and with 60% of the cases occurring in children younger than 2 years. Such tumors usually present as a painless, nontender, and firm scrotal mass often of weeks' to months' duration. Scrotal pain and tenderness may occur if associated torsion occurs. Testicular tumors occasionally are bilateral. Primary testicular tumors are classified according to their tissue of origin.

***Imaging.*** The predominant imaging tool used to search for and evaluate tumors of the scrotum and its contents is US. Most testicular neoplasms tend to be hypoechoic (e-Fig. 125.20). Contained anechoic areas within tumors represent either cystic components or more often are evidence of focal necrosis as the tumor outstrips its blood supply. Acute hemorrhage appears echogenic, and echogenic foci with posterior shadowing may be seen with intratumoral calcifications. Reactive hydroceles are associated in at least 15% to 20% of cases. Color Doppler and power Doppler US demonstrate increased vascularity in the majority of malignant tumors and may help define the mass itself. CT or MRI can be used to evaluate for retroperitoneal lymph node enlargement and search for solid organ metastases. Chest radiographs and CT are used to search for pulmonary metastases and thoracic lymph node enlargement.[5]

### Germ Cell Tumors

***Overview and Imaging.*** Most childhood testicular tumors (65%–75%) are germ cell in origin. Yolk sac tumor is by far the most common malignant germ cell tumor (80%–90%) in children. Three-fourths of yolk sac tumors are diagnosed by 24 months of age. Hemorrhage, particularly after clot dissolution, frequently causes echo-free areas within this typically hypoechoic, somewhat well-circumscribed mass. An elevated serum alpha-fetoprotein level is a tumor marker in approximately 90% of affected patients.[5]

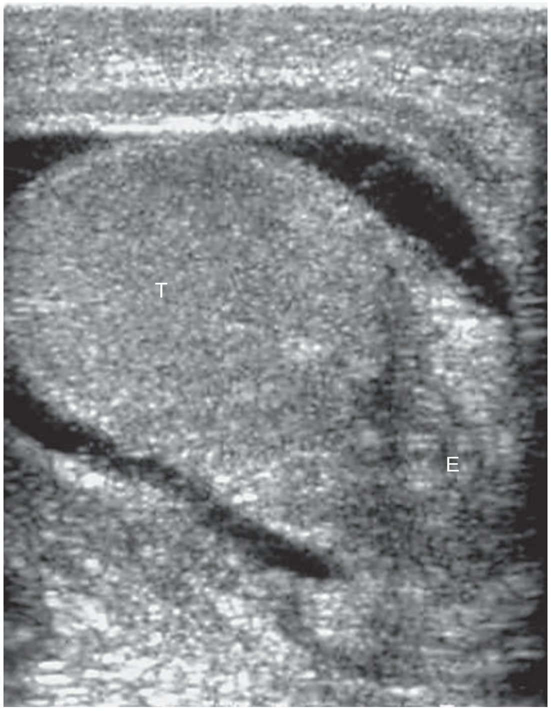
Testicular teratomas represent 10% to 15% of childhood germ cell tumors, with 65% of cases diagnosed before 2 years of age. They are composed of elements derived from all three germ cell layers and may contain may contain cartilage, bone, fat, and epidermal elements, such as keratin. Teratomas appear on US as complex masses with cystic and solid components (Fig. 125.21). Bony and dental elements are echogenic with posterior shadowing on US, whereas the adipose component appears echogenic but without shadowing. Prepubertal teratomas are said to almost always follow a benign course even if they contain islands of malignant germ cells (15%). Postpubertal teratomas, in contrast, are potentially malignant because of their propensity to develop components of other germ cell tumors, resulting in teratocarcinomas. Serum human chorionic gonadotropin level in these cases usually is elevated.[5,35]

### Gonadal Stromal Tumors

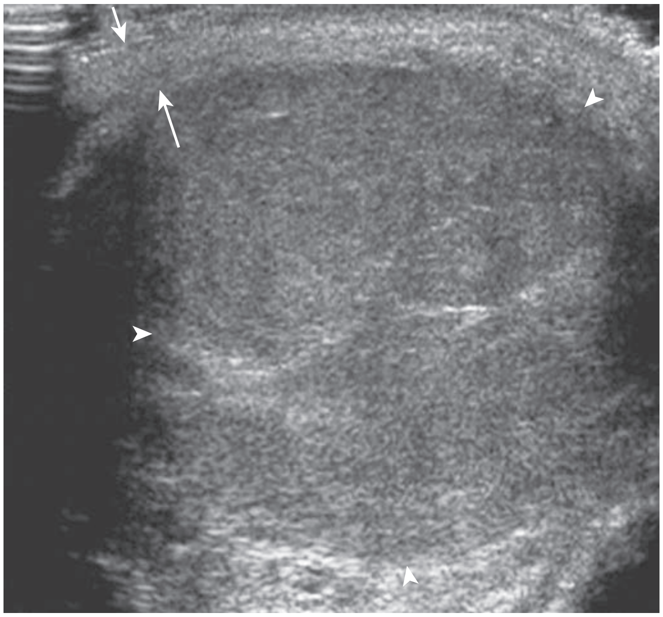
***Overview and Imaging.*** Non–germ cell testicular tumor types represent only 25% to 30% of pediatric testicular tumors. Leydig cell and Sertoli cell tumors represent the most common gonadal stromal tumors of childhood. They are almost always benign. Almost half (45%) of Leydig cell tumors are diagnosed between the ages of 2 and 9 years, with a peak incidence at 4 years of age. Leydig cell tumors typically are painless but may be associated with premature virilization (Fig. 125.22) if androgen is produced or with gynecomastia if estrogen is produced. Sertoli cell tumors represent 20% of the non–germ cell tumors. Half are diagnosed in the first year of life. Gynecomastia may be caused by estrogen production. Tumors containing a mixture of non–germ cell histologic patterns may occur.[5,36,37]

### Epidermoid Cyst

***Overview and Imaging.*** The epidermoid cyst, also known as a keratocyst, is a benign tumor of germ cell origin representing less than 1% of all testis tumors. It consists of a simple squamous cell–lined echopenic area located within the testicular parenchyma, usually just below the tunica albuginea. The wall is made up of fibrous tissue, and its lumen contains "cheesy" keratinized material or amorphous debris. Patients usually present with a painless 0.5- to 4-cm nodule that often is found incidentally on a routine physical examination. Four basic US appearances are seen, including a halo with central increased echogenicity, a sharply defined mass with peripheral calcification, and a solid mass with an echogenic rim. However, the classic appearance is a mass with an onion-skin



**e-Figure 125.19. Epididymo-orchitis.** A longitudinal gray-scale sonogram of the left testis shows that the scrotum is somewhat thickened, and a hydrocele is present. The echopenic portion of the epididymis *(E)* is seen inferiorly and is difficult to separate from the testis *(T)*. The testis is hypoechoic where it is in contact with the inflamed epididymis. The findings are consistent with extension of the infection into the testis.



**e-Figure 125.20. Testicular seminoma.** Longitudinal gray-scale sonogram in a 17-year-old with an enlarging scrotum shows a large mass *(arrowheads)* surrounded by a periphery of normal testicular parenchyma *(arrows)*. It is hypoechoic compared with the normal testicle, as is typical of most testicular neoplasms.

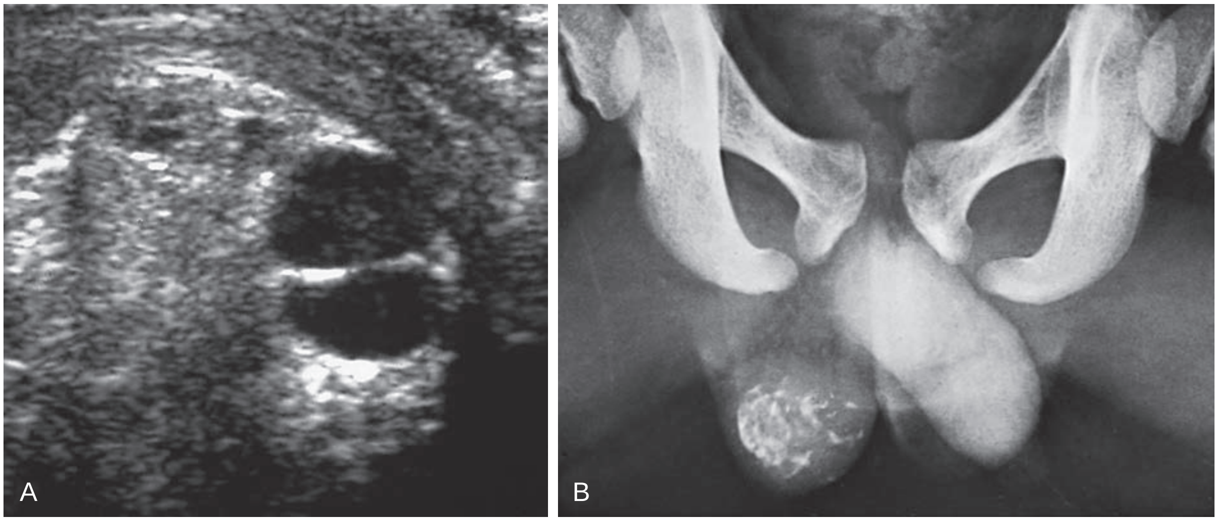


**Figure 125.21. Testicular teratoma.** (A) Transverse gray-scale sonogram of the right testicle shows a complex testicular mass with debris-filled cystic foci and surrounding hyperechogenicity. (B) A coned radiograph of the lower pelvis identifies a calcified right testicular lesion. *(Courtesy Dr. Leslie E. Grissom.)*

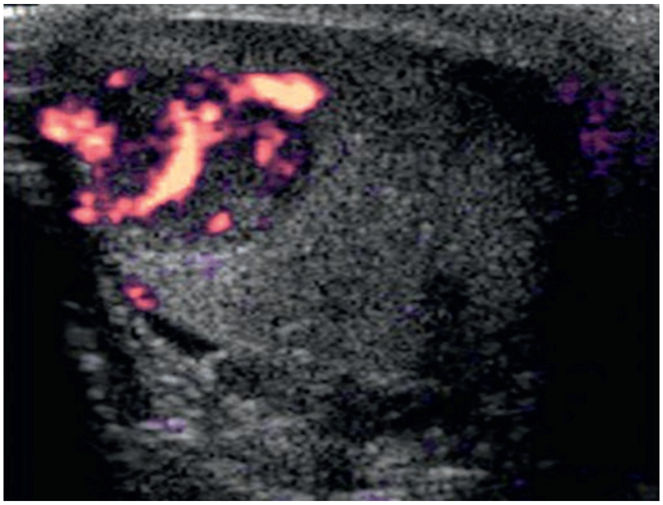

**Figure 125.22. Leydig cell tumor.** Transverse power Doppler image of the right testis in an 8-year-old boy with precocious puberty (early virilization) shows a round hypoechoic mass with associated increased blood flow.

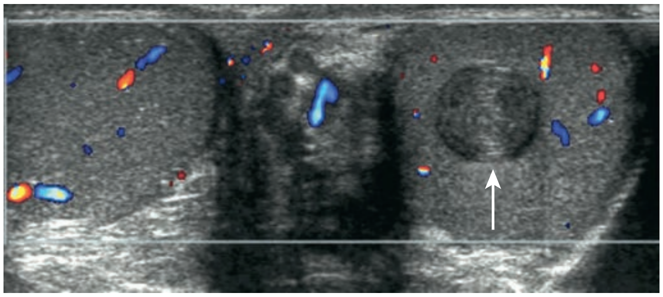

**Figure 125.23. Testicular epidermoid.** Transverse color Doppler sonogram in a teenager shows a normal right testicle. The left testicle contains an avascular mass *(arrow)* with onion skin layering, typical for a testicular epidermoid.

pattern of alternating hyperechoic and hypoechoic rings that is typically avascular (Fig. 125.23).[5,38–40]

## Secondary Testicular Neoplasms

***Overview and Imaging.*** Testicular metastases are rare in children, representing far less than 1% of testicular tumors. Leukemia and lymphoma are the most common causes. Enlarged testes caused by leukemic or lymphomatous infiltration may be the primary manifestation of these diseases or the first sign of relapse after bone marrow remission. The lesions often are bilateral. At least 8% of patients with acute lymphocytic leukemia have testicular involvement at some point during the course of their disease. These enlarged testes have focal or diffuse areas of decreased echogenicity (Fig. 125.24). Areas of hemorrhage appear echogenic, and lymphatic obstruction may lead to a hydrocele. Color Doppler imaging often shows significant increases in flow, often in an

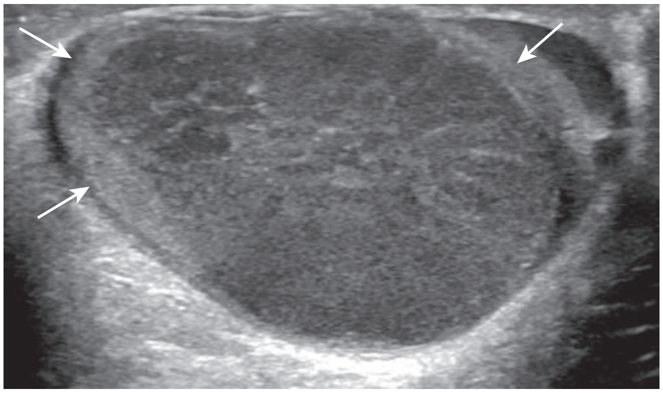

**Figure 125.24. Leukemia recurrence.** Longitudinal gray-scale scrotal sonogram in a 5-year-old boy with leukemia who was thought to be in remission. Patient presented with an enlarged scrotum. A large hypoechoic left testicular mass is seen with a small peripheral rim of normal testicular tissue *(arrows)*. The echopenic area proved to be due to leukemic involvement of the testis.

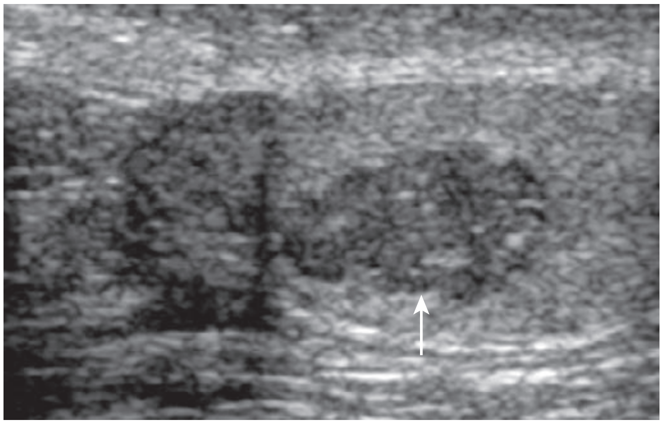

**Figure 125.25. Adrenal rests.** Longitudinal sonogram in a boy with congenital adrenal hyperplasia shows a hypoechoic mass *(arrow)* in the left testis.

asymmetric pattern related to the position of the infiltrating masses within the testis.

### Adrenal Rests

***Overview and Imaging.*** Adrenal rests are simulators of intratesticular tumors. At times, aberrant cells from the adrenal cortex may travel with gonadal tissue and be incorporated into the testis during fetal life. With high levels of adrenocorticotropic hormone and associated cortical cell stimulation (as in persons with congenital adrenal hyperplasia and Cushing syndrome), these rests may enlarge. Patients present with a testicular mass or enlargement. On US, one or more hypoechogenic or hyperechogenic masses generally are seen, typically along the mediastinum testis, usually bilaterally (Fig. 125.25). A typical color Doppler US pattern has been described in which multiple peripheral vessels radiate in a spokelike fashion from the centers of individual rests.[41,42]

### Testicular Microlithiasis

***Overview and Imaging.*** Testicular microlithiasis is characterized by calcifications within the lumina of seminiferous tubules. It is denoted on US by individual, tiny (1–3 mm), hyperechoic foci without shadowing (Fig. 125.26) within the testicular parenchyma. Some clinicians reserve the diagnosis for cases in which more than five microliths are noted on a single US image (classic or diffuse testicular microlithiasis). Testicular microlithiasis is reported in 2.4% of asymptomatic 0- to 19-year-old boys and also has been associated with cryptorchidism, infertility, male intersex, Klinefelter syndrome, and pulmonary alveolar microlithiasis. It usually is an incidental finding; however, there is a likely association between the presence of diffuse testicular microlithiasis and the presence or development of testicular neoplasm (reportedly 13–21.6 times greater than normal risk), particularly germ cell neoplasia (e.g., seminoma). Because of the association of microlithiasis and tumors, patients with testicular microlithiasis are sometimes followed up clinically and by US for possible tumor development.[43–47,47a]

## INTRASCROTAL EXTRATESTICULAR MASSES

### Paratesticular Rhabdomyosarcoma

***Overview and Imaging.*** Rhabdomyosarcoma is the most common malignant paratesticular mass in children, representing 10% of all intrascrotal tumors of childhood. It originates from the supporting stroma of the spermatic cord, testicular appendages, and paratesticular tunics and often is located superior to the testis. Two incidence peaks are seen for intrascrotal rhabdomyosarcoma, one at 2 to 4 years of age and the other between 15 and 17 years. Rhabdomyosarcomas present as a painless mass, grow rapidly, and frequently are large at presentation. They spread early to regional and retroperitoneal lymph nodes. Venous invasion and distant metastases, especially to the lungs, are not uncommon. On US examination, the mass is often heterogeneous, sometimes containing focal anechoic areas caused by necrosis (Fig. 125.27). As with all

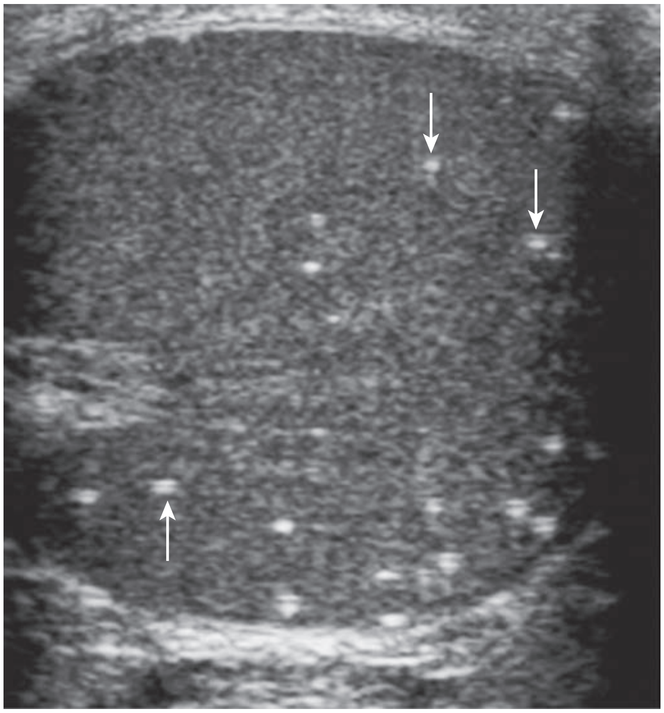

**Figure 125.26. Testicular microlithiasis.** Transverse gray-scale sonogram shows several small, nonshadowing, hyperechoic foci *(arrows)* in this right testicle of an older teenager. This finding was present bilaterally.

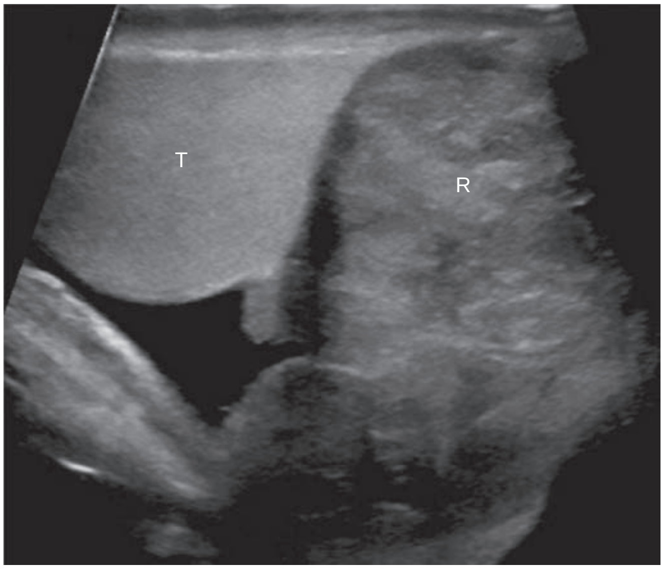

**Figure 125.27. Paratesticular rhabdomyosarcoma.** Longitudinal sonogram shows a large, heterogeneous mass *(R)* adjacent to a normal testis *(T)*. A small associated hydrocele is present.

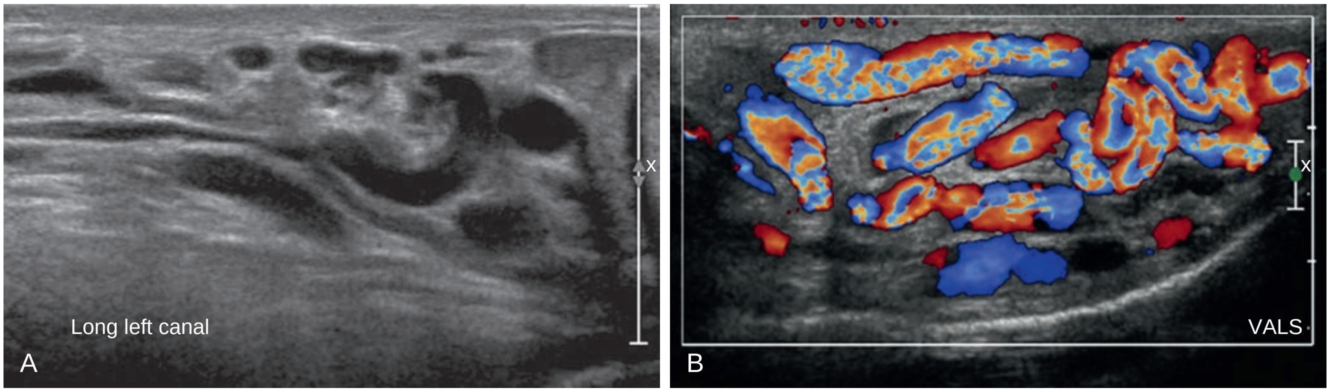

**Figure 125.28. Varicocele.** (A) Longitudinal gray-scale sonogram in a 12-year-old boy shows tubular anechoic structures in the left inguinal canal measuring up to 2 to 3 mm. (B) Longitudinal color Doppler image obtained during Valsalva shows color signal filling the tubular structures due to augmented retrograde blood flow.

### BOX 125.2 Grading of Varicoceles

**Grade I** (65%): Small varicoceles, appearing as only mild thickening of the spermatic cord
**Grade II** (25%): Moderate in size and consisting of a mass of veins up to 2 mm in diameter
**Grade III** (10%): Varicocele made up of individual veins greater than 2 mm in diameter

extratesticular masses, if the testes are invaded, differentiating the lesion from a mass of testicular origin may be difficult.

## Varicoceles

***Overview.*** Varicocele is a common pediatric scrotal mass, which is composed of dilated veins of the pampiniform plexus. Varicoceles are graded according to their size (Box 125.2). When they are unilateral, 99% of varicoceles are left-sided, perhaps because the left spermatic vein enters the left renal vein at a right angle. This anatomic situation is linked to a far greater incidence of venous incompetence compared with the right side, where the right spermatic vein enters the inferior vena cava directly at an oblique angle. The occurrence of bilateral varicoceles is common. However, finding a solitary right-sided varicocele is extremely uncommon, and, if found, the examiner must rule out an intraabdominal neoplasm or another mass as a cause.[5]

***Imaging.*** On US examination, varicoceles are tortuous, tubular, echo-free structures that typically are situated superior, lateral, and/or posterior to the testis (Fig. 125.28A). The diagnosis is confirmed by having the patient perform a Valsalva maneuver, supine or standing, and noting on color Doppler imaging that the tubular vessels, which may not show flow before the maneuver, will fill with color signal (Fig. 125.28B). Such increased flow may also be demonstrated by a change in the spectral Doppler waveform (e-Fig. 125.29).

***Treatment.*** Surgical or interventional varicocele ligation is recommended in cases in which ipsilateral testicular volume loss of 2 mL or greater occurs. Histologic analysis of such testes has shown various degrees of tubal hypoplasia, decreased spermatogenesis, focal fibrosis, or arrest of germ cell maturation.[5,48–53]

### KEY POINTS

- An undescended abdominal testis has a 10 to 40 times greater risk for a future malignancy.
- A hydrocele is the most common scrotal mass in a child.
- Testicular (and epididymal) appendages most typically torse in the 6- to 12-year-old age group.
- Epididymitis is the most common cause of an acute painful scrotum in the postpubescent male.
- Testicular torsion diagnosed in the newborn period can present as painless, firm scrotal mass(es) that appears heterogeneous when acute; in utero torsion may give rise to a small inguinal testis with peripheral calcification.
- Viable torsed testes undergo orchiopexy; nonviable testes are removed. Preventive orchiopexy is performed on the contralateral normal testis.
- Yolk sac tumor is the most common germ cell tumor in prepubertal children.
- Rhabdomyosarcoma is the most common malignant paratesticular mass in children.
- Unilateral right-sided varicoceles raise concern for an intraabdominal or retroperitoneal mass.

# Abnormalities of the Female Genital Tract

*Harris L. Cohen and Anand Dorai Raju*

## IMAGING TECHNIQUES

Ultrasound is the primary imaging modality to assess the pediatric gynecologic tract, its diseases, and the simulators of those diseases. Ultrasound provides quick evaluation of the uterus, ovaries, and cul-de-sac. Computed tomography (CT) and magnetic resonance imaging (MRI) provide a more global view of the pelvis and abdomen than does ultrasound, and they are preferred for the evaluation of tumor extent and metastases. The drawbacks of radiation exposure for CT and potential need for sedation/anesthesia for MRI are of particular relevance in pediatric patients.[1,2]

## OVARIAN AND UTERINE DEVELOPMENT

### Normal Ovary

***Overview and Imaging.*** The two ovaries are ovoid structures generally located posterior or lateral to the uterus within the mesovarium of the broad ligament (Fig. 126.1). Ovaries may be located anywhere along their embryologic course from the inferior border of the kidney to the broad ligament. Ovaries may be involved in indirect inguinal hernias, 15% of which occur in females. Herniated ovaries can extend as low as the labia (Fig. 126.2), the female equivalent of the scrotum.[1–4]

Ovarian volume can be estimated using the formula for a modified prolate ellipse: $0.52 \times L \times W \times D$. Length (L) and depth (D) usually are measured on a longitudinal (parasagittal) image, and width (W) is measured on a transverse view. In the first three months of life, when maternal hormonal stimulation is greatest, ovarian volumes average 1.06 $cm^3$ but have a range of normal as high as 3.6 $cm^3$. The high end of the range of normal is 2.7 $cm^3$ for 4- to 12-month-olds and 1.7 $cm^3$ for 13- to 24-month-olds. The mean ovarian volume reported for children older than 2 years who have not undergone puberty is 1 $cm^3$. For menstruating females, the mean ovarian volume typically is 6 to 9.8 $cm^3$.[5–9]

Ultrasound routinely identifies follicles or cysts in most girls of all ages. Cystic structures were noted in 80% of the imaged ovaries of a group of healthy children who were newborn to 2 years old, 72% of a 2- to 6-year-old group, and 68% of a 7- to 10-year-old group (Fig. 126.3). Macrocysts occasionally are seen in all age groups. The ovary is not a quiescent organ in childhood but rather is a dynamic organ undergoing constant internal change.[10]

### Normal Uterus

***Overview and Imaging.*** The uterus of the newborn has a mean length of 3.5 cm, which decreases to 2.6 to 3 cm by the

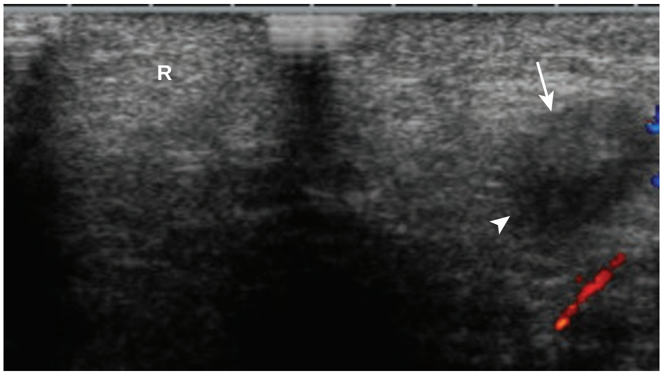

**Figure 126.2. Herniated left ovary.** Transverse color Doppler sonogram shows an unremarkable right labia *(R)*. The left labia contains a hypoechoic structure *(arrow)* with a likely cystic area *(arrowhead)*, proven to be a herniated ovary at surgery.

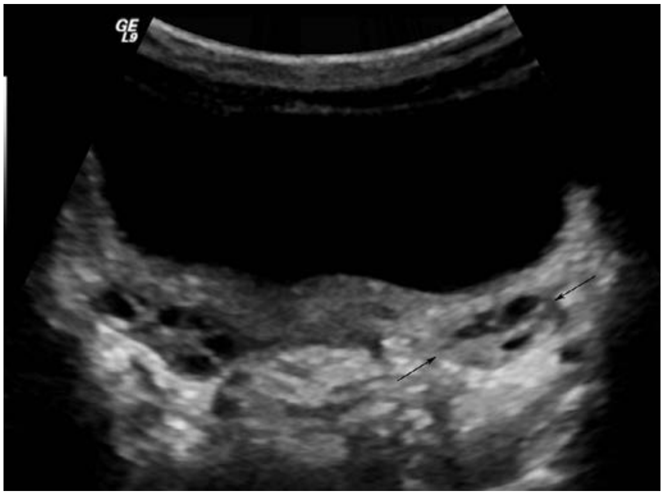

**Figure 126.1. Normal prepubertal ovaries in an 8-year-old girl.** Transverse gray-scale sonogram shows both ovaries located posterior to the bladder, containing a few small hypoechoic follicles. The left ovary is between the arrows.

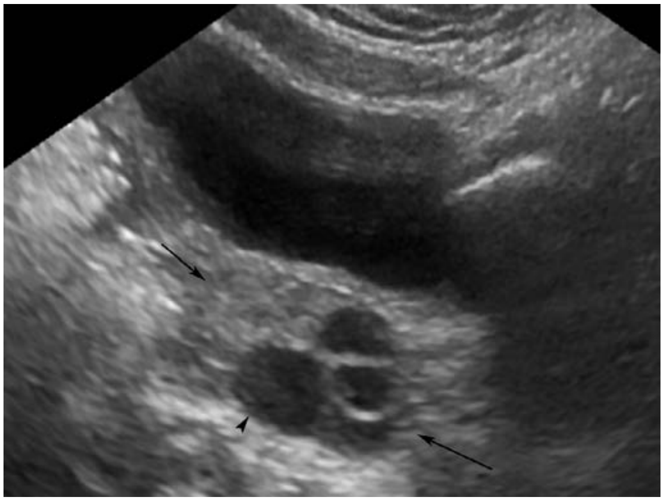

**Figure 126.3. Normal ovarian follicles in an infant.** Longitudinal gray-scale sonogram shows a normal ovary *(arrows)* in a 2-month-old. An *arrowhead* points to one of several prominent follicles seen in the ovary.

## Abstract:

This chapter reviews abnormalities of the female genital tract. It discusses imaging techniques and the imaging of normal ovary and uterus as well as non-neoplastic disorders of the pediatric and adolescent pelvis including Mullerian duct anomalies, causes of hydro and hematocolpos and hematometrocolpos, interlabial masses, pelvic inflammatory disease, ovarian cysts, hemorrhagic cysts and ovarian torsion. It discusses neoplasms of the pediatric and adolescent gynecological tract including vaginal, uterine and predominantly ovarian neoplasms including teratomas, dysgerminomas, cystadenoma and cystadenocarcinomas, granulosa cell tumor and sertoli leydig and leydig cell tumors.

## Keywords:

Pediatric ovary
Pediatric uterus
Mullerian duct system anomaly
Ovarian torsion
Hematometrocolpos

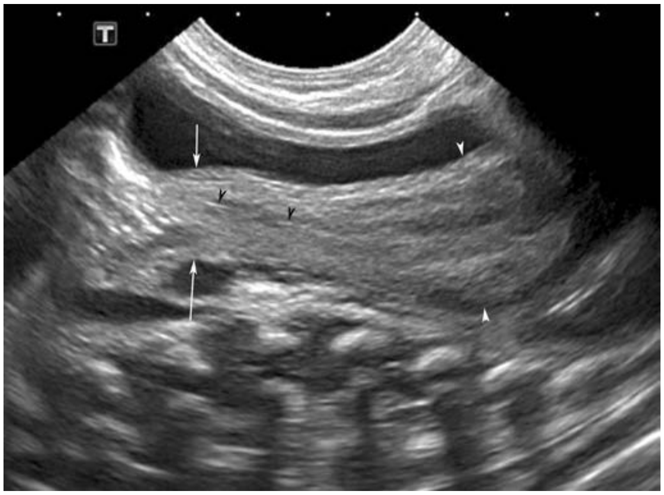

**Figure 126.4. Normal neonatal uterus.** A longitudinal sonogram shows a spade-shaped uterus posterior to the bladder. *White arrows* show a relatively narrow uterine fundus compared with the far wider cervix *(white arrowhead)*. Note the subtle central echogenic line *(black arrowheads)*, which is the coapted endometrial lining.

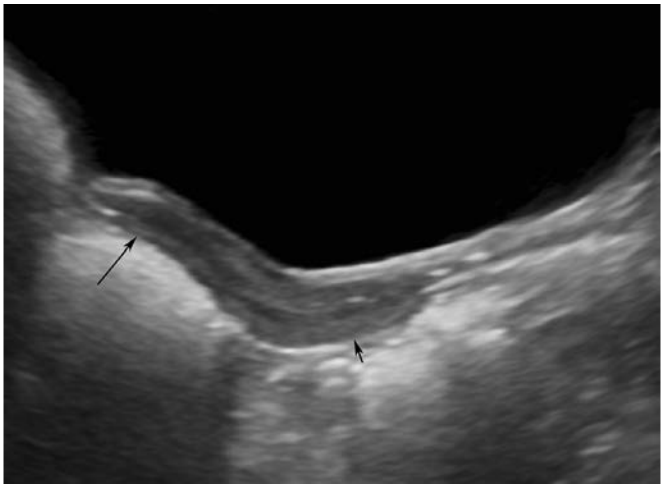

**Figure 126.5. Normal prepubertal uterus.** A longitudinal gray-scale sonogram from a 6-year-old girl shows a small, tubular-shaped uterus *(arrows)*. The cervix *(short arrow)* appears slightly larger than the uterine body and fundus *(long arrow)*. The uterus is smaller than the neonatal uterus shown in Fig. 126.4.

fourth month of life as maternal hormonal stimulation decreases. On ultrasound examination of a newborn's uterus, it is not uncommon to find either a hypoechoic halo around an echogenic endometrial cavity stripe or endometrial cavity fluid.[2,11] The typical newborn's uterus is shaped like a spade, with the anteroposterior diameter of the cervix as much as twice that of its fundus (Fig. 126.4). The newborn's cervix is also longer than the fundus. After the first year of life, the typical uterus is tube-shaped and remains that way for several years (Fig. 126.5).[2,12]

Uterine length increases gradually between 3 and 8 years of age. The mean perimenarchal measurement is 4.3 cm. After puberty and fundal development, the typical pear-shaped uterus measures 5 to 8 cm in length (Fig. 126.6). It is said to descend deeper in the pelvis and no longer maintains the typical neutral position of premenarchal life but instead may be anteverted or retroverted.[13]

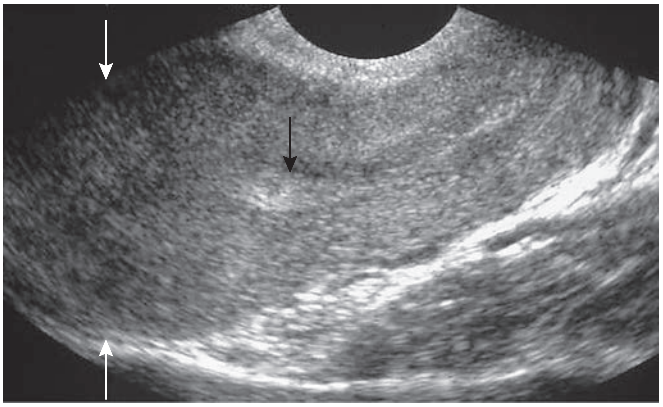

**Figure 126.6. Normal postmenarchal uterus.** Transvaginal longitudinal gray-scale sonogram from a teenager shows that the fundus is the widest part of the uterus (between the *white arrows*). The cervix, to the right, is far less wide. A *black arrow* points to the normally echogenic endometrial cavity.

## NONNEOPLASTIC DISORDERS OF THE FEMALE PELVIS

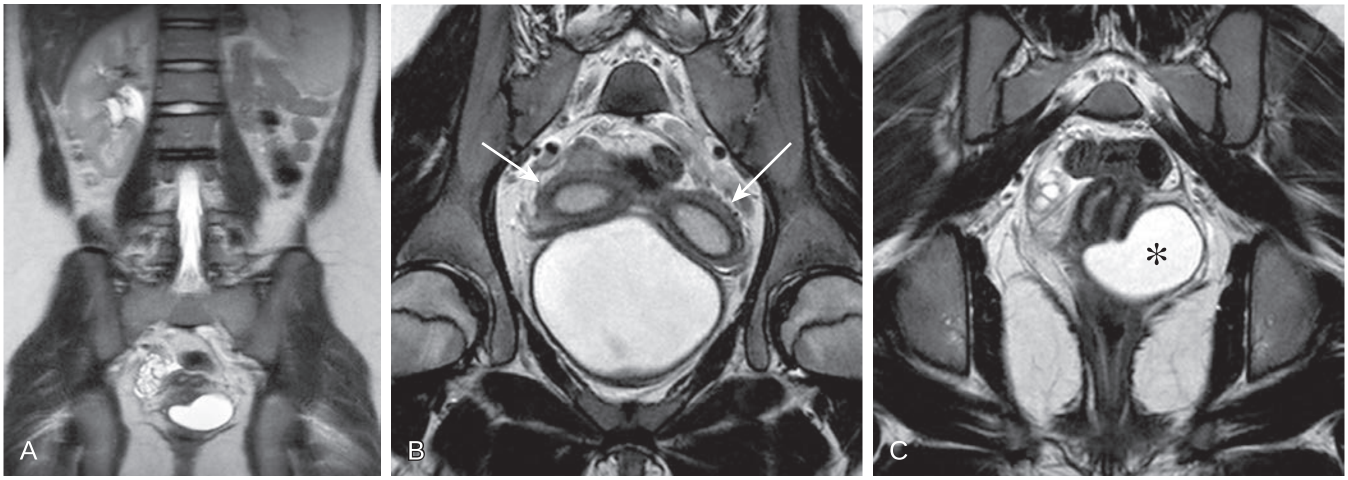
### Müllerian Duct Anomalies

***Overview.*** In females, the Müllerian duct system (MDS) normally develops into the fallopian tubes, uterus, and upper vagina, while the wolffian system involutes. External genital development proceeds along female lines except in the presence of androgens. By 11 weeks, a Y-shaped uterovaginal primordium has developed into the two fallopian tubes and fusion of a large portion of the bilateral MDS into a single uterus and upper vagina. Incomplete septal resorption of the fused bilateral MDS can lead to a septate uterus (which may extend into the cervix and vagina) or an arcuate uterus (generally considered a normal variant). Nonfusion or variably incomplete fusion of the MDS can lead to a wide spectrum of anomalies, including partial or complete absence of the uterus, fallopian tubes, and upper vagina (Mayer-Rokitansky-Küster-Hauser syndrome), uterus didelphys, and bicornuate uterus (Fig. 126.7). The association of uterine and renal anomalies is well established, including "obstructed hemivagina with ipsilateral renal agenesis (OHVIRA)," and when a gynecologic anomaly is present, one should evaluate the kidneys and urinary tract (e-Fig. 126.8) and vice versa.[14] While ultrasound may suggest anomalies of the MDS, postpubertal pelvic MRI is the imaging test of choice for characterization.

### Transverse Vaginal Septum and Imperforate Hymen

***Overview.*** In a girl with a transverse vaginal septum, the vagina is obliterated by fibrous connective tissue with vascular and muscular elements lined by squamous epithelium. The area of obliteration may be a thin membrane, but more commonly it involves a segment of the vagina (segmental vaginal atresia). The imperforate hymen is a thin membrane that forms at the junction of the caudal end of the MDS and the cranial end of the urogenital sinus. Both a transverse vaginal septum and imperforate hymen may present with an obstructed uterus and vagina.[11,15–18]

A distended vagina (colpos) or uterus (metros) is filled with secretions (muco), watery fluid (hydro), or blood (hemato). For example, hematometrocolpos is defined as hemorrhagic material filling a distended vagina and uterus. It is suggested on physical examination by either seeing an interlabial mass or palpating a pelvic mass. Clinical presentation in the teenage years includes amenorrhea



**e-Figure 126.8. Obstructed hemivagina with ipsilateral renal agenesis (OHVIRA).** (A) Coronal T2-weighted magnetic resonance (MR) image in a 13-year-old girl shows a normal right kidney; the left kidney is absent and bowel is present in the left renal fossa. (B) Coronal T2-weighted MR images shows two separate uteri *(arrows)*. (C) Coronal T2-weighted image shows two cervices. Imaging confirmed uterus didelphys. Fluid signal *(asterisk)* surrounds the left cervix and distends the left hemivagina due to an obstructing vaginal septum.

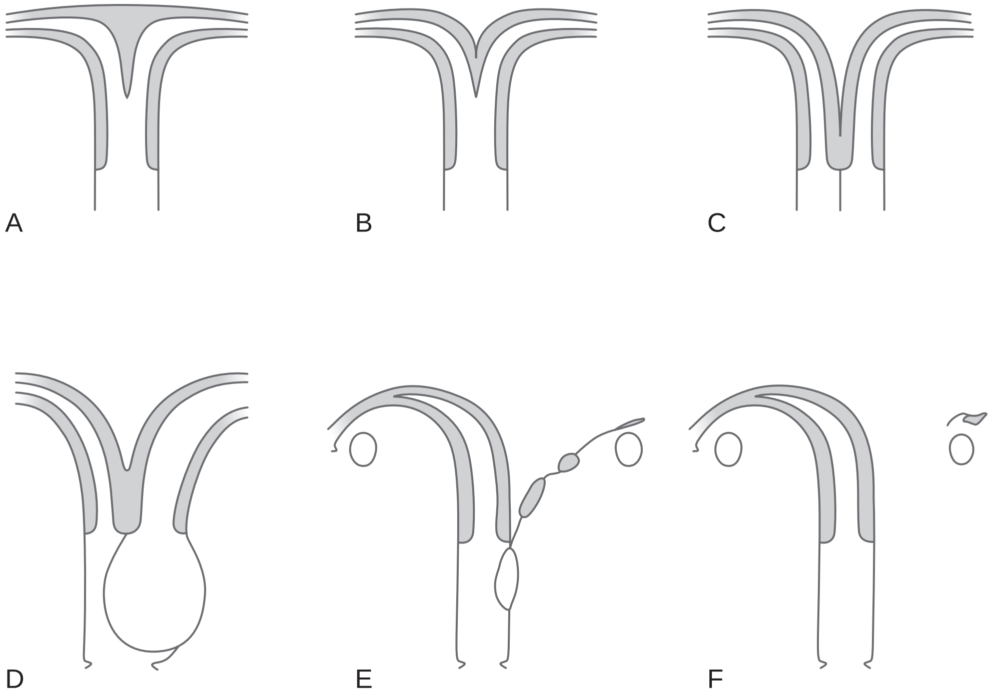


**Figure 126.7. Müllerian ductal system anomalies.** (A) Septate uterus. (B) Bicornuate uterus with single cervix. (C) Uterus didelphys with a septate vagina. (D) Uterus didelphys with congenitally obstructed hemivagina. (E) Unicornuate uterus with rudimentary hemiuterus (the rudimentary hemiuterus is nondilated, suggesting no functional endometrial tissue). (F) Unicornuate uterus with no rudimentary hemiuterus.

(despite normal development of secondary sex characteristics) and cyclic crampy abdominopelvic pains, or a pelvic mass resulting from accumulation of menstrual blood in the proximal vagina (and uterus and tubes). Complete or partial obstructions may occur in association with various MDS anomalies.[14,19–21]

***Imaging.*** Ultrasound images are similar in appearance whether seen in a neonate or a menarchal teenager. The distended vagina appears as a round or tubular cystic mass that usually is midline, often containing internal echoes from accumulated cervical mucus secretions or hemorrhage from sloughing of a hormonally stimulated endometrial lining. The uterus can be identified separately from the vagina by the thick muscular uterine wall, whereas the vaginal wall is thin. Pelvic MRI also can show the obstructed vagina and confirm the presence of blood products (Fig. 126.9).[14,15,22,23]

***Treatment.*** Vaginal obstruction detected in the neonate or infant is typically immediately corrected. In patients presenting with hematometrocolpos at puberty, the obstruction should be corrected as promptly as possible to avoid endometriosis from reverse spillage of menstrual blood into the peritoneal cavity through the fallopian tubes. Hysterectomy is indicated in patients with vaginal agenesis with a rudimentary uterus and a functional endometrium and in patients with cervical atresia occurring as an isolated lesion or in association with vaginal agenesis (forms of Mayer-Rokitansky-Küster-Hauser syndrome).[2,21–24]

## Interlabial Masses in Young Girls

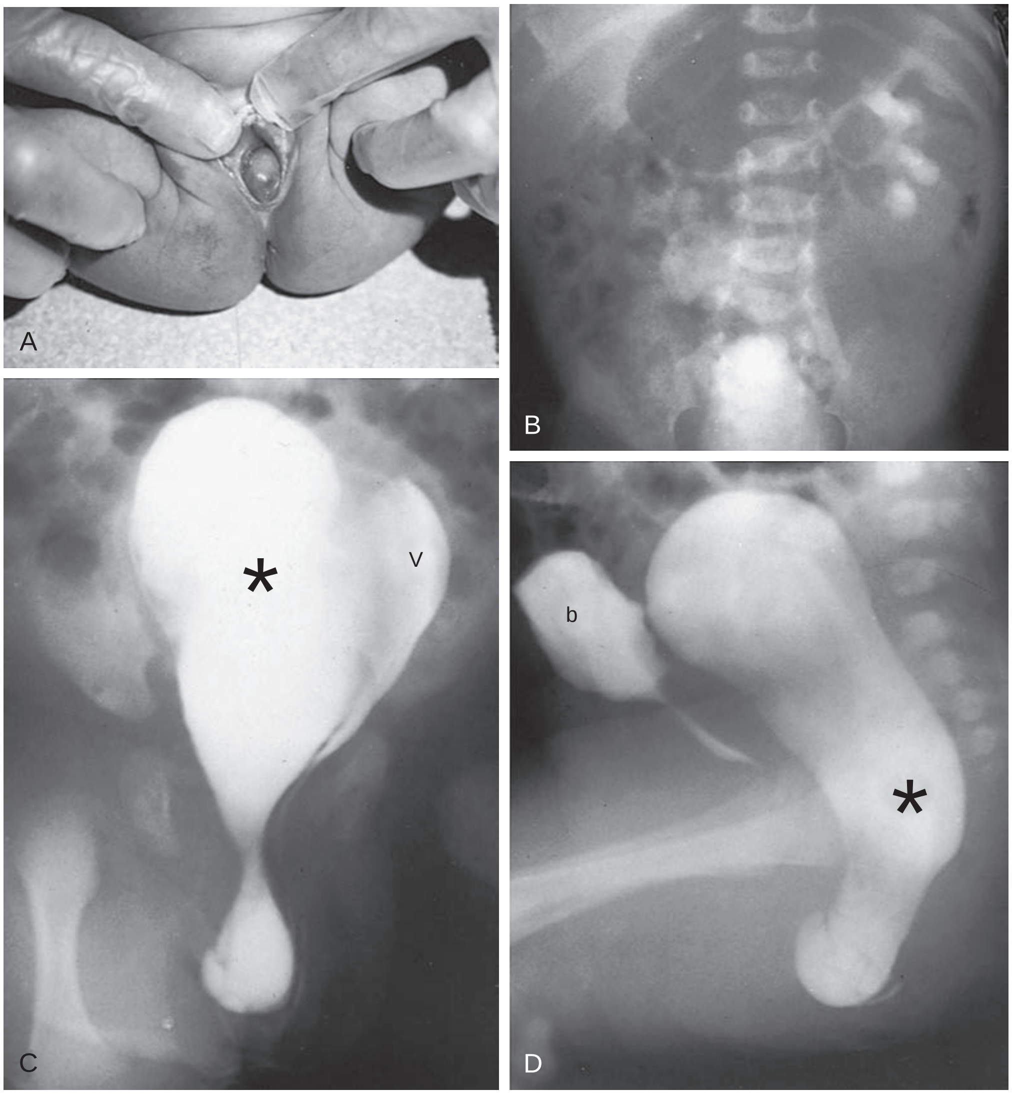
***Overview and Imaging.*** The differential diagnosis of interlabial masses is usually made on visual inspection based on the location and external appearance of the mass. Masses associated with the urethral orifice include prolapse of an ectopic ureterocele (identified as a small, reddened, doughnut-like mass with its central opening being the ureteral meatus itself) and cystic dilatation of an obstructed paraurethral (Skene) gland (presenting as a mass located on either side of a displaced urethral meatus). Masses associated with the vaginal introitus include prolapse of a vaginal cyst (a remnant of the wolffian or Müllerian duct systems or epithelial inclusions originating from elements of the urogenital sinus), an imperforate hymen (e-Fig. 126.10), cystic dilatation of an obstructed Bartholin gland, and prolapse of a sarcoma botryoides (embryonal rhabdomyosarcoma) of the vagina.[2,6]

A cystogram or vaginogram as well as ultrasound of the bladder and vagina may be necessary to further define the lesion. CT or MRI may help if continued anatomic questions remain. At times, only examination under anesthesia and surgical exploration are conclusive.[6,21]

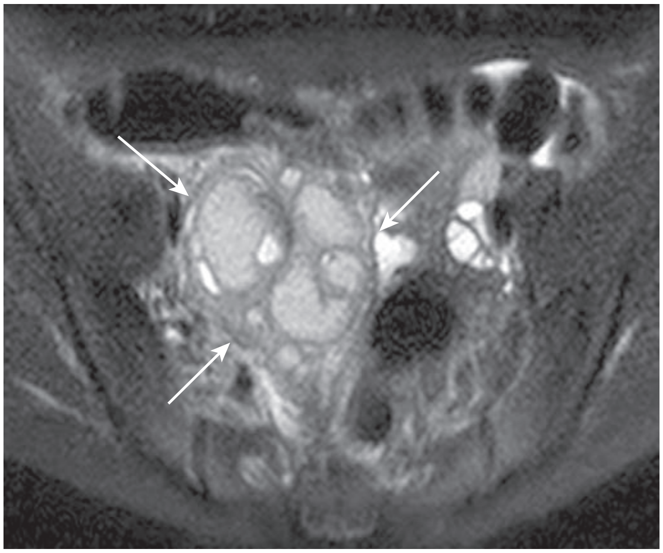
## Pelvic Inflammatory Disease

***Overview.*** Pelvic inflammatory disease (PID) is the most serious complication of sexually transmitted diseases. PID includes a spectrum of ascending infection that ranges from isolated endometritis to extension of infection into the Fallopian tubes (salpingitis) and ovaries (oophoritis), potentially resulting in a tuboovarian abscess (TOA), and even extension into the peritoneal cavity with resultant peritonitis. *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are the most common etiologic agents.[25,26] Clinical presentation includes lower abdominal/pelvic pain, purulent vaginal discharge, fever, leukocytosis, and an elevated erythrocyte sedimentation rate. Adnexal tenderness, generally bilateral, and cervical motion tenderness are hallmarks for the clinical diagnosis on physical examination.[25,26]

***Imaging and Treatment.*** Early in the course of PID or salpingitis, no abnormal ultrasound findings may be present, and the diagnosis will be based solely on clinical and laboratory evaluation. A helpful ultrasound finding in cases of salpingo-oophoritis is prominent ovaries that may be adherent to the uterus. More advanced cases of acute or, more often, chronic PID may demonstrate evidence of hydrosalpinx, pyosalpinx, or TOA (Figs. 126.11, 126.12, and e-Fig. 126.13). The affected fallopian



**e-Figure 126.10. Obstructed right hemivagina.** (A) A 2-day-old girl presented with a gray cystic mass at the vaginal introitus. (B) Intravenous urography shows no right renal function (probably because of an absent kidney). On frontal (C) and lateral (D) vaginograms, contrast material introduced through a needle inserted in the cystic mass at the introitus opacifies a markedly distended right hemivagina and uterus (unilateral hydrometrocolpos) *(asterisks)*. Contrast material from previous studies is still present in the patent left hemivagina *(V)* and bladder *(b)*.



**e-Figure 126.13. Pyosalpinx and tubo-ovarian abscess.** Axial T2-weighted fat-saturated MR image from a 14-year-old sexually active girl shows a mass *(arrows)* consisting of multiple round and ovoid intermediate signal structures in the right hemipelvis surrounded by inflammation. A normal right ovary was not identified. The left adnexa is normal.

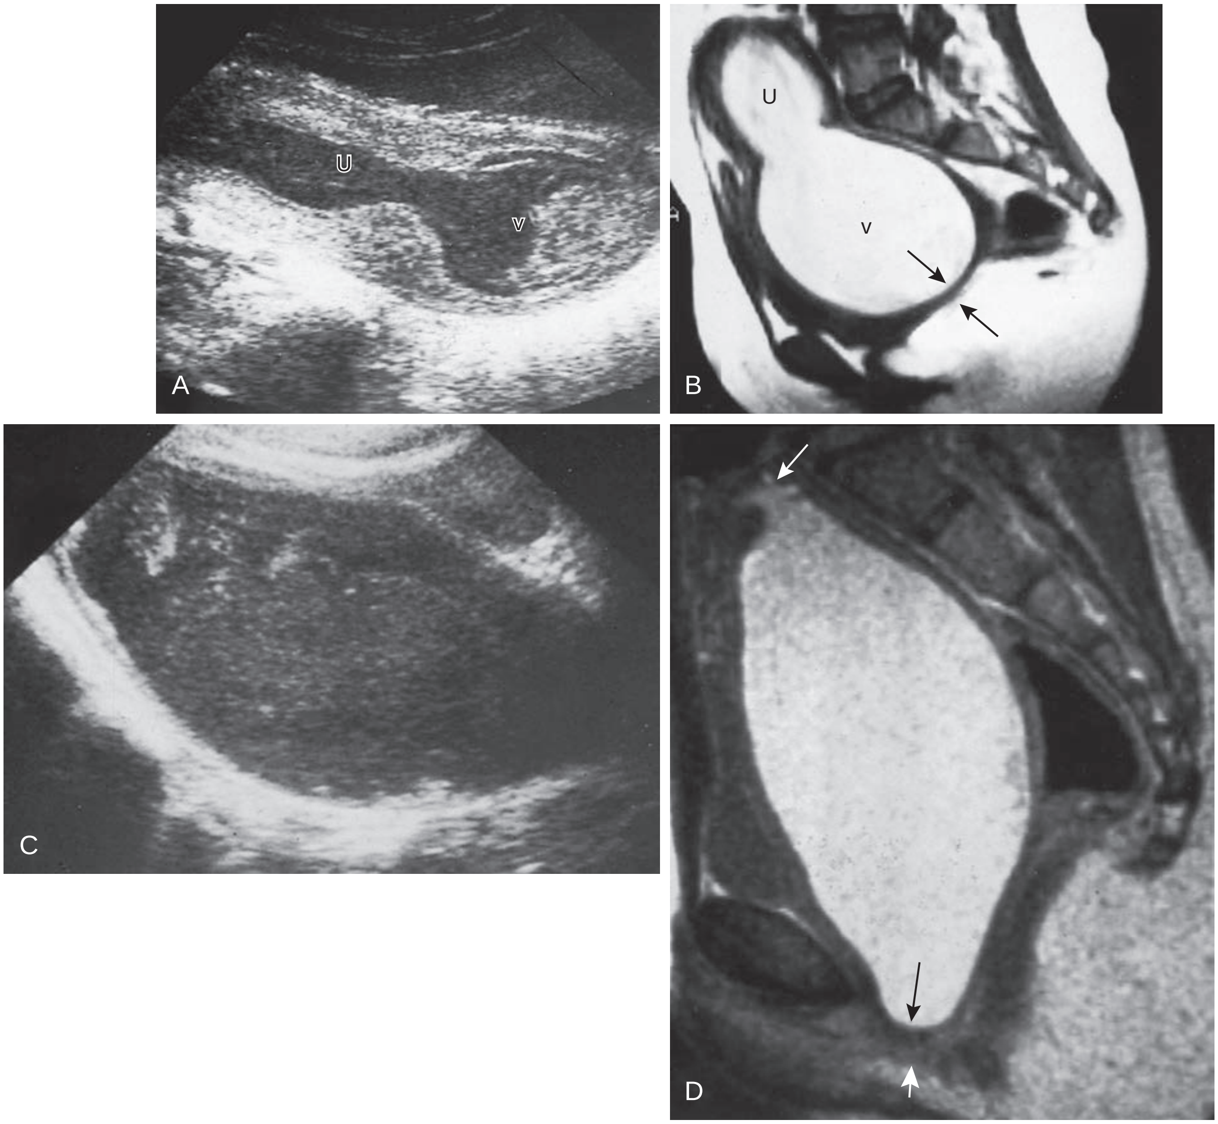


**Figure 126.9. Hematometrocolpos in two different girls.** (A) Longitudinal gray-scale sonogram shows a large midline cystic structure consistent with a distended vagina *(v)* and uterus *(U)*. The lower part of the vagina contains echogenic material. The external genitalia appeared normal on inspection. (B) Midline sagittal T1-weighted magnetic resonance (MR) image obtained for presurgical planning shows the enlarged vagina *(v)* and uterus *(U)* filled with material proven to be blood. The obstruction is at the level of the lower vagina and measures 0.5 cm in thickness *(arrows)*. At surgery, this was either a very low transverse vaginal septum or thick imperforate hymen. (C) Longitudinal gray-scale sonogram shows a large midline cystic structure containing debris, consistent with hematocolpos. (D) Midline T1-weighted MR image shows a markedly distended vagina filled with blood. The uterus *(long white arrow)* is not enlarged. The obstruction is at the level of the lower vagina and measures more than 0.5 cm in thickness *(between short white and black arrows)*. At surgery, the obstruction was found to be a thick transverse vaginal septum or short zone of vaginal atresia.

tube walls may be thickened with intraluminal linear echoes. The echogenicity of the fluid within the fallopian tube is not a reliable indicator of the presence or absence of infection. TOA appears on ultrasound as partial or complete replacement of the normal ovarian tissue by a heterogeneous mass or an echopenic region with contained debris. The contents of a suspected TOA often can be better evaluated by transvaginal ultrasound examination. CT and MRI can also be used to evaluate the extent of inflammation. TOA usually is treated aggressively with intravenous antibiotic regimens and, if necessary, percutaneous drainage or surgery.[26,27]

## Ovarian Torsion

***Overview.*** Ovarian torsion is caused by partial or complete rotation of the ovary on its pedicle, compromising first lymphatic flow, then venous drainage, and finally arterial inflow, leading to hemorrhagic infarction. Torsion of the ovary is most often seen in peripubertal or older girls. Ovarian torsion is often associated ovarian or paraovarian cysts or masses.[28,29] Classic ovarian torsion pain is sudden and acute. Associated complaints of nausea, vomiting, or constipation may occur and mislead the clinician; fever is rare. Leukocytosis with a left shift may be present. At least half of patients with ovarian torsion claim prior bouts of such pain, suggesting previous torsion and detorsion.[28,29]

***Imaging.*** Ovaries involved in torsion have a variable ultrasound appearance related to the degree of internal hemorrhage, stromal edema, and infarction that has occurred by the time they are imaged. The ovaries may appear cystic, cystic with septations, cystic with a debris layer, complex with mixed solid and cystic components, or solid. One relatively specific ultrasound image is a unilaterally enlarged solid ovary with multiple peripheral (cortical zone) follicles (Fig. 126.14).[30]

An ovary that has sustained acute torsion is generally much larger than a normal ovary. Reported volumes range from only 3.2 to 24 times normal, to ovarian volumes of 150 cm$^3$ or larger in postmenarchal patients. Comparison with the volume and morphology of the contralateral ovary may help make the diagnosis under the appropriate clinical circumstances.[29,30]

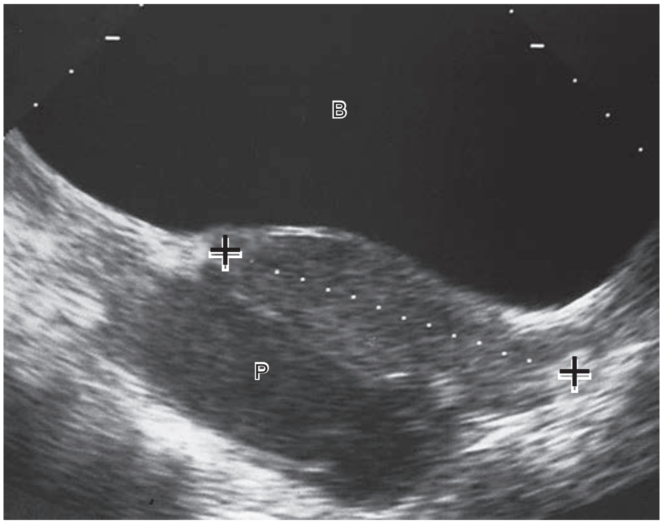

**Figure 126.11. Pyosalpinx.** Midline longitudinal gray-scale sonogram shows a fluid-filled tubular structure *(P)* containing debris, allowing through-transmission of sound, located posterior to the uterus *(cursors)*. *B,* Bladder.

Color Doppler imaging in the evaluation of cases of suspected ovarian torsion can sometimes be confusing. Well-documented cases exist of surgically proven torsed ovaries for which color Doppler imaging showed peripheral and even central arterial flow. Other investigators have reported that an assurance of viability can only be made by imaging central venous flow in an ovary that has undergone torsion. An 87% diagnostic accuracy for determining viability is reported by verifying blood flow changes at the twisted vascular pedicle itself. Patients with no blood flow at the twisted pedicle may have necrotic ovaries.[31–33]

A fallopian tube may rarely torse without torsion of the associated ovary (Fig. 126.15). When this occurs, patients may have sudden pain or nonspecific complaints. A cystic, sometimes tubular or C-shaped structure may be seen at ultrasound, CT, or MRI, and may be mistaken for acute appendicitis.

***Treatment.*** It is hoped that detorsion and, if necessary, removal of a mass causing torsion will save the gonad and preserve its function. The time from clinical complaint to diagnosis and treatment plays a large role in preserving ovarian function. Doppler imaging may have a role in assessing the recovery of an ovary that has undergone torsion in follow-up studies after surgical detorsion.[1,35,36] The role of oopheropexy remains controversial.

## Nonneoplastic Ovarian Cysts

***Overview and Imaging.*** Nonneoplastic cysts of follicular origin (i.e., functional ovarian cysts) are the most common cause of ovarian enlargement. Beyond puberty, the adolescent ovary is similar to that of the adult, developing several follicles early in the menstrual cycle until a dominant follicle develops and ruptures at midcycle, while the others atrophy and resorb. Occasionally, one or more of these follicles fails to resorb and instead enlarges as a functional or retention cyst. These cysts can reach a large size but usually are no larger than 3 cm. The classic cyst on ultrasound examination is echoless with a sharp back wall and excellent acoustic through-transmission. Most functional ovarian cysts are treated conservatively and resolve spontaneously. If there is concern for a neoplastic etiology, a 6-week follow-up ultrasound evaluation allows analysis of cyst in the other half of a different menstrual cycle, thus

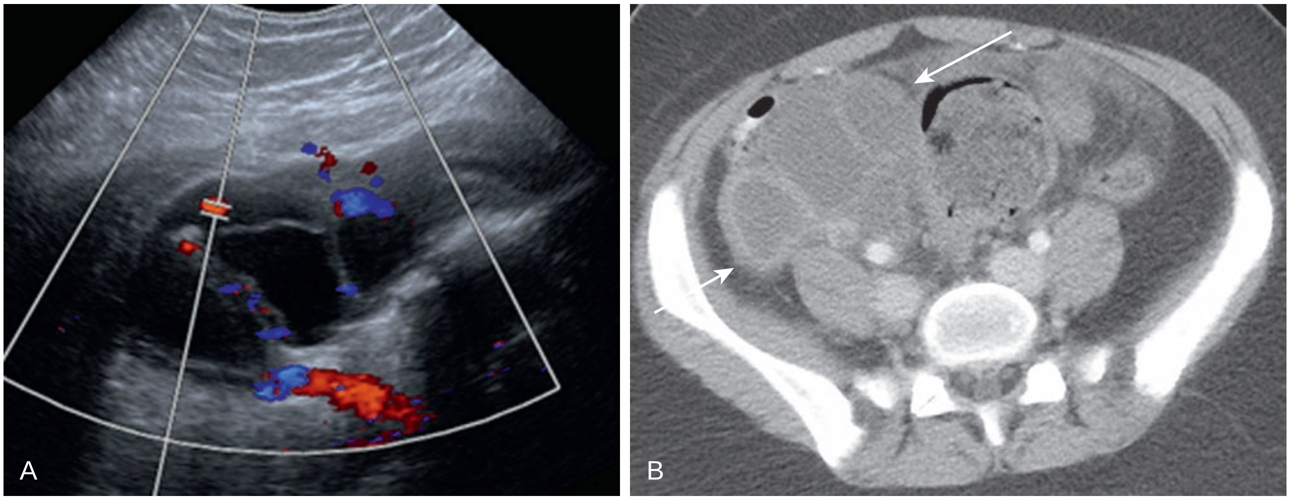

**Figure 126.12. Tubo-ovarian abscess from pelvic inflammatory disease.** (A) Color Doppler image through the right adnexa in a 16-year-old girl shows multiple fluid-filled structures with a discrete wall. (B) Axial contrast-enhanced CT image shows multiple peripherally enhancing fluid-filled structures *(arrows)* in the right lower quadrant, proven to be a tubo-ovarian abscess. Percutaneous image-guided needle aspiration yielded streptococcal species.

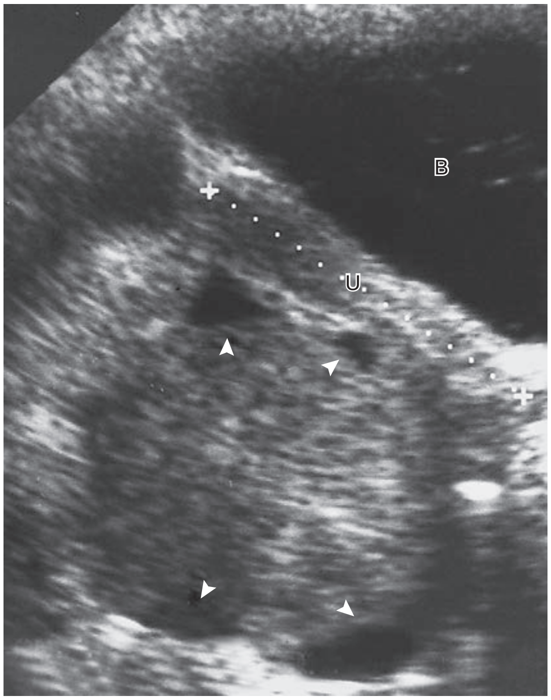

**Figure 126.14. Ovarian torsion.** Longitudinal sonogram shows a tubular uterus *(U*; *cursors)* that is posterior to the bladder *(B)* and anterior to a large solid mass with a few peripheral cysts *(arrowheads)*. This is a classic image of acute ovarian torsion. Infarction or acute hemorrhage would make the internal contents of the ovary more heterogeneous. *(From Cohen HL, Safriel YI. Ovarian torsion. In: Cohen HL, Sivit C, eds.* Fetal and Pediatric Ultrasound: A Casebook Approach*. New York: McGraw-Hill; 2001:516.)*

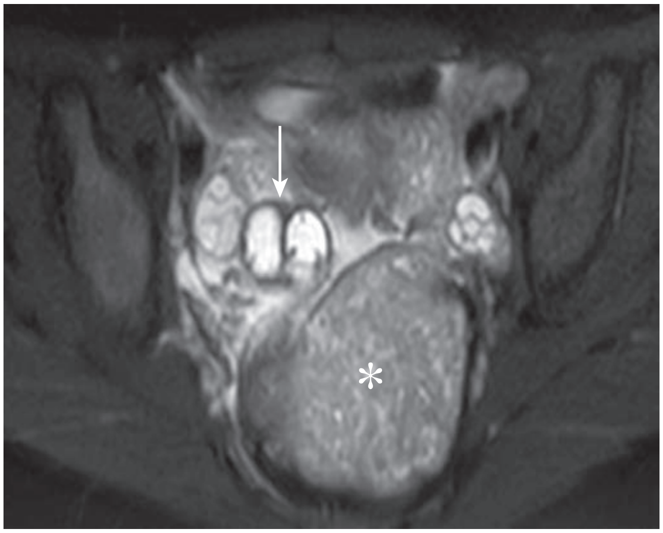

**Figure 126.15. Isolated fallopian tube torsion.** Axial T2-weighted fat-saturated MR image in an 11-year-old girl with suspected acute appendicitis shows two round fluid-filled structures *(arrows)* in the right adnexa adjacent to the normal right ovary. There is extensive inflammation in the right hemipelvis. A large amount of stool is present in the rectum *(asterisk)*. Surgical exploration confirmed isolated fallopian tube torsion.

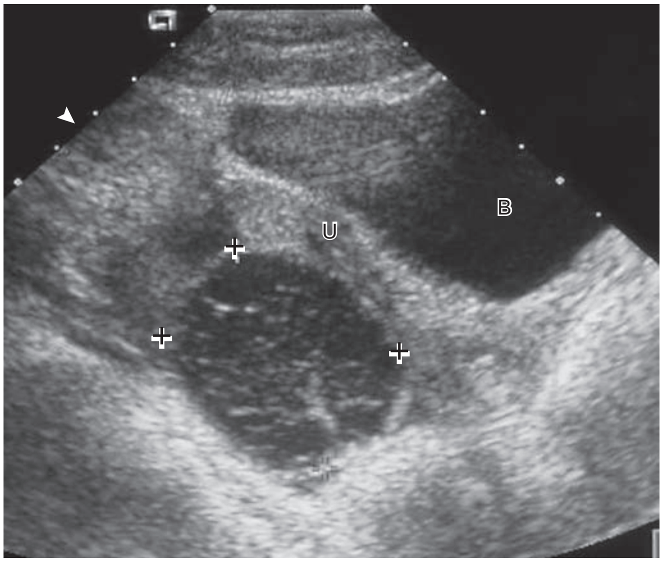

**Figure 126.16. Hemorrhagic ovarian cyst.** Longitudinal gray-scale sonogram shows a hypoechoic mass *(cursors)* containing mesh-like linear echogenicities in the adnexal area of a 12-year-old girl with acute abdominal pain. A tubo-ovarian abscess and endometrioma may look similar but present with different clinical scenarios. *B,* Bladder; *U,* uterus.

documenting resolution or diminution, and, thereby, helping to prove that it is a physiologic cyst and helping to disprove cystic neoplasm.[36–39]

### Hemorrhagic Ovarian Cysts

***Overview.*** Functional cysts may develop internal hemorrhage, which occurs when theca interna vessels rupture into the cyst cavity. Such hemorrhagic ovarian cysts can arise from ovarian follicles at any stage in their maturation, even as they involute. The typical clinical presentation of a hemorrhagic ovarian cyst is commonly sudden, severe, transient lower abdominal or pelvic pain of 1 to 3 hours' duration. The pain is thought to result from sudden distention of the ovarian cyst by the hemorrhage.[40]

***Imaging.*** Most hemorrhagic ovarian cysts are heterogeneous in echogenicity. There may be hypoechoic or hyperechoic areas separated by thin or thick linear echoes of various orientations (Fig. 126.16), echoless with a contained focal echogenicity of variable size clot, contain fluid-debris levels, or appear as a solid mass when clot fills the cyst. A changing ultrasound appearance over time can help confirm the diagnosis as the clot lyses and cyst resolves.[37,40]

## Polycystic Ovary Syndrome

***Overview.*** Polycystic ovary syndrome (PCOS; also known as *Stein-Leventhal syndrome*) is a hyperandrogenic state with resultant peripheral conversion of larger than normal amounts of estrogen. The chronic hyperestrogenic, hyperandrogenic stimulation leads to chronic anovulation and is responsible for the classic bilaterally enlarged ovaries, which may be asymmetric but usually contain numerous small follicles/cysts. PCOS is the most common secondary cause of amenorrhea in adolescents and young adults. Patients sometimes, but far from always, experience the classic triad of obesity (31%), hirsutism (62%), and menstrual abnormalities (80%), including amenorrhea, irregular menses, and prolonged uterine bleeding. Laboratory diagnosis is made by noting an increased luteinizing hormone: follicle-stimulating hormone ratio and elevated androstenedione level.[41]

***Imaging.*** A helpful indicator of PCOS is increased ovarian echogenicity, which is thought to be due to ovarian stromal hypertrophy and considered to be evidence of hyperandrogenism. Persons with PCOS have high numbers of subcapsular follicles in their ovaries (Fig. 126.17). Typically, numerous cysts of 5 to 8 mm in diameter are noted on transabdominal ultrasound evaluation of each ovary; a greater number of cysts may be appreciated on transvaginal examination. Follicles of classic cases should not be larger than 10 mm in diameter. Larger follicles or the presence of a single large (dominant) cyst makes the diagnosis of PCOS unlikely. Ovarian volumes may or may not be greater than the mean for their control group.[42–45]

## NEOPLASMS OF THE GYNECOLOGIC TRACT

### Vagina and Uterus

***Overview and Imaging.*** Embryonal rhabdomyosarcoma is the most common genital neoplasm in children of both sexes. It generally is seen before the age of 3 years, is rarely noted at birth, and is uncommon but can occur in older female patients. Urogenital sinus remnants are thought to be the origin of some rhabdomyosarcomas, usually originating from the anterior vagina near the cervix. Occasionally, they may arise from the cervix. The mass may protrude from the vaginal introitus, often with a polypoid or cluster-of-grapes appearance (sarcoma botryoides). These rhabdomyosarcomas are aggressive tumors that spread rapidly by direct invasion of the vaginal wall and pelvic structures. The tumor may extend to the uterus, bladder, ureters, or rectum. Metastases to regional lymph nodes, the lungs, and other organs may occur. Local recurrence is common.[46–48]

Endodermal sinus tumor of the vagina, also known as yolk sac carcinoma or adenocarcinoma of the infant vagina, usually is seen in infants between 8 and 15 months and rarely after the second year. It often originates in the posterior wall of the vagina (e-Fig. 126.18) and may have a polypoid appearance very similar to that of sarcoma botryoides. The tumor spreads to pelvic soft tissues, pelvic and retroperitoneal nodes, liver, and lungs.[46,48]

Clear cell (or mesonephric) adenocarcinoma usually originates from the vagina and uncommonly from the cervix. It usually is seen after menarche. In the past few decades, about two-thirds of patients with this tumor had a history of maternal exposure to diethylstilbestrol or related substances during the first 3 months of pregnancy. These tumors can become quite large, filling the entire vagina by the time of diagnosis. Tumor spread is via the lymphatics to pelvic nodes. Local recurrence is common, and pulmonary metastases can occur.[46,48]

### Ovary

***Overview.*** Ovarian neoplasms commonly are divided into groups based on the apparent origin of their cellular components: germ cell tumors, sex cord/stromal tumors, and surface epithelial tumors. Sixty percent of all pediatric ovarian neoplasms are of germ cell origin. Of the germ cell tumors, 70% are teratomas, 25% are dysgerminomas, and 5% are endodermal sinus or yolk sac tumors. About one-fifth of pediatric ovarian tumors are epithelial cell in origin, including cystadenoma (80%) and cystadenocarcinoma (10%). The remaining pediatric ovarian tumors are sex cord tumors or tumors of stromal/mesenchymal origin. Fifteen percent of those are arrhenoblastomas (also called Seroli-Leydig cell tumors), and 75% are granulosa/theca cell tumors.[46,47]

Overall, about one-third of ovarian neoplasms are malignant. This percentage decreases with increasing age. About 50% of hormonally active tumors are malignant. Of the malignant lesions, 85% are germ cell tumors (dysgerminomas, immature teratomas, endodermal sinus tumors, embryonal cell carcinomas, and choriocarcinomas), 10% are stromal (Sertoli–Leydig cell, granulosa/theca cell, and undifferentiated neoplasms), and 5% are epithelial cell tumors (serous and mucinous cystadenocarcinomas). Malignant neoplasms can break through the ovarian capsule and spread to adjacent organs. Metastases are most often to the peritoneal cavity, opposite ovary, pelvic and retroperitoneal lymph nodes, omentum, liver, and abdominal organs (Fig. 126.19). Involvement of peritoneal and pleural linings may lead to ascites or pleural effusions. Staging of malignant ovarian tumors is presented in Box 126.1.[46,49]

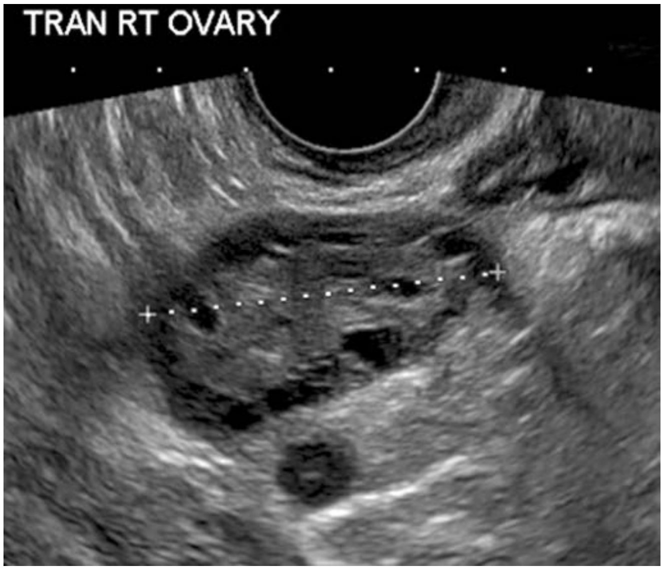

**Figure 126.17. Polycystic ovary disease.** Transverse gray-scale sonogram in an 18-year-old young woman with dysfunctional uterine bleeding shows increased echogenicity of the ovarian stroma and many peripheral follicles of similar size.

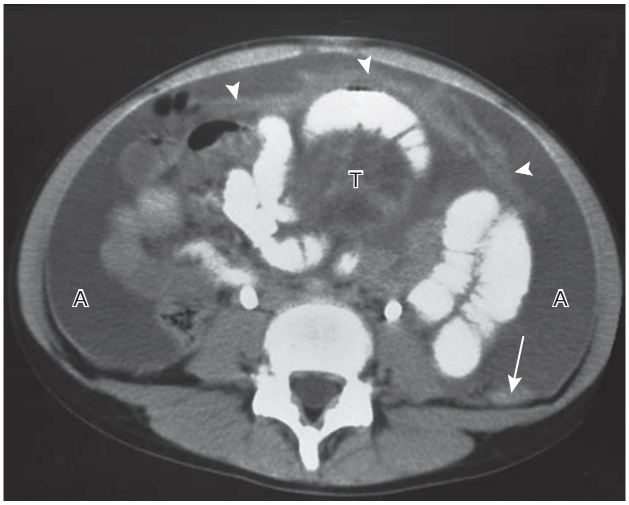

**Figure 126.19. Endodermal sinus tumor.** Axial contrast-enhanced CT image shows malignant omental spread with omental “caking” *(arrowheads)* and peritoneal implants in this 13-year-old girl with endodermal sinus tumor of the ovary. Moderate ascites *(A)* is present. An arrow points to a posterior left-sided peritoneal metastasis. *T,* The most superior portion of the ovarian tumor. *(From Cohen HL, Bober S, Bow S. Imaging the pediatric pelvis: the normal and abnormal genital tract and simulators of its diseases.* Urol Radiol. *1992;14:273-283.)*

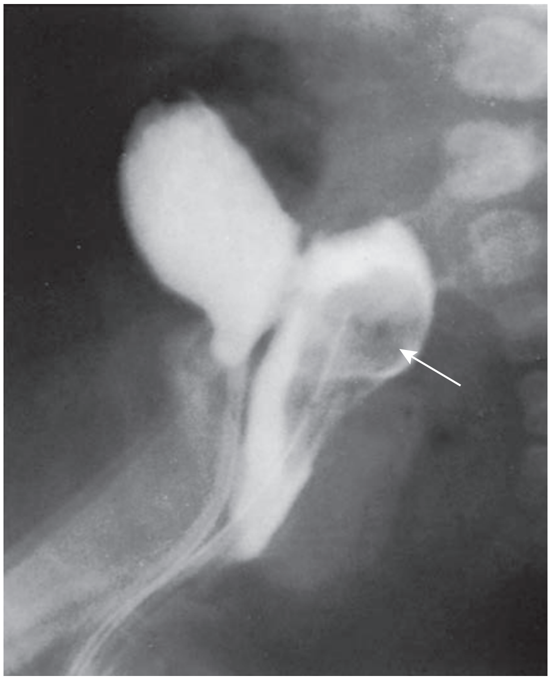

**e-Figure 126.18. Endodermal sinus tumor of the vagina.** A lateral vaginogram shows a mass *(arrow)* within the contrast-filled vagina of a 6-month-old girl, originating from the vagina's posterior wall. The contrast-filled bladder seen anterior to the vagina was filled by a separate injection.

**BOX 126.1** Staging for Ovarian Neoplasms

Stage I: Tumor limited to the ovaries
Stage IA: Tumor limited to one ovary, no malignant ascites
Stage IB: Tumor limited to both ovaries, no malignant ascites
Stage IC: Stage IA or IB with malignant ascites
Stage II: Tumor involves one or both ovaries with pelvic extension
Stage IIA: Extension or implants on the uterus or fallopian tubes, no malignant ascites
Stage IIB: Extension to other pelvic tissues, no malignant ascites
Stage IIC: Stage IIA or IIB with malignant ascites
Stage III: Tumor involves one or both ovaries with peritoneal implants outside the pelvis or retroperitoneal lymph node metastasis
Stage IIIA: Microscopic peritoneal metastasis beyond the pelvis
Stage IIIB: Macroscopic peritoneal metastasis beyond the pelvis 2 cm or less
Stage IIIC: Peritoneal metastasis beyond the pelvis more than 2 cm or regional lymph node metastasis
Stage IV: Distant metastasis, including liver parenchyma

*Based on the American Joint Committee on Cancer and the International Federation of Gynecology and Obstetrics staging of carcinoma of the ovary. Modified from Emans S, Laufer M, Goldstein D, eds.* Pediatric and Adolescent Gynecology, *5th ed. Philadelphia: Lippincott Williams & Wilkins; 2005.*

## Ovarian Teratomas

***Overview.*** Mature ovarian teratomas (or dermoid cysts) are the most common ovarian neoplasm in pediatric patients and usually are found in adolescents. The tumors may vary in size from those contained solely within the ovary itself to those that extend 5 to 10 cm beyond the ovary. Almost all teratomas are benign, with malignancy found in 2% to 10% of cases or less. Teratomas usually are discovered by chance during pelvic ultrasound examinations performed on adolescents for other reasons; about one-fourth are bilateral. Occasionally, they may be diagnosed by the incidental discovery of calcification or ossification (including teeth or bone) in the adnexal area on radiograph examinations (Fig. 126.20).[49,50]

***Imaging.*** Most teratomas appear sonographically as complex cysts with anechoic, hypoechoic, and echogenic components. A minority of cases are either anechoic (perhaps because the solid component is at the mass's periphery and not imaged) or entirely echogenic. The classic ultrasound appearance shows a prominent cystic component and at least one associated nodule (a dermoid plug or Rokitansky nodule) (Fig. 126.21) that often is echogenic, with posterior shadowing as a result of contained fat, hair, sebum, and/or calcium. The shadowing may obscure deeper portions of the mass, a phenomenon called the "tip of the iceberg" sign. The anechoic component of teratomas is made up of serous fluid or sebum, which is in a fluid state when at body temperature. Fat–fluid levels and hair–fluid levels may be seen as part of the cystic component.

Similar findings are seen on CT (e-Fig. 126.22) or MRI. CT may show calcifications that are not seen by other methods. MRI is particularly valuable in demonstrating the fatty components of the mass. Signal characteristics on MRI reflect the composition of a teratoma. Calcification, bone, and hair have low-signal intensity on both T1- and T2-weighted images. Fat has a high signal on T1-weighted studies and may show India ink artifact on T1-weighted gradient echo opposed-phase imaging. Fluid has a high signal on T2-weighted studies. Immature, partially differentiated malignant teratomas are uncommon and generally are solid and almost universally unilateral.[47,49–52]

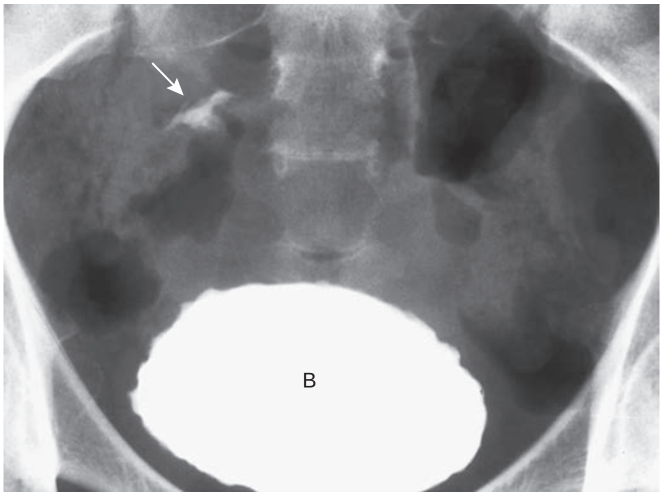

**Figure 126.20. Ovarian teratoma.** Plain radiograph of the pelvis shows a triangular calcification *(arrow)* in the right side of the pelvis. It was proven to be within a right ovarian teratoma. *B,* Bladder.

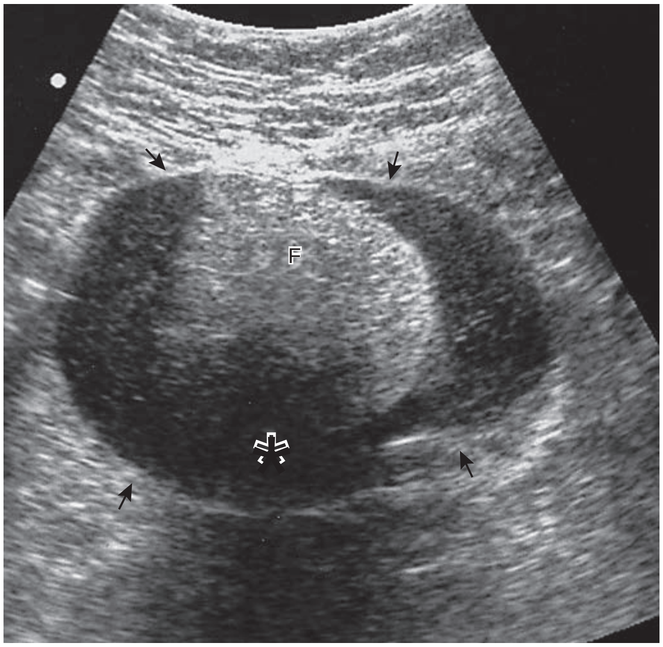

**Figure 126.21. Ovarian teratoma.** Transverse gray-scale sonogram shows a left adnexal mass *(arrows)* with a central highly echogenic component. Posterior shadowing is present *(asterisk)*, suggesting a dermoid plug. The periphery of the mass is composed of complex fluid. *(From Ruggierro M, Awobuluyi M, Cohen H, et al. Imaging the pediatric pelvis: role of ultrasound.* Radiologist. *1997;4:155-170.)*

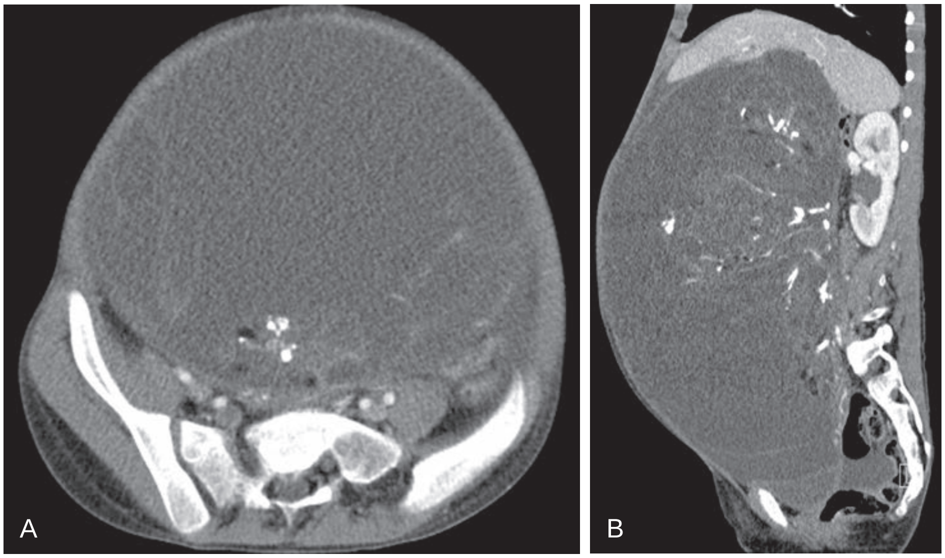
## Ovarian Dysgerminoma

***Overview and Imaging.*** Dysgerminoma is the second-most common ovarian neoplasm in children and adolescents after mature teratoma. It is the most common malignant ovarian tumor of the pediatric period. It is said to be the histologic counterpart to the testicular seminoma of boys. Imaging or visual inspection shows it to be solid, smooth, and typically well encapsulated. These tumors often are large when first diagnosed (Fig. 126.23). About one-fifth of cases have bilateral involvement. Dysgerminomas may arise in dysgenetic gonads, but this presentation is much less common than



**e-Figure 126.22. Ovarian teratoma.** (A) Axial and (B) sagittal contrast-enhanced CT images in an 11-year-old girl with enlarging abdomen show a very large mass arising from the pelvis. The mass is predominantly fluid attenuation and contains high attenuation foci consistent with calcification/ossification and low attenuation foci consistent with fat.

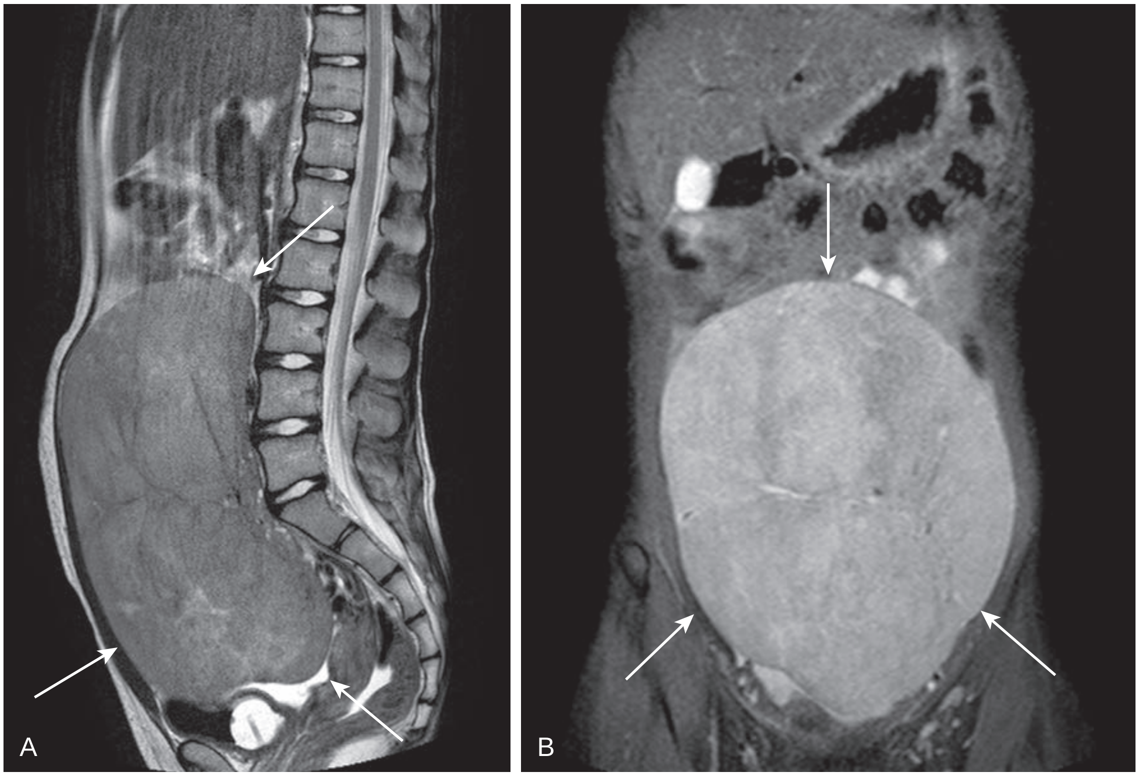


**Figure 126.23. Dysgerminoma.** (A) Sagittal T2-weighted and (B) coronal T2-weighted fat-saturated MR images in a 15-year-old girl with an enlarging abdomen show a large, heterogeneous, predominantly hyperintense mass *(arrows)* arising from the pelvis. The mass was proven to arise from the left ovary at surgery.

with gonadoblastomas. Pure dysgerminomas are nonfunctioning tumors, but hormonal function may be observed in dysgerminomas that contain islands of other germ cell tumors (mixed germ cell tumors). These tumors can spread locally and to retroperitoneal nodes. They are very radiosensitive, and prognosis with treatment is generally good, with an overall survival of more than 90%.[49,50]

## Endodermal Sinus Tumor

***Overview and Imaging.*** An endodermal sinus tumor (yolk sac tumor or carcinoma) is an uncommon malignant neoplasm that can occur at any age. It often is bulky at the time of diagnosis and is predominantly solid on ultrasound but may contain cystic spaces. In most cases, serum alpha-fetoprotein levels are increased. Some endodermal sinus tumors secrete human chorionic gonadotropin, causing incomplete precocious puberty by stimulating ovarian estrogen production. This phenomenon can cause menstrual irregularities in postpubertal girls. The tumor is radiosensitive. Although the incidence of recurrence is high, the survival rate is high among treated patients.[53]

## Cystadenomas and Cystadenocarcinomas

***Overview and Imaging.*** Surface epithelial tumors in children are similar to those in adults and consist predominantly of cystadenomas and cystadenocarcinomas. Cystadenomas are very uncommon before puberty and usually are unilateral, although they may be bilateral in some girls (Fig. 126.24). They vary in size from 3 to 30 cm. Of the two types of cystadenomas, serous cystadenomas contain clear, watery fluid, and the less common mucinous cystadenomas contain mucin, a jelly-like material. Most of these tumors are multiseptated cystic masses (Fig. 126.25) when imaged by ultrasound, CT, and MRI. Cystadenomas are benign neoplasms, but a serous papillary form is reported to be prone to rupture, with spillage of tumor material into the peritoneal cavity, causing a serous papillomatosis. Cystadenocarcinomas are much less common than their benign counterparts. They may appear similar to cystadenomas, but the presence of irregular margins, thick septations, and papillary projections suggests malignancy. Ascites, omental or peritoneal implants, lymphadenopathy, and hepatic metastases indicate malignant spread.[46,49]

## Juvenile Granulosa Cell Tumors

***Overview and Imaging.*** Juvenile granulosa cell tumors are predominantly solid, but mixed solid and cystic or predominantly cystic masses are seen. These lesions may be large at diagnosis and can appear complex at MRI. About three-fourths of juvenile granulosa cell tumors produce estrogen, which causes isosexual precocious puberty; uterine and endometrial stripe enlargement may be observed. Nonfunctioning tumors may be discovered incidentally as a mass on physical examination or ultrasound. The vast majority of juvenile granulosa cell tumors are successfully managed with surgical resection, with recurrences and metastases a rarity.[46,49]

## Sertoli-Leydig/Leydig Cell Tumors

***Overview and Imaging.*** Formerly called arrhenoblastomas, these tumors are usually large and unilateral. They may be solid or cystic. They usually are well differentiated and benign, but a poorly differentiated form also occurs. Most produce androgenic substances, causing virilization in prepubertal girls and signs of virilization, hirsutism, and oligomenorrhea or amenorrhea after puberty.[54] These tumors have recently been associated with *DICER1* germline mutations.[55]

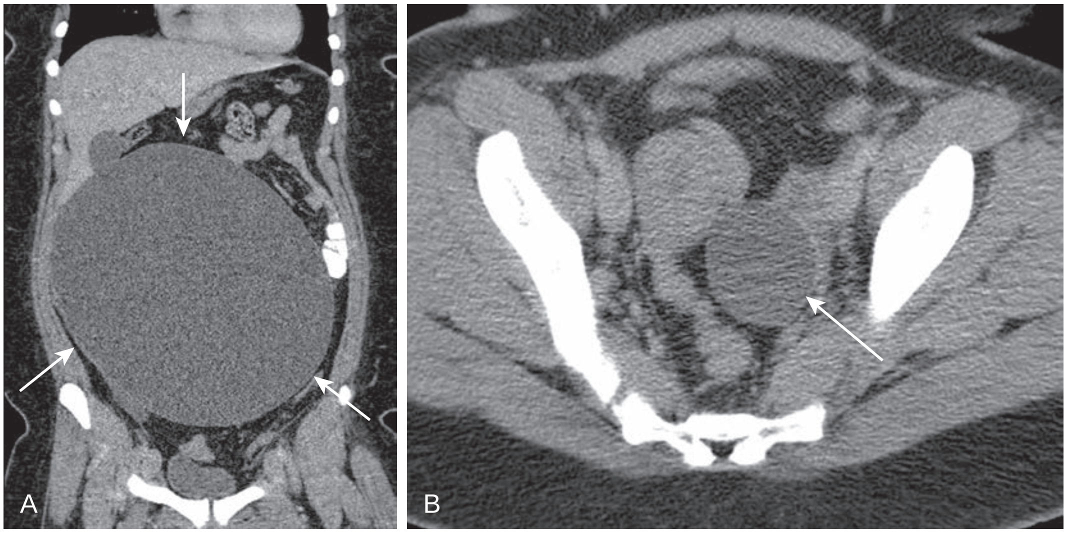

**Figure 126.24. Bilateral ovarian serous cystadenomas.** (A) Coronal contrast-enhanced CT image in a 17-year-old girl shows a very large cystic mass *(arrows)* filling most of the abdomen and pelvis, proven to be a serous cystadenoma arising from the right ovary. (B) Axial CT image through the pelvis shows a second cyst *(arrow)* arising from the left ovary, also proven to be a serous cystadenoma.

**Figure 126.25. Ovarian mucinous cystadenoma.** (A) Side-by-side longitudinal and transverse gray-scale ultrasound images in a 14-year-old girl show a large abdominopelvic complex cystic mass containing many septations and echogenic fluid *(asterisk)*. (B) Coronal contrast-enhanced CT image shows similar findings, including considerable mass-effect upon adjacent structures. Surgical pathology confirmed a mucinous cystadenoma arising from the right ovary.

## KEY POINTS

- Ultrasound is the primary imaging modality used to assess the pediatric gynecologic tract.
- Follicles/cysts exist in the ovaries of most girls of all ages.
- A changing ultrasound appearance over time can help confirm the diagnosis of a hemorrhagic ovarian cyst.
- The predominant pelvic mass found in neonates and infants is a distended, obstructed vagina or uterus filled with secretions, fluid, or blood.
- Patient history, physical examination, and laboratory findings may be necessary to differentiate among TOA, hemorrhagic cyst, and endometrioma, which may look alike on ultrasound.
- Ovaries in persons with PCOS show increased ovarian echogenicity and typically contain numerous 5 to 8 mm peripheral follicles on transabdominal ultrasound.
- An acutely torsed ovary is much larger than a normal ovary.
- Mature ovarian teratomas are the most common pediatric ovarian neoplasm.
- Embryonal rhabdomyosarcoma is the most common genital tract neoplasm in children of both sexes.
- About one-third of all ovarian neoplasms are malignant. As many as 50% of hormonally active tumors are malignant.

# 127 Amenorrhea and Abnormalities of Puberty

Harris L. Cohen and Anand Dorai Raju

Indications for evaluation of the adolescent pelvis usually are based on complaints of abdominal pain, pelvic pain, or a mass. Other clinical symptoms resulting in imaging evaluation in female patients relate to abnormalities of development of secondary sexual characteristics of puberty. These changes may be seen earlier than normal (i.e., precocious puberty), may be delayed (i.e., delayed puberty), or may fail to develop (e.g., hypogonadism and sexual infantilism) in adolescents. The other key reason for adolescent gynecologic evaluation is amenorrhea (lack of menses), whether primary or secondary. Conditions causing pubertal delay may also cause primary or secondary amenorrhea.[1,2]

## PUBERTY

Puberty among girls is the stage of development between childhood and adulthood when activation of the hypothalamic-pituitary-ovarian-uterine axis produces maturation of the gonads, resulting in an increased production of sex hormones, development of secondary sex characteristics, a growth spurt, and development of reproductive capability. The earliest signs of puberty among girls are breast development (usually occurring between ages 8–13 years) and pubic hair growth (usually between ages 8–14 years). These signs are followed by a growth spurt (usually between ages 9.5–14.5 years), axillary hair development, and menarche (usually between ages 10–16 years). Puberty is typically completed within about 4 years.[1,3–5]

Puberty among boys usually begins between 9 and 14 years of age and is completed in 3.5 to 4 years. It begins with testicular enlargement (usually occurring between ages 9–13.5 years), followed by the appearance of pubic hair (usually between ages 10–15 years), enlargement of the penis (usually between ages 11–12.5 years), and development of axillary and facial hair as well as a growth spurt (usually between ages 10.5–16 years).[1,3]

### Physiologic Changes at Puberty and the Normal Ovulatory Menstrual Cycle

Ordinarily, until the age of at least 8 years, an unknown “central restraining mechanism” prevents the pulsatile release of gonadotropin-releasing hormone (GnRH) from the arcuate nucleus of the hypothalamus. Pulsatile release of GnRH appears necessary for ovulation and development of the corpus luteum. In early puberty, the pulsatile GnRH release is maximal only at night, but with time the typical adult pattern of continuous pulsatile GnRH secretion develops.[1,5,6]

With the earliest activation of GnRH, most girls undergo ovarian folliculogenesis without ovulation. Unopposed estrogen production leads to progressive uterine growth and endometrial proliferation. Breast budding, physiologic leukorrhea, and accelerated linear growth occur. As the hypothalamic-pituitary-ovarian-uterine axis matures over approximately a 2-year span, cycles with subnormal progesterone production and shortened intermenstrual intervals are replaced by fertile cycles and normal corpus luteum function.[1,5,6]

The typical ovulatory cycle has a 24- to 35-day intermenstrual interval and usually a premenstrual molimina (mild group of symptoms, including breast tenderness, food craving, fatigue, headaches, sleep problems, and/or fluid retention). Longer intervals often are associated with anovulation. Improved nutrition and living conditions are thought to be at least in part responsible for the gradual decrease in mean menarchal age during the past century. In North America, the mean menarchal age currently is 12.4 years, with a range of 9 to 17 years. Menarche usually occurs 2 to 5 years after breast bud development.[1,6]

### Premature Thelarche and Adrenarche

***Overview and Clinical Presentation.*** Premature thelarche and adrenarche are relatively common, self-limited variants of normal pubertal development in girls. Premature thelarche refers to premature breast development without other signs of precocious sexual maturation in girls younger than 8 years of age. It usually is seen between 1 and 4 years of age; one-third of the cases resolve spontaneously. Premature adrenarche refers to the appearance of pubic and axillary hair without other signs of precocious sexual maturity. In both premature thelarche and premature adrenarche, bone age and patient height are normal to only slightly advanced/increased. The cause of premature thelarche or adrenarche is not certain. The levels of circulating sex hormones usually are normal. Increased end-organ sensitivity to normal levels of estrogen or androgen is a possible cause.[1,7,8]

In boys, premature appearance of pubic and axillary hair without other signs or only minor signs of precocious puberty is a relatively common variant of normal development that may be due to an increase in circulating androgens from premature maturation of the adrenal glands of unknown cause. No penile enlargement is present, presumably because the levels of circulating androgens are not sufficiently elevated. The bone age and growth rate are slightly increased. The remainder of pubertal development occurs at a normal age.[1,8]

## PRECOCIOUS PUBERTY

Precocious puberty refers traditionally to the appearance of secondary sex characteristics before 8 years of age in girls and before 9 years of age in boys. A Pediatric Endocrine Society task force suggested that the definition ages be modified to secondary sexual characteristics noted in white girls under age 7 and African American girls under age 6. Precocious puberty is divided into two main types: (1) complete, central, gonadotropin-dependent, or true precocious puberty and (2) incomplete, peripheral, gonadotropin-independent, pseudoprecocious puberty, or precocious pseudopuberty. Whereas the complete form is characteristically isosexual, with development of secondary sex characteristics that are appropriate for the patient’s gender, the incomplete form may be either isosexual or heterosexual. Incomplete heterosexual precocious puberty is manifested by signs of virilization in girls and by gynecomastia or other signs of feminization in boys.[1,4,7,8]

### Complete or Central Isosexual Precocious Puberty

***Overview and Pathophysiology.*** Complete or central isosexual precocious puberty results from premature activation of the hypothalamic-pituitary-gonadal complex with increased production of gonadotropic and sex hormones and an early onset of ovulation or spermatogenesis. Complete precocious puberty may be idiopathic or secondary to organic central nervous system (CNS) lesions.[1,9,10]

## Abstract:

This chapter reviews amenorrhea and abnormalities related to puberty. The concepts of puberty, expected age-related physiologic changes, and the menstrual cycle are discussed. Definitions allowing the diagnosis of premature thelarche, premature adrenarche, and precocious puberty (PP) are presented. There are various forms including complete or central isosexual PP, incomplete PP, and virilizing disorders or heterosexual PP. The clinical, laboratory, and imaging evaluation of PP and delayed puberty are reviewed. Finally, amenorrhea, including both primary and secondary causes, is discussed.

## Keywords:

Amenorrhea
Congenital adrenal hyperplasia
Precocious puberty
Virilization
Feminization

***Etiology and Imaging.*** The cause of precocious puberty in girls is idiopathic in at least 80% of cases. About 20% of affected girls have a hypothalamic or pituitary lesion. Fewer than 10% of cases of true precocious puberty in boys have an idiopathic cause. A familial tendency to idiopathic early pubertal development is observed in some cases (i.e., constitutional or genetic precocious puberty).[1,9,10]

Possible causes of precocious puberty in either sex include intracranial tumors or cysts, hydrocephalus, sequelae of intracranial inflammatory processes or trauma, and other intracranial lesions that may activate the hypothalamus by pressure or invasion. Of the CNS tumors/neoplasms that may cause true precocious puberty, hamartoma of the hypothalamic tuber cinereum (Fig. 127.1) is the most common. This usually small CNS tumor secretes GnRH, is more common in boys than in girls, is generally benign and nonprogressive, and usually cannot be surgically corrected. It may be pedunculated or appear as an excrescence of the tuber cinereum, below the mammillary body. The onset of puberty in patients with this lesion is usually at a younger age (~2 years) than in patients with idiopathic precocious puberty. Other CNS neoplasms that may cause true precocious puberty in either sex usually are located in or near the hypothalamus and include hypothalamic or optic gliomas, astrocytoma, ependymoma, dysgerminoma, and prolactinoma. Suprasellar dysgerminoma in boys also may cause incomplete precocious puberty through tumor secretion of human chorionic gonadotropin (hCG).[1,10,11]

True precocious puberty may be observed in some children with long-standing untreated hypothyroidism. The increased production of gonadotropic hormones and prolactin seen in these patients may be due to a hormonal overlap in the pituitary response to thyroid deficiency. Affected patients show little, if any, development of secondary sexual characteristics, especially pubic hair. These changes regress with treatment of the hypothyroidism.[1,8]

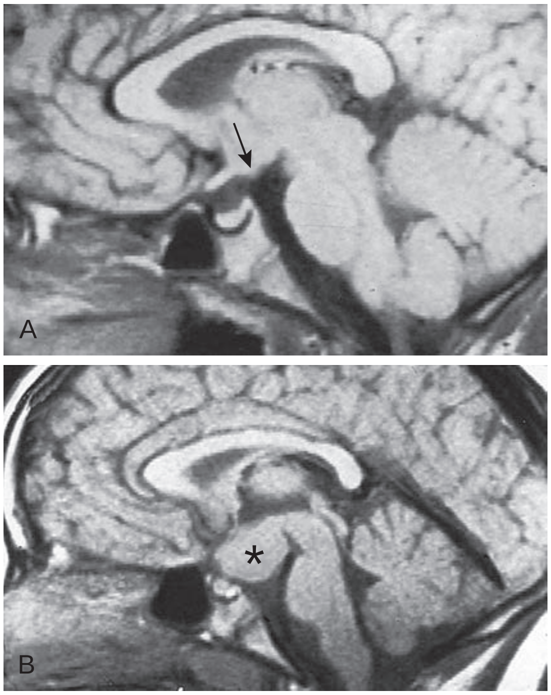

**Figure 127.1. Hamartoma of the tuber cinereum causing precocious puberty.** On midline sagittal T1-weighted magnetic resonance (MR) images of the brain from two different patients, an *arrow* points to a small hamartoma in an 8-year-old (A) and an *asterisk* indicates an unusually large hamartoma in a 7-year-old (B). Both patients had a history of precocious puberty.

## Incomplete (Pseudosexual) Precocious Puberty in Girls

***Overview.*** Pseudosexual (or incomplete) precocious puberty in girls usually presents before 5 years of age. Excess circulating estrogens or related substances develop independently of the hypothalamus and pituitary gland. These estrogens usually are produced by the ovaries or adrenal glands or may be from an exogenous source, such as food, parenteral or oral medications, or other substances.[1,7,12]

***Etiology and Imaging.*** Gonadotropin levels are low, and the gonads remain immature. The most common ovarian source is an autonomous estrogen-secreting follicular (granulosa-thecal) cyst (Fig. 127.2). Other causes are estrogen-producing ovarian neoplasms, particularly granulosa cell (or granulosa-theca cell) tumors (Fig. 127.3) and rare estrogen-secreting adrenal neoplasms (adenomas or carcinomas).[1,7,12]

McCune-Albright syndrome consists of polyostotic fibrous dysplasia, cutaneous café au lait spots, and precocious puberty. The syndrome is found predominantly in females. Autonomously functioning ovarian cysts are seen in some cases. In others, no anatomic cause is noted. McCune-Albright syndrome occasionally presents as complete or true precocious puberty. It has been suggested that the initially partial or incomplete precocious puberty in these patients becomes complete (gonadotropin dependent) as the result of an early maturation of the hypothalamic-pituitary-gonadal complex, which is caused by a long-standing exposure to estrogen.[1,7]

## Virilizing Disorders (Heterosexual Precocious Puberty)

***Overview and Clinical Presentation.*** Testosterone is produced in normal females by the adrenal gland (25%), by the ovary (25%), and by peripheral conversion of D4-androstenedione (50%), with only 1% typically free and biologically active. A form of pseudosexual precocity may occur in girls when androgen levels are excessive or end organs become excessively sensitive to normal amounts of circulating androgens. Either case may lead to heterosexual pseudoprecocious puberty as the girls undergo virilization and masculine secondary sexual characteristics develop. Clinical findings include increases in body and facial hair (hirsutism), acne, deepening of the voice, clitoromegaly, increased muscle mass, and temporal balding. Menstrual abnormalities are common among affected adolescents.[1,12]

### Congenital Adrenal Hyperplasia

***Overview and Imaging.*** Congenital adrenal hyperplasia (CAH) is the most common form of hyperandrogenism. The increased production of androgenic substance is due in most cases to a deficiency of 21-hydroxylase and far less commonly to deficiencies in 11β-hydroxylase, 3β-hydroxysteroid dehydrogenase, or other enzymes involved in cortisol and/or aldosterone synthesis. Imaging of the adrenal gland will show enlargement (Fig. 127.4) that is usually bilateral and diffuse. The normal adrenal gland shape is maintained.[1,13]

### Other Causes of Virilization in Girls

***Overview, Etiology, and Pathophysiology.*** Adrenal adenomas (Fig. 127.5) or adrenal carcinomas (Fig. 127.6) may produce increased levels of androgens and virilization. Signs of Cushing syndrome may be seen as a result of associated tumor secretion of glucocorticoid hormones.[1,13]

Ovarian neoplasms may secrete androgens and cause virilization. These neoplasms include Sertoli-Leydig cell tumors, thecomas (luteoma—a virilizing dysgerminoma that contains theca cells), or

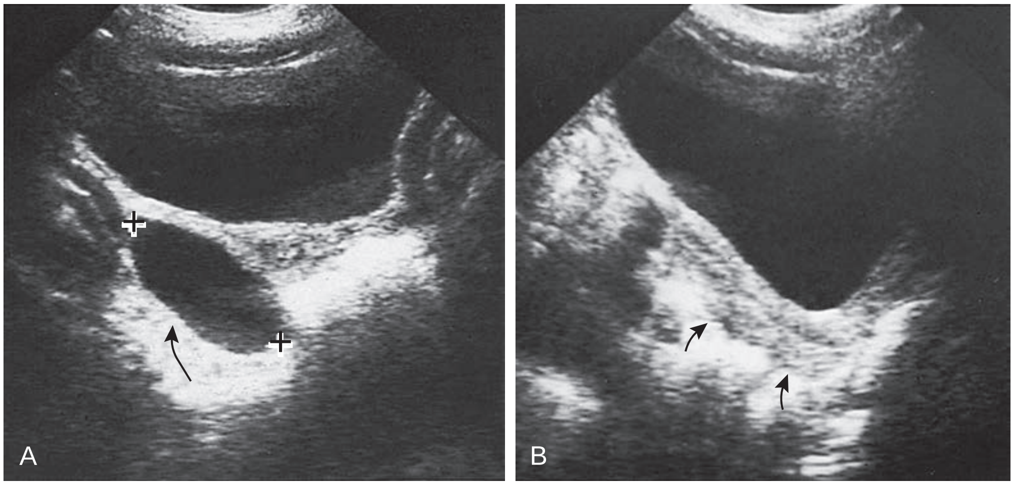

**Figure 127.2. Autonomous estrogen-secreting ovarian cyst causing precocious puberty.** (A) Longitudinal sonogram of the right adnexa *(arrow)* of a 3-year-old girl with precocious puberty shows a large cyst *(cursors)*. This cyst was proved to autonomously secrete estrogen. The left adnexa was normal. (B) Midline longitudinal sonogram shows that the child's uterus *(arrows)* is longer than normal for her age. It is not the tubular shape typical of childhood but appears almost pear-shaped, with an echogenic central endometrial cavity indicating estrogenization.

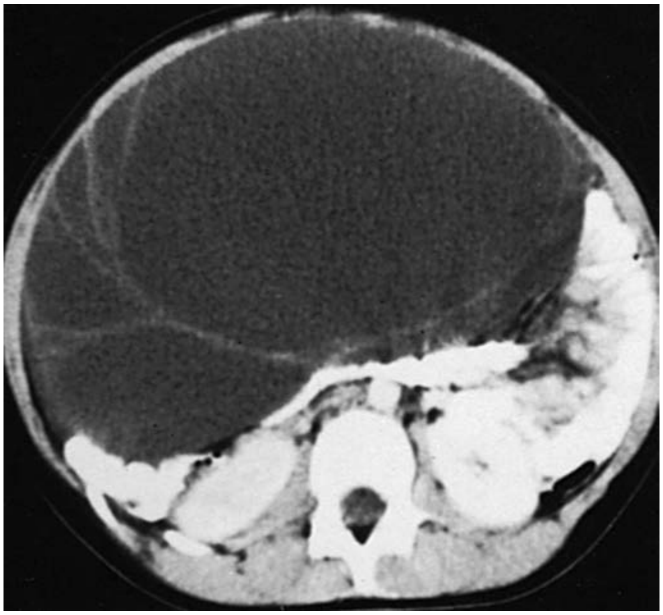

**Figure 127.3. Granulosa cell tumor of the ovary causing precocious puberty.** Axial contrast-enhanced CT image shows a large, cystic, multiseptated mass occupying most of the abdomen in a 10-year-old girl. The mass proved to be an ovarian estrogen-producing juvenile granulosa cell tumor.

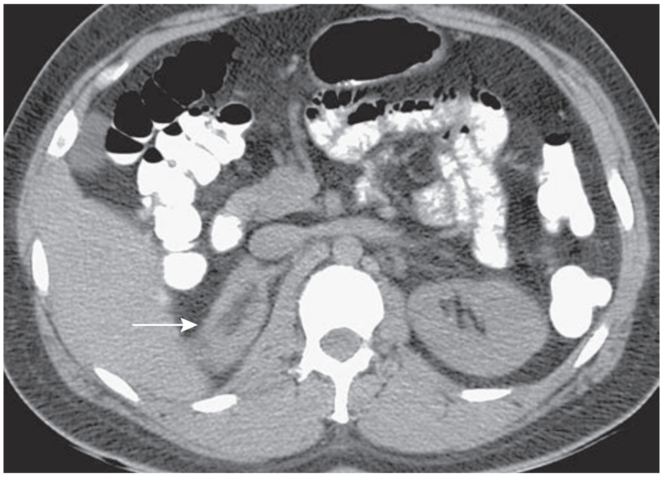

**Figure 127.4. Congenital adrenal hyperplasia.** Axial CT image shows that the right adrenal gland *(arrow)* is thicker than normal in this 24-year-old with simple virilizing congenital adrenal hyperplasia. As is typical with this disorder, the adrenal gland maintains its normal shape.

gonadoblastomas. Exogenous exposure to androgens or androgen-like substances may cause virilization at all ages. Again, virilization at puberty may develop in some girls with rare anomalies of sex differentiation, such as 46,XY gonadal dysgenesis, even though they are phenotypically normal females at birth.[1,14]

Idiopathic hirsutism and polycystic ovarian syndrome also are considered to be among the virilizing disorders of females. Idiopathic hirsutism consists of an increase in body and facial hair that occurs as the sole or predominant abnormality and is a relatively common problem in otherwise normal pubertal and postpubertal girls. Idiopathic hirsutism may be precipitated by any of the causes of virilization. It may be seen in families or as a result of polycystic ovary syndrome and the increased androgen production by the many small follicular cysts (see Chapter 126). The cause is usually idiopathic and believed to be a result of an altered response of the end organ (hair follicle) to normal levels of circulating androgens.[1,15–17]

## Incomplete Isosexual (Pseudoprecocious) Puberty in Boys

***Overview, Etiology, and Pathophysiology.*** Isosexual pseudoprecocity of sexual development in boys is due to an increase in circulating androgen or androgen-like substances either from production by adrenal glands or testes or from an exogenous source. CAH is the most common cause for excessive androgen production by the adrenal gland of either sex. Affected males are born with normal external genitalia, but if CAH is untreated, signs of sexual precocity soon develop. Isosexual pseudoprecocious puberty in males, sometimes associated with signs of glucocorticoid excess, also can occur because of androgen-secreting neoplasms of the adrenal cortex (e.g., adenocarcinoma or adenoma). A rare cause of isosexual precocity in boys is an androgen-secreting Leydig cell tumor of the testis (see Chapter 125). Several extrapituitary hCG-secreting tumors also can result in an incomplete form of isosexual precocious puberty by stimulating testosterone production by testicular Leydig cells. These tumors include some hepatocellular carcinomas, hepatoblastomas, teratomas or chorioepitheliomas of the mediastinum and retroperitoneum, and suprasellar germinomas. A familial form of gonadotropin-independent precocious puberty in boys is caused by premature maturation and sometimes hyperplasia of the Leydig cells of the testis, with production of testosterone. Exposure to exogenous androgens or the administration of hCG for undescended testes may be further causes of incomplete virilization in males.[1,8,13]

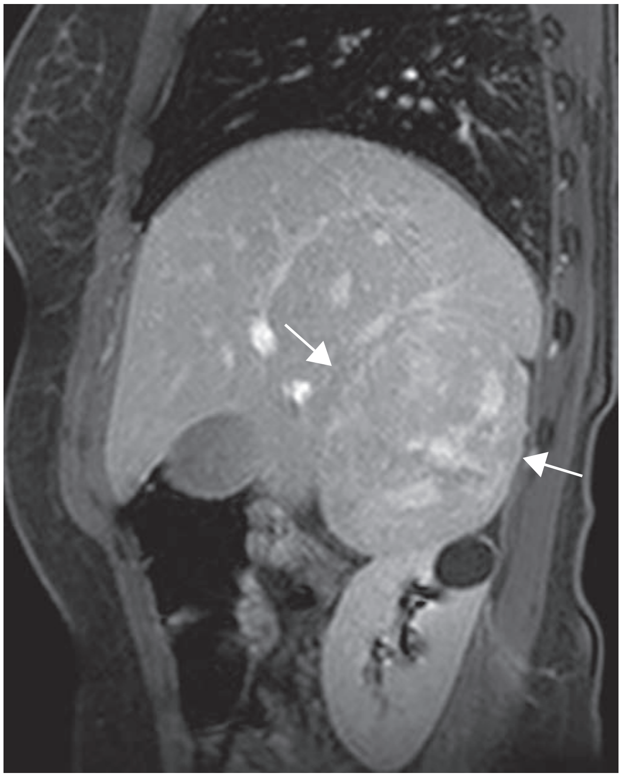

**Figure 127.5. Adrenocortical adenoma causing virilization in a 17-year-old girl presenting with secondary amenorrhea and hirsutism.** Sagittal postcontrast T1-weighted MR image shows a large heterogeneous mass arising from the right adrenal gland *(arrows)* proven to be a hormonally active adrenocortical adenoma. An incidental cyst is present in the right kidney.

## Adolescent Gynecomastia and Feminizing Disorders in Boys

***Overview and Etiology.*** Mild breast development may occur transiently in adolescent boys between 13 and 15 years of age. It is usually bilateral, idiopathic, and may be familial. Typically no hormonal abnormality is found. The gynecomastia generally regresses in 2 or 3 years, but in a few cases it may persist into adult life. Pathologic causes of gynecomastia in boys may be exposure to exogenous estrogens, an estrogen-secreting neoplasm of the testis or adrenal cortex, a prolactin-secreting neoplasm of the pituitary gland, Klinefelter syndrome, congenital bilateral anorchia, acquired testicular failure, and other conditions with some biochemical defect in testosterone production or androgen end-organ receptor.[1,18]

## Clinical and Laboratory Evaluation of Precocious Puberty

***Overview and Clinical Presentation.*** Physical examination can help determine the correct diagnosis. Physical examination should denote the type and degree of pubertal development as well as the size, shape, and firmness of the testes. In complete precocious puberty, both testes are enlarged; in partial sexual precocity, they often are of normal size. Unilateral testicular enlargement suggests a testicular neoplasm. The abdomen should be evaluated for a flank or pelvic mass. The presence of café au lait spots should suggest the diagnosis of fibrous dysplasia or neurofibromatosis. Laboratory studies may include luteinizing hormone, follicle-stimulating hormone, and estradiol levels; gonadotropin response to GnRH; thyroid studies; and a vaginal smear in girls, as well as plasma and urinary testosterone levels.[1,8]

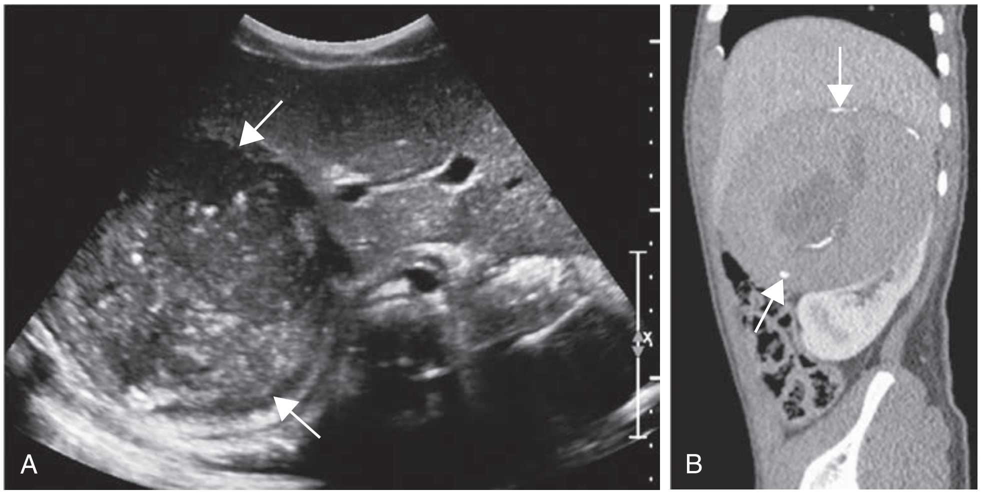

**Figure 127.6. Adrenocortical carcinoma causing virilization in a 3-year-old girl.** (A) Transverse sonogram through the upper abdomen shows a large heterogeneous mass *(arrows)* posterior to the right lobe of the liver. (B) Sagittal contrast-enhanced CT image shows that the mass arises from the right suprarenal fossa, exerts substantial mass effect upon the right kidney, and contains calcifications *(arrows)*.

### Imaging Evaluation of Precocious Puberty

***Imaging.*** An anteroposterior film of the left hand, including carpal bones and the distal forearm, is commonly used for bone age determination. Bone age often is advanced in patients with true precocious puberty and in patients with androgenic stimulation. The skeletal length often is increased early in patients with advanced bone age. However, if the precocious puberty is not treated, premature fusion of the epiphyses may develop and result in a limitation to the patient's potential height.[1,8]

Ultrasound, with emphasis on the adrenal glands and the ovaries, is the primary initial radiologic study of patients with precocious puberty. In girls with true precocious puberty, a pelvic ultrasound may show some bilateral enlargement of the ovaries and prominence of the uterus, and in rare cases a large estrogen-secreting ovarian cyst that has resulted from stimulation of the hypothalamic-pituitary complex. Small and multiple ovarian cysts/follicles may be seen in girls with true precocious puberty because of high gonadotropin levels. Pseudoprecocity caused by the autonomous estrogen secretion of an ovarian cyst or tumor will be denoted by ovarian asymmetry, with the autonomous lesion being found in the larger ovary (see Fig. 127.2). The finding in prepubertal girls of an increased uterine size and a well-defined central endometrial echo indicates an increase in circulating estrogen from any cause. A skeletal survey is indicated when fibrous dysplasia is suspected.[1,8,19]

Patients with isosexual precocious puberty that is suspected to be of the complete or central type should have magnetic resonance imaging (MRI) of the brain with special attention to the tuber cinereum. Skull radiographs are of limited diagnostic value but may show intracranial calcifications, enlargement of the sella turcica, signs of increased intracranial pressure, or skull changes of fibrous dysplasia.[1,8]

## DELAYED OR ABSENT PUBERTAL DEVELOPMENT

Puberty is considered to be delayed and should be investigated in girls when secondary sex characteristics fail to appear by 13 years of age, which is considered two standard deviations beyond the norm. Evaluation for pubertal delays in boys is suggested when pubic and axillary hair or other external secondary characteristics, particularly enlargement of the testes and penis, fail to appear by age 14 years. Delayed puberty or failure of puberty to develop may be idiopathic (constitutional) or due to chronic systemic disorders, disorders of the hypothalamic-pituitary complex causing decreased gonadotropin secretion (i.e., secondary or hypogonadotropic hypogonadism), or primary disorders of the gonads with a secondary elevation of gonadotropic hormone secretion (i.e., primary or hypergonadotropic hypogonadism).[1,20,21]

### Idiopathic (Constitutional) Pubertal Delay

***Overview and Clinical Presentation.*** In some otherwise normal children, the onset of puberty is delayed for up to several years. When puberty eventually starts, it usually continues to completely normal secondary sexual development. These occurrences underline the fact that there may be constitutional or genetic causes for delay in the maturation of the hypothalamic-pituitary complex. Often, such children may experience a delay in bone age and height development. The ability to differentiate between constitutional pubertal delays in otherwise normal children and true disorders of the hypothalamic-pituitary axis may not be simple.[1,21]

### Delayed Puberty in Chronic Systemic Disorders

***Overview and Etiology.*** Delayed puberty may occur on a physiologic basis in patients with chronic diseases. Patients with other long-term debilitating processes, as well as anorexia nervosa, may have delays in pubertal development. Such delays also may be noted in children or adolescents who undergo prolonged and vigorous physical exertion, such as long-distance running, gymnastics, or dance. Puberty may develop or proceed normally in some of these patients after improvement or removal of the precipitating cause. However, any halt in the pubertal development of a patient is a cause for concern and an immediate endocrinologic workup.[1,22,23]

### Hypogonadism Caused by Hypothalamic-Pituitary Disorders (Hypogonadotropic Hypogonadism)

***Overview and Clinical Presentation.*** Several disorders of the hypothalamic-pituitary complex result in decreased gonadotropin production, and secondarily a decrease in gonadal sex steroids. Impaired or absent gonadal function causes an absence of pubertal development. In girls, the uterus remains infantile, menses does not occur, and breast budding and other secondary sexual characteristics do not develop. In boys, the penis and scrotum are infantile, and the testes remain immature and smaller than expected for age. Pubic and axillary hair is scanty or absent, the voice remains high pitched, and increased fat deposition often occurs, particularly at the hips, pelvis, abdomen, and breast. Delayed closure of the epiphyses with elongation of the limbs is observed unless an associated growth hormone deficiency is present.[1,21,22]

***Etiology and Pathophysiology.*** Causative abnormalities include intracranial tumors such as craniopharyngioma, hypothalamic and optic gliomas, dysgerminoma, and other tumors of the pituitary gland and hypothalamus or adjacent areas. Other manifestations of pituitary insufficiency, such as diabetes insipidus and short stature, may be present. Primary or secondary hypogonadotropic hypogonadism also may be seen in patients with Langerhans cell histiocytosis and in patients with certain congenital midline defects of the face, the base of the skull, and the CNS (e.g., septo-optic dysplasia or holoprosencephaly), which may be associated with developmental anomalies of the hypothalamus and pituitary gland, resulting in hypogonadism.[1,21]

Functional causes of hypogonadism include idiopathic hypopituitarism, characterized by short stature resulting from growth hormone deficiency, and sometimes other findings associated with deficiencies of other pituitary hormones. Cases of isolated gonadotropic deficiency, sporadic or familial, may occur in association with anosmia or hyposmia and other abnormalities that characterize Kallmann syndrome. Isolated luteinizing hormone deficiency in males, which sometimes is familial, results in failure of pubertal development; it usually is associated with gynecomastia but with the preservation of spermatogenesis (i.e., fertile eunuch syndrome). Hypogonadism, which probably also is related to abnormalities of hypothalamic function, can be observed in Prader-Willi and Laurence-Moon-Biedl syndromes.[1,21]

### Hypogonadism Caused by Gonadal Lesions (Hypergonadotropic Hypogonadism)

***Overview, Etiology, and Pathophysiology.*** Certain congenital or acquired lesions of the gonads may result in hypogonadism and failure of pubertal development. Gonadal sex steroids are decreased, and as a result, an increase in pituitary secretion of gonadotropins occurs. Just as in hypogonadotropic hypogonadism, pubertal development is absent in girls or boys. The key gonadal lesions in girls include Turner syndrome (45,XO), XX gonadal dysgenesis, XY gonadal dysgenesis, and a gonadal dysgenesis with galactosemia and immune oophoritis (often associated with Hashimoto thyroiditis, hypoparathyroidism, adrenal insufficiency, pernicious anemia, chronic active hepatitis, and candidiasis). Hypergonadotropic hypogonadism also can occur among patients with normal karyotypes who experience secondary ovarian failure either by infarction, as with cases of bilateral ovarian torsion, surgical removal of both ovaries, radiation therapy to the pelvis (usually of 800 cGy or greater), chemotherapy, or autoimmune oophoritis.[1,21,24]

Gonadal lesions in boys leading to hypogonadism include congenital bilateral anorchia with otherwise normal external genitalia, which is caused by resorption of the testes after the 13th week of gestation (e.g., vanishing testes syndrome) and acquired testicular atrophy resulting from bilateral testicular torsion, surgical injury during bilateral orchiopexy, radiation, or other causes. Absence of puberty also is observed in some genetic males born with an entirely female phenotype, including those with XY gonadal dysgenesis and some forms of male intersex states with impaired biosynthesis of active sex steroids as a result of an inherited enzymatic deficiency.[1,25,26]

## Diagnostic and Historical Considerations

***Overview, Clinical Presentation, and Imaging.*** Important information may be obtained from the patient's family history, medical history, associated medical disorders, and physical examination. At the physical examination, special emphasis should be placed on pubertal staging (Tanner classification), assessment of general growth and maturation, detection of signs and symptoms of CNS disease, and systemic diseases or syndromes. Visual fields testing, gynecologic evaluation, and chromosomal analysis should be carried out if indicated. The hormonal studies include measurements of serum testosterone, estradiol, and gonadotropins; gonadotropic response to GnRH stimulation; and testosterone response to hCG stimulation. Measurements of circulating prolactin and growth hormone, as well as thyroid function tests, may be undertaken. Radiologic procedures include bone age determination, brain MRI, pelvic ultrasound to evaluate the size of the ovaries and uterus, and other studies as indicated.[1,21]

## Evaluation of Patients With Amenorrhea

***Overview and Etiology.*** Causes of pubertal delay in girls may be similar to causes of primary or secondary amenorrhea. Primary amenorrhea is defined as a lack of menses by age 16 years. Secondary amenorrhea is defined as a cessation of menses at any point in time after menarche and before menopause.[1,27,28]

Primary amenorrhea has many causes and involves several organ systems (Box 127.1). It may be seen in adolescents with normal pubertal development, as well as those with delayed sexual development, delayed menarche with some pubertal development, and delayed menarche plus virilization. Many of its causes have already been reviewed, including hypogonadotropic hypogonadism, hypergonadotropic hypogonadism, intersex states, female adolescents with virilization (see Fig. 127.6), polycystic ovarian syndrome (PCOS), genital obstruction (e.g., hematometra/hematometrocolpos), and uterine aplasia or hypoplasia. Secondary amenorrhea often is due physiologically to pregnancy and pathologically to PCOS.[1,27,28]

### KEY POINTS

- Unopposed estrogen production leads to progressive uterine growth and endometrial proliferation. Axillary and pubic hair development result from ovarian and adrenal gland androgen production.
- Precocious puberty classically refers to the appearance of external signs of adolescence before 8 years of age in girls and before 9 years of age in boys.
- The cause of precocious puberty is idiopathic in at least 80% of girls but in less than 10% of boys.
- Hypothalamic hamartoma is the most common CNS mass to cause true precocious puberty.
- Pseudosexual precocious puberty in girls usually presents before 5 years of age. Excess circulating estrogens or related substances develop independent of central stimulation.

*Modified from Emans SJ. Amenorrhea in the adolescent. In: Emans S, Goldstein D, eds.* Pediatric and adolescent gynecology. *5th ed, Philadelphia: Lippincott Williams and Wilkins; 2005.*

- The most common source is an autonomous estrogen-secreting ovarian follicular cyst.
- CAH is the most common form of hyperandrogenism; in most cases it is due to 21-hydroxylase deficiency.
- Puberty is considered to be delayed when secondary sex characteristics fail to appear by 13 years of age in girls and 14 years of age in boys.
- Delayed puberty may occur on a physiologic basis in patients with chronic or debilitating disease, extreme or prolonged exercise, and anorexia nervosa.
- Primary amenorrhea is defined as a lack of menses by age 16 years. Secondary amenorrhea is defined as a cessation of menses at any time after menarche and before menopause.

SECTION 8

# Musculoskeletal System

## PART 1 Overview

# 128 Embryology, Anatomy, and Normal Findings

J. Herman Kan and Peter J. Strouse

## EMBRYOLOGY

Both striated muscle and bone are derived from the mesodermal germ layer. The limb buds form at the end of the fourth week of fetal life. Near the end of the second month of fetal life, the embryonic cartilaginous skeleton is already subdivided into its principal segments, which are the forerunners of bones of the limbs. Primary ossification centers are formed by deposition of calcium in the cartilaginous matrix after hypertrophy and vacuolization of local cartilage cells.[1] In tubular bones, this process occurs at approximately the midpoint of the shaft and is followed by central resorption, which gives rise to the primary marrow cavity. Calcified disks proximal and distal to the primary cavity become preparatory zones of calcification after the development of the advancing, proliferating shaft during growth. Cartilage proximal and distal to the zones of calcification becomes the epiphyses. A layer of cells within the epiphyses near the shaft produces new cells interposed between the resting cartilage of the epiphysis and the older cells and calcified cartilage adjacent to the shaft. The matrix around the old cells calcifies and is invaded by capillaries and bone cells from the marrow. Bone is formed on the calcified cartilage, and new bone and cartilage undergo remodeling by osteoclasts and osteoblasts, so the length of the bone is increased (Fig. 128.1). The girth of the bone and the thickness of the cortex are increased by subperiosteal accretion via activity of subperiosteal osteoblasts. Peripheral resorption of bone at the advancing ends of the shaft maintains the gentle flaring that characterizes normal tubular bone and is the mechanism responsible for what is termed *modeling*. Disproportionate osteoclastic activity within the shaft of the bone reams out a marrow cavity. Continued, balanced activity of all these processes permits a small tubular bone to become a large tubular bone while functional shape and relations with adjacent structures are maintained.

Secondary ossification centers appear in the cartilaginous epiphyses and apophyses and enlarge by similar but much slower processes than those that enlarge the shaft. Irregularities in density and discontinuities in the structure of secondary ossification centers are frequent during normal mineralization and may simulate disease. The known ages at first appearance and upon fusion of these ossification centers can serve as indicators of physical maturation (Figs. 128.2 and 128.3; Table 128.1).

The cartilaginous epiphyses are terminal remnants of the original cartilaginous models of bone. Longitudinal growth takes place at the junction of the physis and the metaphysis by proliferation of cartilage cells in the physis, calcification of the surrounding matrix, and transformation to bone through the activity of metaphyseal vessels and accompanying osteoblasts and osteoclasts. Ossification centers develop within the epiphyses; growth ceases when these secondary centers fuse, through the physis, with the metaphysis. Apophyses are outgrowths of a bone that develop where muscle tendons originate or insert. Similar to the epiphyses, the apophyses develop ossification centers that eventually fuse with the main body of the underlying bone. Apophyses are different from epiphyses in that they do not contribute to longitudinal growth. Epiphyseal and apophyseal ossification and growth occur related to matrix deposition by the spherical growth plate, which has physiology similar to the physis. When epiphyseal ossification is complete, the spherical growth plate and epiphyseal cartilage are no longer appreciable, and only articular cartilage overlies the epiphyseal bone. This process occurs simultaneously with closure of the physis at skeletal maturity.

## PHYSIOLOGY

The bones provide rigid support for the body and sites of insertion for muscles, to which the bones respond as levers. The bones are active physiologically in infants and children, changing size and shape with growth and hormone activity (related to levels of vitamin D, parathyroid hormone, calcitonin, or serum calcium and phosphate levels) and in response to mechanical stresses.[2]

During growth, in addition to its constant increase in length and breadth, the shaft is continuously molded or reshaped to its final form in a process called *modeling* or *tubulation*. One of the most conspicuous features of modeling is progressive concentric contraction of the shaft behind the wider, advancing terminal segment (e-Fig. 128.4); this process results in the flared ends of tubular bones.

Significant disturbances in configuration of the shafts occur in many chronic diseases that affect the growing skeleton. With overtubulation, a diaphysis is abnormally narrow in caliber with accentuation of metaphyseal flaring. This usually is seen in children with cerebral palsy or other neuromuscular diseases in which normal muscular stresses are not present. With undertubulation, the diaphysis is abnormally broad in caliber with loss of the normal metaphyseal flaring; causes may include Gaucher disease, Pyle dysplasia, and osteochondromatosis.

Acute changes related to systemic disease are most commonly seen at the juxtaphyseal metaphysis, which is the most metabolically active component of the growing bone unit, and the location of primary bone deposition (e.g., metaphyseal fraying seen in persons with rickets or juxtaphyseal sclerosis with intervening areas of bony rarefaction in persons with leukemia).

## ANATOMY

Three types of bones are found in the limbs: (1) long and short tubular bones, (2) round bones in the wrists and ankles, and (3) sesamoids, which are small bones in the tendons and articular capsules. Functionally, a growing tubular bone is made up of the following segments: diaphysis, metaphysis, physis, and epiphysis (Fig. 128.5). "Long bones" have epiphyses at both ends. Short tubular bones ("short bones") have epiphyses at one end. In the

## Abstract:

To describe the embryology, anatomy, and normal variants of the growing skeleton and to differentiate from pathologic conditions. Normal developmental variants of the growing skeleton may superficially mimic traumatic and neoplastic entities. By understanding the embryologic and development of these normal variations, radiologists can improve identification of pathologic processes that may affect the growing skeleton.

**e-Figure 128.4. Growth and configuration of the tibia with advancing age.** The progressive concentric constriction of the shaft away from the wider epiphyseal plate is shown schematically on superimposed tracings of radiographs.

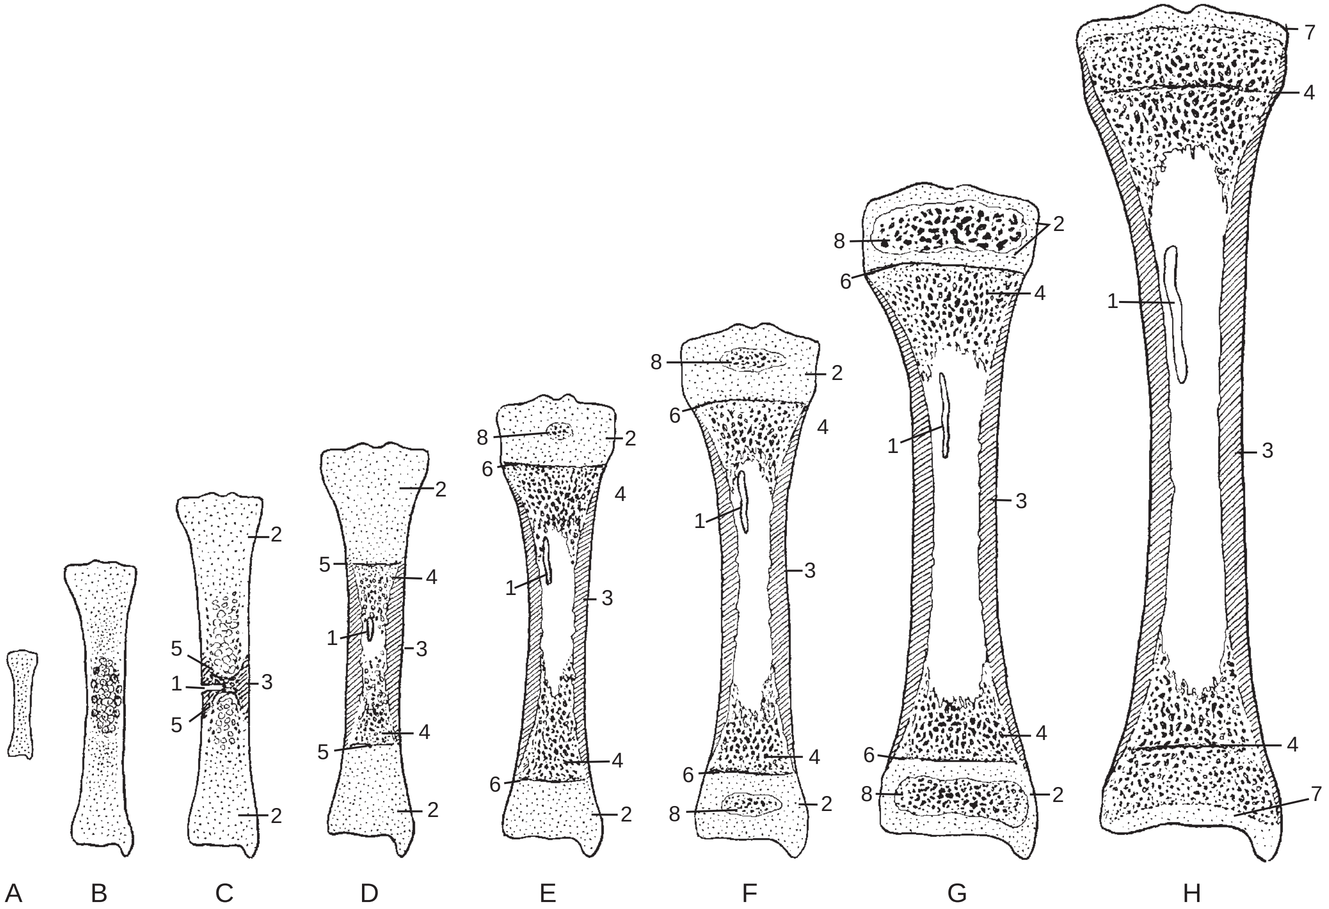

**Figure 128.1. Schema of progressive stages in the growth and maturation of the tibia.** (A) The mass of embryonal cartilage that is the anlage of the tibia. (B) Initial enlargement and multiplication of the central cartilage cells and an increase in cartilaginous matrix—the chondrification center that is the forerunner of the primary ossification center. (C) The early primary ossification center shows the formation of a central belt of subperiosteal bone (early cortex) and penetration of the cartilaginous matrix by the periosteal elements; the channel of this penetration persists as the nutrient canal. (D) Extension of ossification toward both ends of the shaft, with central resorption forming the medullary cavity. (E) The tibia at birth, with a secondary ossification center in the proximal epiphyseal cartilage. (F) At approximately the fourth postnatal month, ossification centers are seen in both of the epiphyseal cartilages. (G) The juvenile tibia shows the growth of all components and enlargement of the epiphyseal secondary ossification centers. (H) The adult tibia, with complete fusion of the shaft and both epiphyses. The narrow plates of articular cartilage that cap each end of the bone persist throughout life. *1,* nutrient canal; *2,* epiphyseal cartilage; *3,* corticalis; *4,* spongiosa; *5 and 6,* provisional zones of calcification or epiphyseal plates; *7,* articular cartilages; *8,* secondary epiphyseal ossification centers. *(Modified from an original drawing by W. M. Rogers, MD.)*

hands and feet, secondary ossification centers appear in the bases of the phalanges and in the distal ends of the second through fifth metacarpals and metatarsals. Epiphyses for the first metacarpal and first metatarsal are found in the proximal ends of the bones. The location of the secondary centers appears to be related to the sites of maximal joint motion of individual short tubular bones. Apparent epiphyseal ossification centers observed at the ends of short bones, where their occurrence is not expected, are termed *pseudoepiphyses*.

## NORMAL FINDINGS

### Determining Skeletal Age

The gestational age of a newborn can be estimated radiographically through several methods. The proximal humeral ossification center

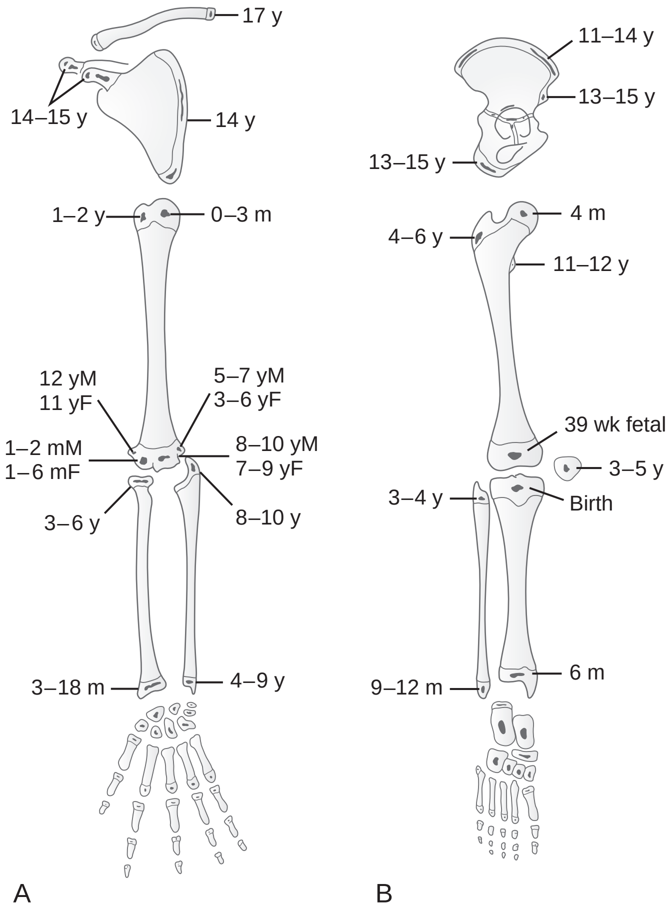

**Figure 128.2.** Ages of onset of secondary (epiphyseal and apophyseal) ossification of the major bones of the upper (A) and lower (B) extremity. *F,* Female; *M,* male; *m,* month; *wk,* week; *y,* year. *(Reproduced from Ogden JA.* Skeletal Injury in the Child. *3rd ed. New York: Springer; 2000.)*

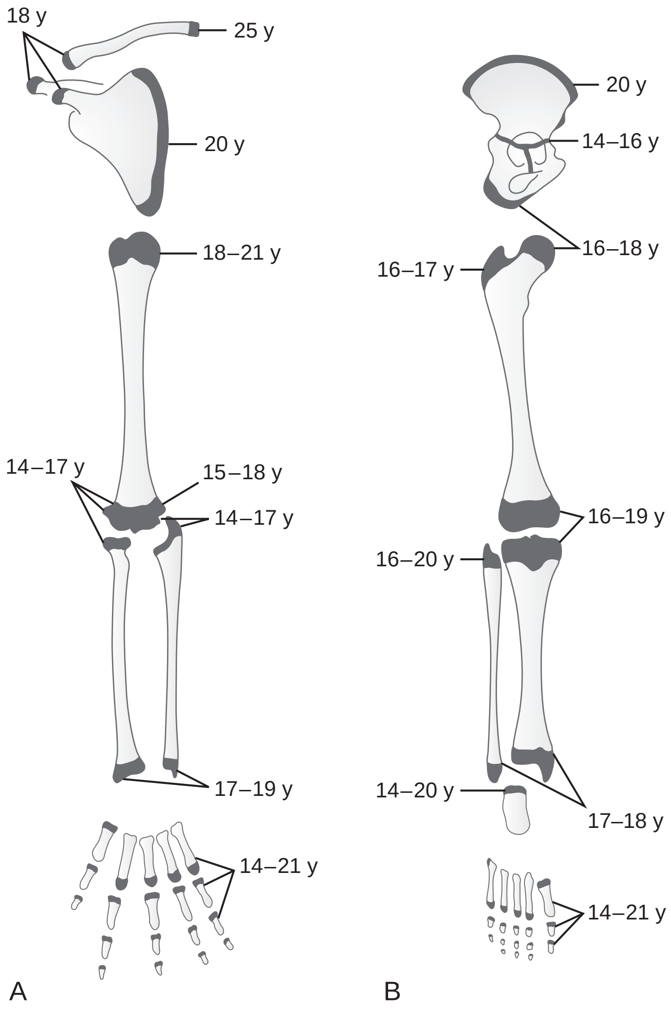

**Figure 128.3.** Ages of physeal closure of the major bones of the upper (A) and lower (B) extremities. *y,* Year. *(Reproduced from Ogden JA.* Skeletal Injury in the Child. *3rd ed. New York: Springer; 2000.)*

appears shortly after birth, with a 95% confidence interval between 37 weeks' gestation and 16 weeks' postnatal life.[3] Ossification before 37 weeks is unusual; therefore the presence of the proximal humeral ossification center is an indication that a newborn is at term or near term. Teeth appear at a characteristic time; the first deciduous molars form at 33 weeks, and the second deciduous molars form at 36 weeks. The range of values is great for the radiographic appearance of various appendicular bone epiphyseal ossification centers, even in premature infants (Table 128.1).

Evaluation of bone age is used to estimate biologic maturation relative to chronologic age. Differences in familial, racial, and socioeconomic factors limit the applicability of the standards of Greulich and Pyle (which were developed in the 1940s) to today's children.[4,5] It is well accepted that maturation varies between races. For instance, African American children mature faster than do white children.[6] The hand, with its numerous secondary centers in phalanges and metacarpals, and to a lesser degree the wrist, are used as an index of total skeletal maturation. Standard deviations, which are based on chronologic age, are somewhat broad. A bone age within the 5% to 95% confidence interval (or ±2 standard deviations) is considered normal.

In children younger than 2 years, use of the standards of Greulich and Pyle is limited because relatively little change is noted in the ossification centers of the hand and wrist during this period. More rapid changes may be observed in the knee or foot, however. Radiographs of the left knee or left foot—anteroposterior

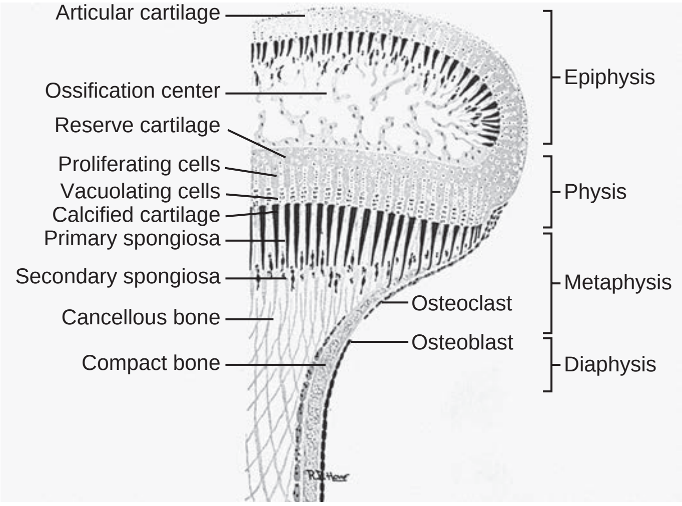

**Figure 128.5.** Functional components of the growing end of a tubular bone and their anatomic substrate.

and lateral—can be obtained in children younger than 2 years of age and compared with published standards.[7,8]

The Risser classification can be used to assess skeletal maturation through evaluation of the appearance and state of fusion of the iliac crest.[9] Ossification of the iliac crest begins laterally and proceeds medially: stage 0—no ossification; stage I—up to 25% ossified; stage II—25% to 50% ossified; stage III—50% to 75% ossified; stage IV—75% to 100% ossified; and stage V—fully ossified and fused (e-Fig. 128.6 and Fig. 134.2).

Assessment of skeletal age by radiography is useful in many clinical scenarios. Boxes 128.1 and 128.2 list causes of advanced and delayed skeletal maturation, respectively. Menarche typically occurs after fusion of the physes of the distal phalanges. Bone age can be used with long bone measurements to predict adult height. Assessment of bone age is also valuable in the planning of orthopedic treatments, including epiphysiodesis, leg-lengthening procedures, and scoliosis management.

**BOX 128.1** Causes of Advanced Skeletal Maturation

- Acrodysostosis
- Adrenogenital syndrome (adrenocortical tumor or hyperplasia)
- Cerebral gigantism
- Gonadal tumors (androgen or estrogen secreting)
- Growth hormone excess (gigantism)
- Hyperthyroidism (maternal or acquired)
- Hypothalamic tumors
- Idiopathic familial advanced bone age
- Idiopathic isosexual precocious puberty
- Lipodystrophy
- Liver tumors (choriocarcinoma, hepatoma)
- McCune-Albright syndrome (polyostotic fibrous dysplasia)
- Medication with sex hormones
- Pinealoma
- Premature adrenarche
- Premature thelarche
- Pseudohypoparathyroidism
- Various syndromes

**BOX 128.2** Causes of Delayed Skeletal Maturation

- Addison disease
- Chromosomal disorders (e.g., trisomy 21 and trisomy 18)
- Chronic illness
- Chronic renal disease
- Chronic severe anemia (e.g., sickle cell anemia and thalassemia)
- Congenital heart disease (especially cyanotic)
- Congenital malformation syndromes
- Constitutional delay
- Cushing syndrome
- Growth hormone deficiency
- Hypogonadism (e.g., Turner syndrome)
- Hypothyroidism
- Idiopathic causes
- Inflammatory bowel disease
- Intrauterine growth retardation
- Juvenile diabetes mellitus
- Malabsorption syndromes (e.g., celiac disease)
- Malnutrition
- Neurologic disorders
- Panhypopituitarism
- Rickets
- Skeletal dysplasias (most)
- Steroid therapy

## Anatomic Variants

Experience and knowledge often are the best resources for successfully identifying normal variants. Compendiums of normal variants (e.g., *An Atlas of Normal Roentgen Variants That May Simulate Disease* by Keats and Anderson[10] and *Borderlands of Normal and Early Pathological Findings in Skeletal Radiography* by Freyschmidt et al.[11]) are invaluable resources.

Many epiphyseal and apophyseal ossification centers are irregular and fragmented in their early development (Fig. 128.7). When evaluating the significance of irregular ossification in a single area, it is important to remember that normal irregularities of ossification usually are symmetric and accompanied by similar changes in other areas of the skeleton. Normal epiphyseal and apophyseal fragmentary ossification tends to have a smooth, round, and sclerotic appearance. Sometimes epiphyseal fragmentary ossification centers may have a jigsaw configuration. Normal epiphyseal fragmentary ossification should be differentiated from acute fractures that tend to have a linear contour with nonsclerotic margins with accompanying soft tissue swelling and joint effusions.

Physiologic osteosclerosis of the newborn is a common finding. The long tubular bones of fetuses, premature infants, and term newborn infants often appear sclerotic compared with the bones of older children because of proportionately thicker cortical bone and more abundant spongiosa during fetal and neonatal life (e-Fig. 128.8). The sclerotic features disappear gradually during the first weeks of life and resolve by 2 to 3 months of age.

Physiologic periosteal reaction in the newborn also is a common finding seen in infants from 1 to 4 months of age and in both premature and term infants. Physiologic periosteal new bone is diaphyseal, smooth, regular, and 2 mm or less in thickness (Fig. 128.9).[12] Physiologic periosteal new bone is most common in the tibia, femur, and humeral diaphysis and occasionally is seen in the radius and ulna. In most infants, physiologic periosteal new bone is symmetric; however, it may be asymmetric in one-third to one-half of patients. Traumatic periosteal new bone tends to be asymmetric, metaphyseal, thicker, and irregular compared with physiologic periosteal new bone.

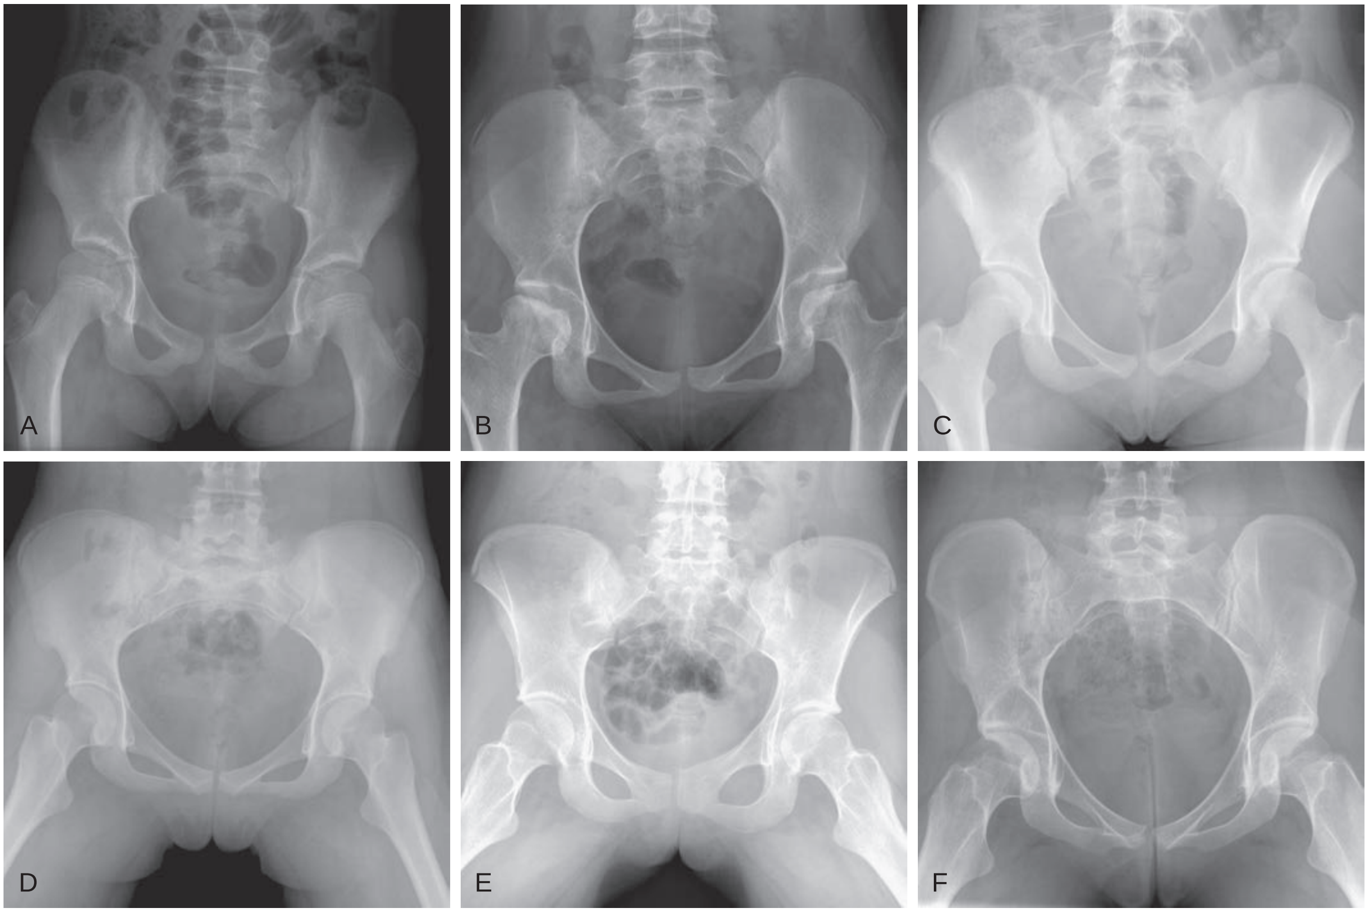
A variety of normal variants in the metaphyses of infants may simulate injury. It is important to distinguish these findings from the classic metaphyseal lesions of child abuse (see Chapter 143). The most common variant is the subperiosteal bone collar of the juxtaphyseal metaphysis, which has a normal step-off that may mimic a metaphyseal lesion of child abuse (Fig. 128.10).[13]

Gas (nitrogen) is commonly seen in joints of young children as a result of traction needed to appropriately position the child. Some authors hold that the presence of this vacuum phenomenon within the joint on radiography excludes a joint effusion.

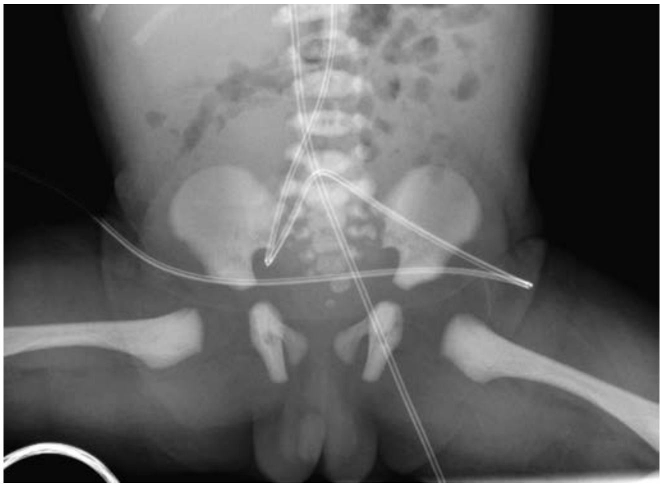
The following selected, important variants should not be confused with pathology.

### Hands and Feet

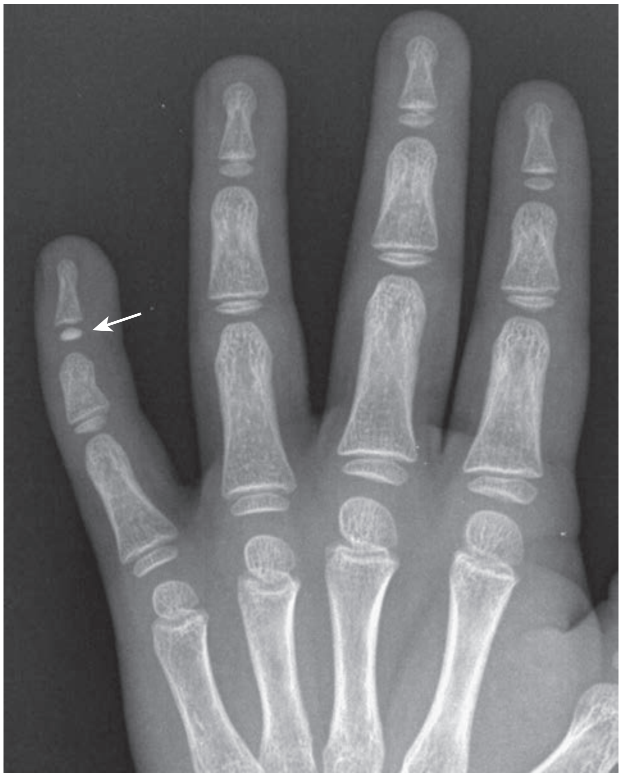
**Ivory Epiphyses.** Sclerotic epiphyseal ossification centers of the phalanges are called *ivory epiphyses* (e-Fig. 128.11).[14] They occur in approximately 1 in every 300 patients. Ivory epiphyses usually are found in the distal phalanges and in the middle phalanx of the fifth digit. Maturation may be retarded. Ivory epiphyses are usually sporadic and occur in developmentally normal children but may occur in association with cone-shaped epiphyses in dysplastic syndromes such as Cockayne's syndrome, trichorhinophalangeal syndrome, and multiple epiphyseal dysplasia.[14] Ivory epiphyses are more frequently found in the toes compared with the fingers.



**e-Figure 128.6. Risser stages.** (A) Risser stage 0. (B) Risser stage 1 (with bilateral Perthes). (C) Risser stage 2. (D) Risser stage 3. (E) Risser stage 4. (F) Risser stage 5.



**e-Figure 128.8. Normal osteosclerosis of the newborn.** All of the bones appear dense. The medullary cavities of the pubic bones and proximal femurs are obscured.



**e-Figure 128.11.** Ivory epiphysis *(arrow)* of the distal phalanx in a 6-year-old boy.

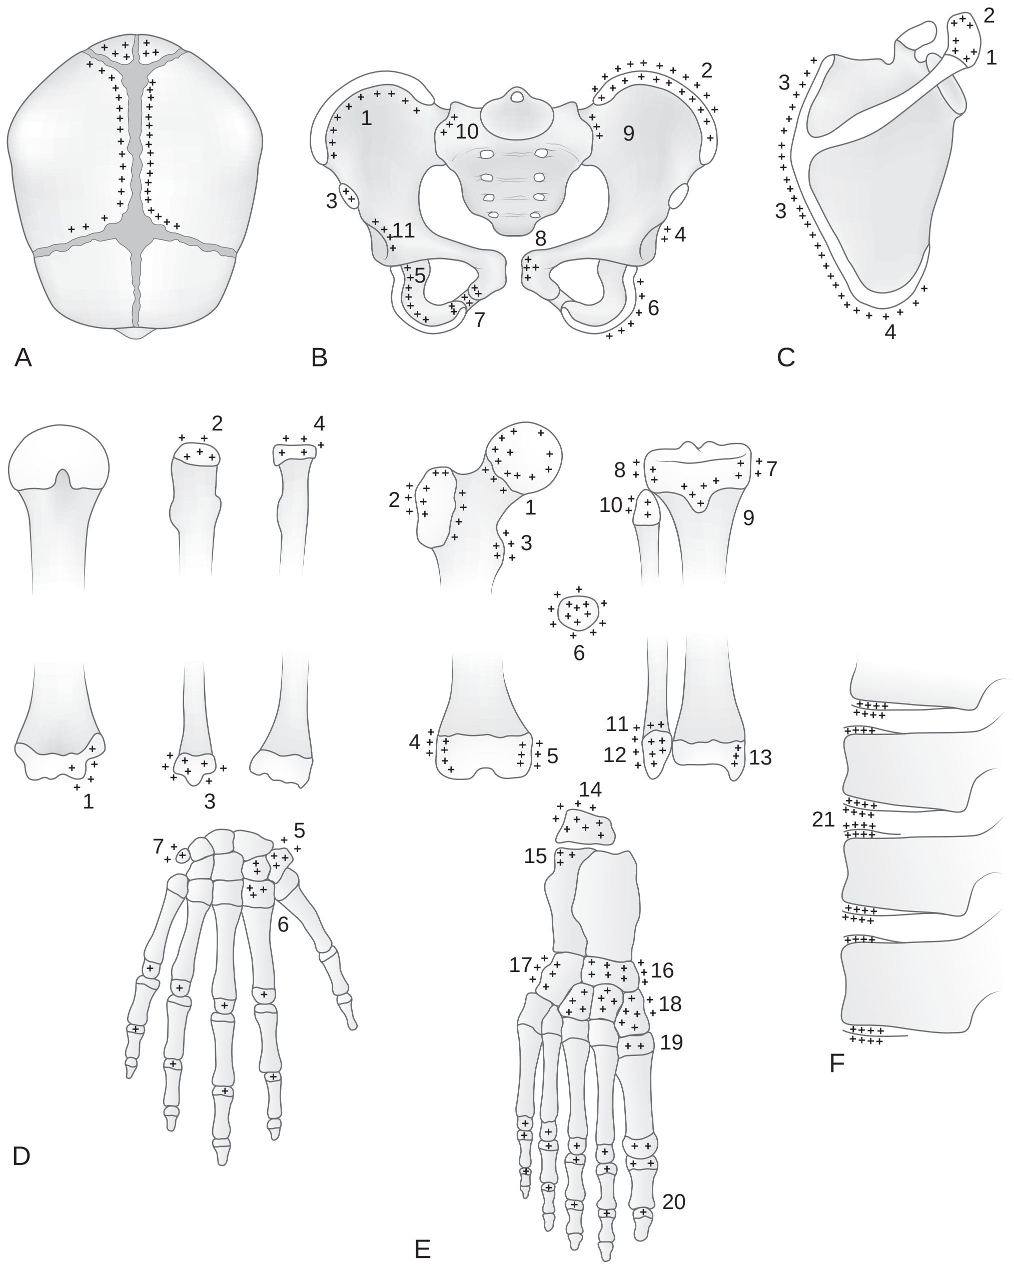


**Figure 128.7. Common sites of normally irregular mineralization in the growing skeleton are marked by crosses.** (A) The cranium. During the first weeks of life and continuing for several months, edges of the bones at the great sutures are commonly irregular, and in many infants deep fissures extend from the sutures into the bodies of the bones. Irregularities also are common on the edges of the temporal suture (not shown). (B) The pelvis: *1,* crest of ilium; *2,* secondary center in iliac crest; *3,* secondary center of anterior superior spine; *4,* os acetabuli marginalis; *5,* body of ischium; *6,* secondary center of ischium; *7,* ischium and pubis at the ischiopubic synchondrosis; *8,* body of pubis; *9,* ilium at sacroiliac joint; *10,* sacrum at sacroiliac joint; *11,* iliac edge and roof of the acetabular cavity. (C) The scapula: *1 and 2,* secondary centers of acromion process; *3,* secondary center of vertebral edge; *4,* secondary center of inferior angle. (D) The upper limb: *1,* secondary center of trochlea, always irregular; *2 and 3,* proximal and distal epiphyseal centers of ulna; *4,* proximal epiphyseal center of radius; *5,* greater and lesser multangulars; *6,* inconstant center of second metacarpal (pseudoepiphysis); *7,* pisiform. (E) The lower limb: *1,* proximal metaphysis of femur; *2 and 3,* secondary center and edges of shaft at greater and lesser trochanters, respectively; *4 and 5,* lateral and medial edges, respectively, of distal epiphyseal center of femur; *6,* patella; *7 and 8,* medial and lateral edges, respectively, of proximal epiphyseal center of tibia; *9,* secondary center in anterior tibial process; *10,* proximal epiphyseal center of fibula; *11 and 12,* distal metaphysis and distal epiphyseal center of fibula, respectively; *13,* internal malleolus of distal epiphyseal center of tibia; *14,* apophysis of calcaneus; *15,* primary center of calcaneus; *16,* navicular; *17,* cuboid; *18,* cuneiforms; *19,* proximal epiphyseal center of first metatarsal; *20,* epiphyseal centers of phalanges. (F) The spine: *21,* marginal centers (end plate ring apophyses).

**Cone-Shaped Epiphyses.** Cone-shaped epiphyses of the phalanges (e-Fig. 128.12) occur singly or in combination and most commonly affect the terminal phalanges. When they occur in isolation, they may be related to trauma with resultant central physeal growth disturbance. When they are multiple, they may be seen in association with dysplastic syndromes such as trichorhinophalangeal syndrome and cartilage hair hypoplasia.[15] Cone-shaped epiphyses are found more frequently in the toes than in the fingers (Fig. 128.13).

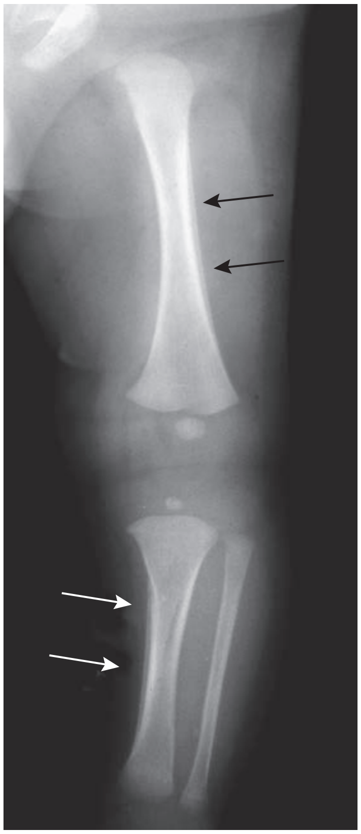

**Figure 128.9. Physiologic periosteal new bone in a 9-week-old boy.** Smooth periosteal new bone is seen on the lateral aspect of the femoral and medial aspect of the tibial diaphyses *(arrows)*.

**Fifth Metatarsal Apophysis.** During puberty, a longitudinally oriented, scalelike secondary ossification center appears within the proximal apophyseal cartilage of the fifth metatarsal (Fig. 128.14). Irregular ossification of the apophysis is common. The normal apophyseal ossification center may appear widely spaced from the underlying fifth metatarsal, simulating fracture.[16] The fifth metatarsal apophysis also may be bifid (e-Fig. 128.15). This presentation should be differentiated from a fifth metatarsal avulsion fracture related to the peroneus brevis insertion, which has a horizontal orientation (e-Fig. 128.16) (see also Chapter 142).

**Pseudoepiphyses.** Pseudoepiphyseal ossification centers may appear in the proximal cartilaginous portion of the growing second through fifth metacarpals and metatarsals and in the distal cartilage of the first metacarpals and metatarsals (Fig. 128.17 and e-Fig. 128.18).[17] They are formed from a thin rod of osteogenic tissue that invades the proximal or distal cartilage from the shaft. The end of the rod enlarges to form a mushroom-shaped mass of bone that appears radiographically as the “pseudoepiphysis.” The site of fusion of the pseudoepiphysis with the shaft often is indicated by a notch. Pseudoepiphyses are well formed by 4 to 5 years of age and fuse with the underlying shaft at the time of skeletal maturation. Sporadic pseudoepiphysis most commonly affects the second metacarpal bone of the hand, occurring in approximately 15% of children.[18,19] Pseudoepiphyses may be seen with higher frequency in children with hypothyroidism, Down syndrome, and cleidocranial dysplasia.

**Sesamoid Bones.** Sesamoid bones are present in the foot and hand. Sesamoids of the great toe reside within the medial and lateral slips of the flexor hallucis brevis tendon overlying the head of the first metatarsal. The medial great toe sesamoid is bipartite in 4% to 33% of patients (e-Fig. 128.19). Sesamoids of the feet may develop a stress reaction or a complete fracture and may be difficult to distinguish from a bipartite sesamoid on radiographs; magnetic resonance imaging (MRI) may be useful in distinguishing a normal bipartite sesamoid and underlying stress injury. For the first metatarsal phalangeal, stress injury tends to affect the medial sesamoid more frequently than the lateral sesamoid.[20] In addition to the sesamoids, numerous other supernumerary ossicles of the foot and ankle exist (Fig. 128.20).

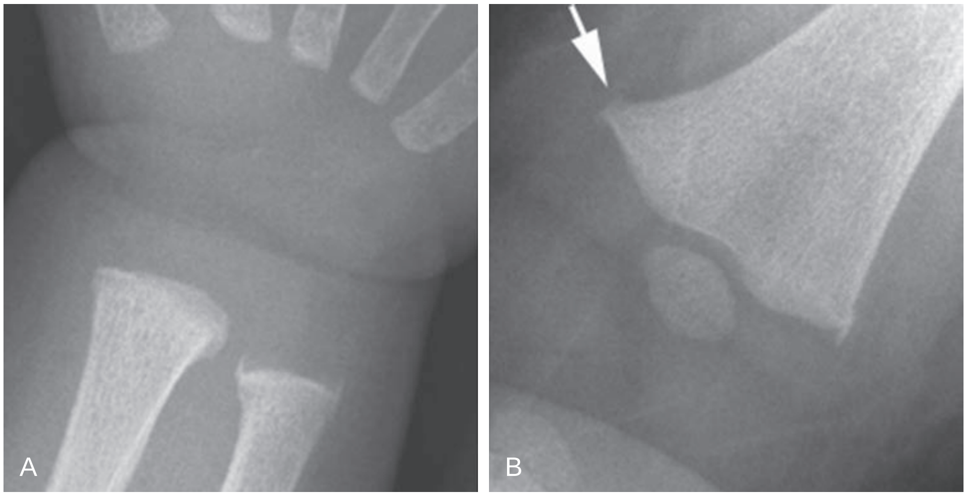

**Figure 128.10. Normal metaphyseal collar.** Small spurs on the distal ulnar (A) and distal femoral (B) metaphyses in a 5-month-old girl due to extension of the subperiosteal bone collar beyond the metaphysis. A normal “step-off” also is noted on the distal femur *(arrow)*.

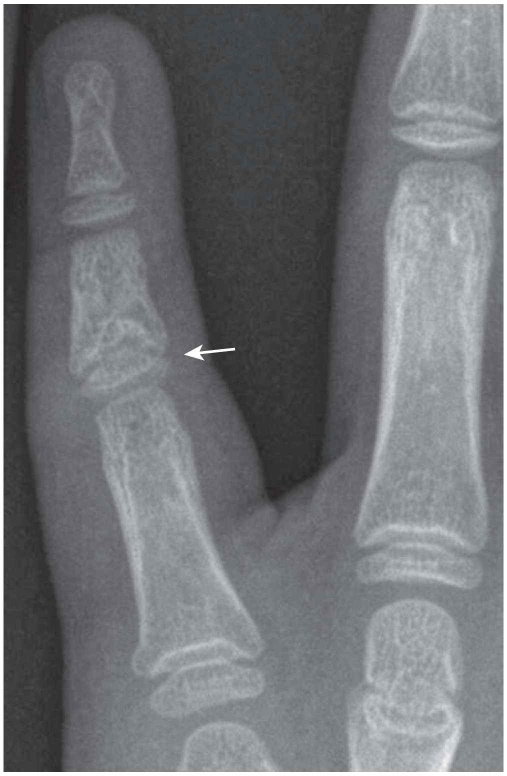
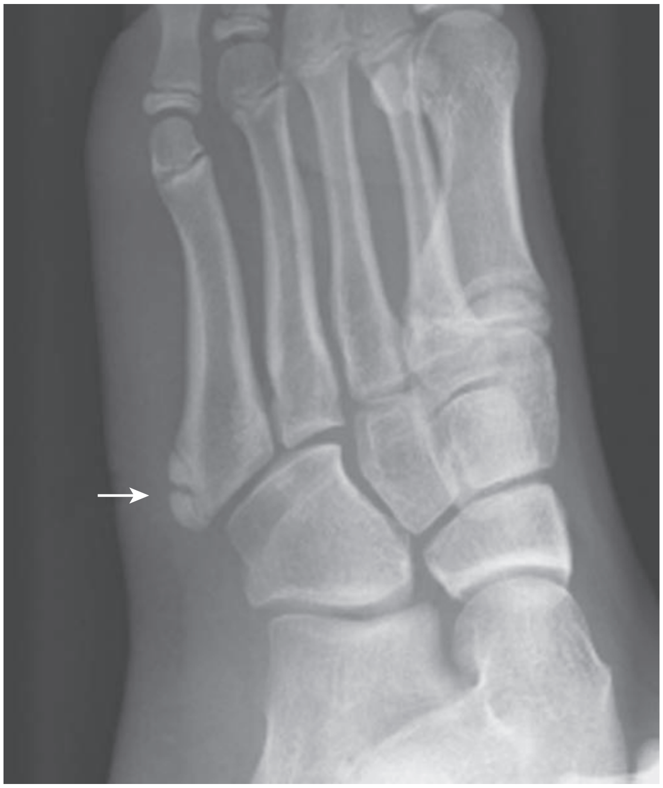
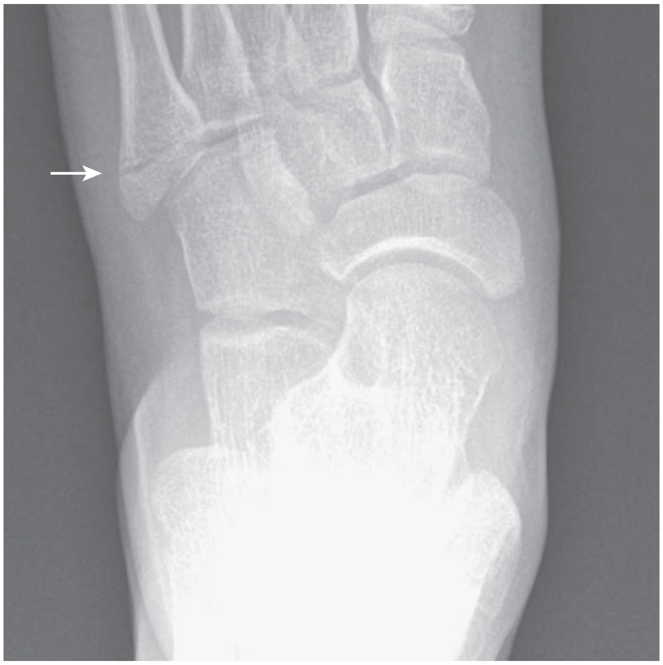


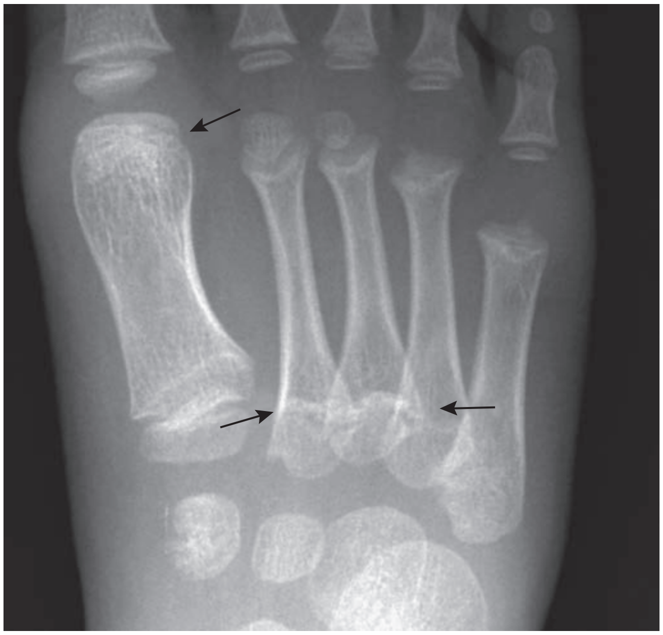
**e-Figure 128.12.** Cone-shaped epiphysis *(arrow)* of the middle phalanx of the fifth digit in a 9-year-old.



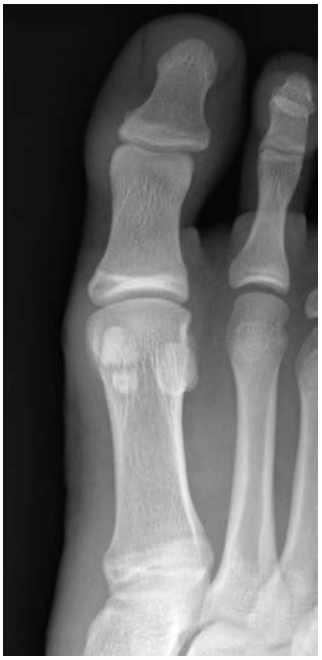
**e-Figure 128.15. Bifid apophysis of the fifth metatarsal in a 13-year-old girl *(arrow)*.** Findings persisted on follow-up examinations without change.



**e-Figure 128.16.** Nondisplaced avulsion fracture *(arrow)* of the base of the fifth metatarsal in a 9-year-old girl.



**e-Figure 128.18.** Pseudoepiphyses of the first metatarsal *(distal arrow)* and the second and third metatarsals *(proximal arrows)* in a 6-year-old boy.



**e-Figure 128.19.** Bipartite medial sesamoid of the great toe in a 15-year-old boy.

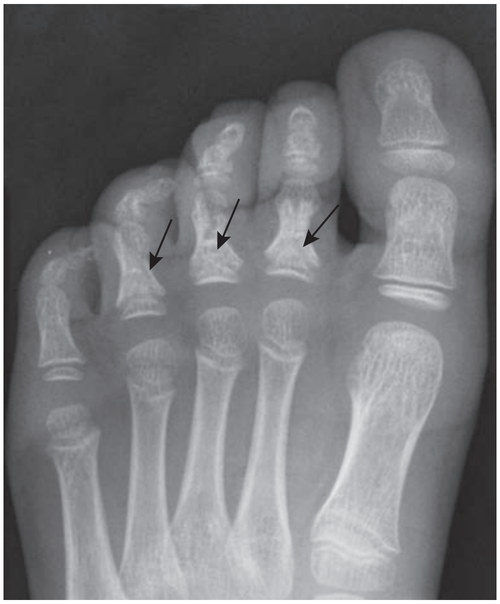


**Figure 128.13. Symmetric conical or bell-shaped epiphyseal ossification centers *(arrows)* in the proximal phalanges of the second, third, and fourth toes of an asymptomatic 5-year-old girl.** The contiguous distal end of each shaft is recessed to receive its elongated ossification center. The epiphyseal ossification centers in the proximal phalanges of the first and fifth toes are the normal, flat, shallow, transverse disks usually present in all of the phalanges.

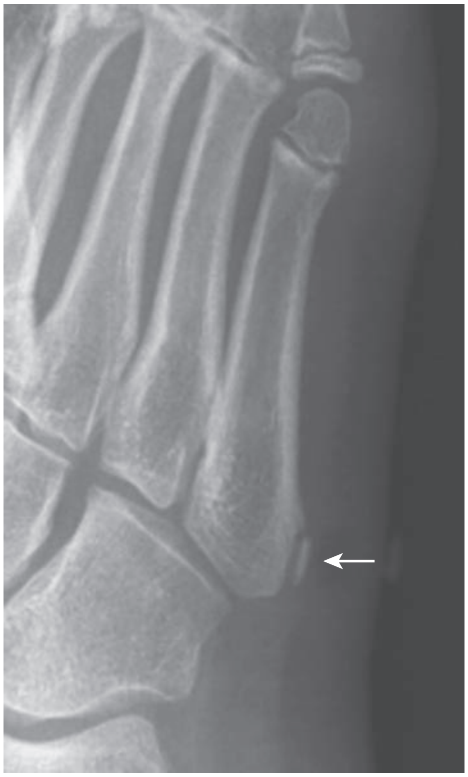

**Figure 128.14. Normal apophysis of the fifth metatarsal in a 10-year-old girl *(arrow)*.** The apophyseal growth plate is longitudinal in orientation, and the apophysis appears "scalelike."

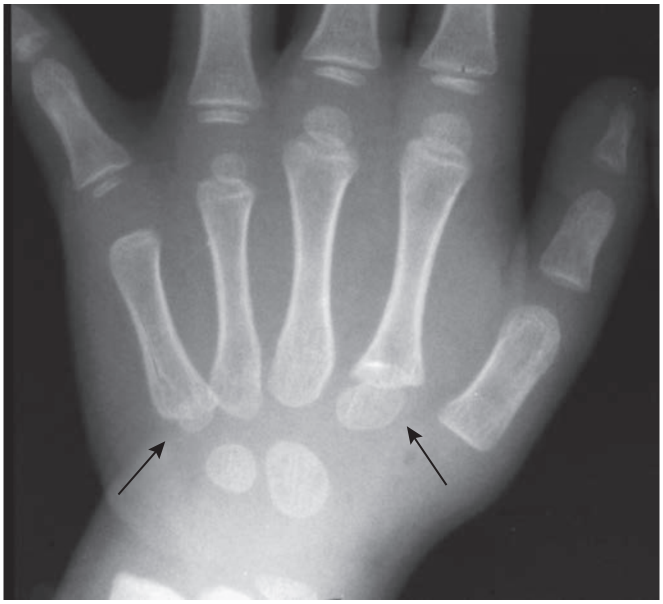

**Figure 128.17.** Pseudoepiphyses *(arrows)* in the proximal second and fifth metacarpals of a 3-year-old boy.

**Irregular Carpal Ossification.** Irregular mineralization often occurs in the developing carpal bones (e-Fig. 128.21). The pisiform is the bone most frequently affected (e-Fig. 128.22). In addition, carpal bones sometimes may have wavy cortical contours most commonly affecting the capitate, which should not be confused with erosions.[21]

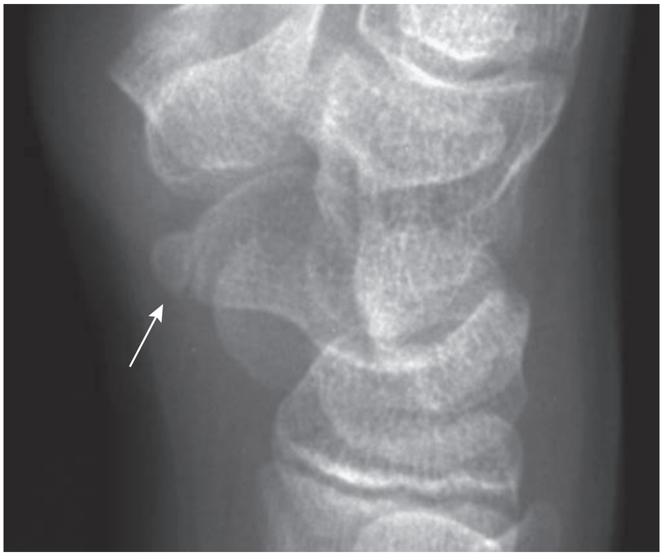
**Os Styloideum (Carpal Boss).** The os styloideum is a bony protrusion at the dorsum of the wrist between the trapezoid, capitate, and second and third metacarpals.[22] It may be isolated and mobile or fused to an adjacent bone. The os styloideum is present in 1% to 3% of patients and presents as a palpable mass (Fig. 128.23). The differential diagnosis for a dorsal palpable abnormality along the wrist is an os styloideum versus a ganglion.

**Radial and Ulnar Styloid Processes.** Separate ossification centers may appear in the regions of the ulnar (e-Fig. 128.24) and radial (Fig. 128.25) styloid processes before uniting with the main ossification center. The ulnar accessory ossification center should not be confused with ulnar styloid fracture nonunions.[23]

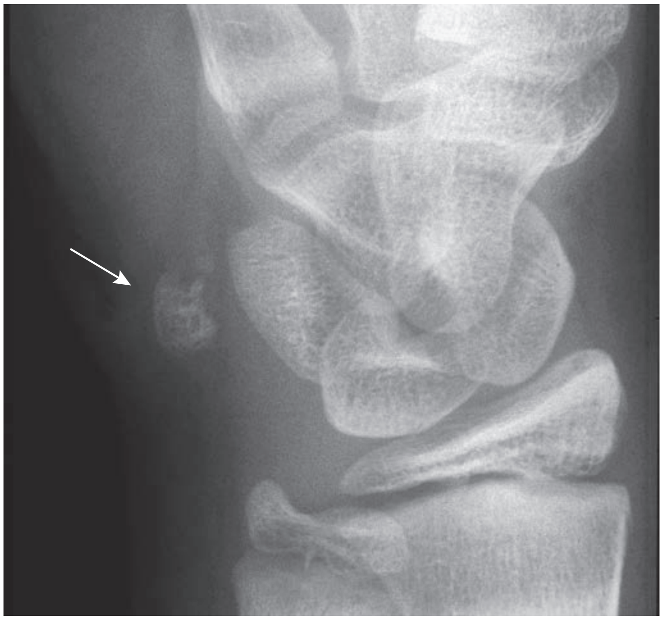
**Bifid Epiphyses.** Accessory ossification centers may occur in the epiphyses of phalanges and metatarsal bones. Bifid epiphysis is most common in the great toes, where examination before fusion of the centers is complete may simulate fracture (e-Fig. 128.26). The affected epiphysis is relatively sclerotic.[24]

**Absent Epiphyses.** The phalanges, especially the middle group, frequently lack epiphyseal centers in healthy children; this absence may be associated with symphalangism at the affected joints. Forty percent of the population have a biphalangeal (e-Fig. 128.27) fifth toe that may predispose to hammer or claw toe deformities.[25]

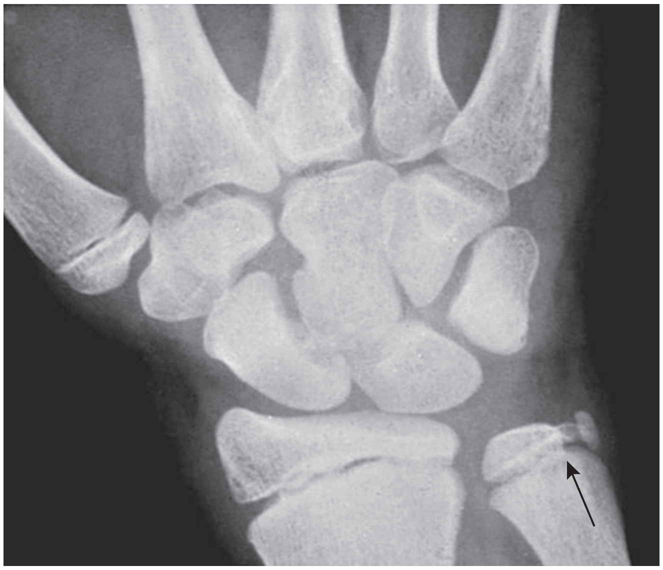
**Bifid Calcaneus.** The ossification center for the calcaneus is present at birth. Occasionally the body of the calcaneus may ossify from two or more independent centers (Fig. 128.28). This finding is rare as a normal variant. More often it is associated with an underlying disorder such as Down syndrome, mucolipidosis, or Larsen syndrome.



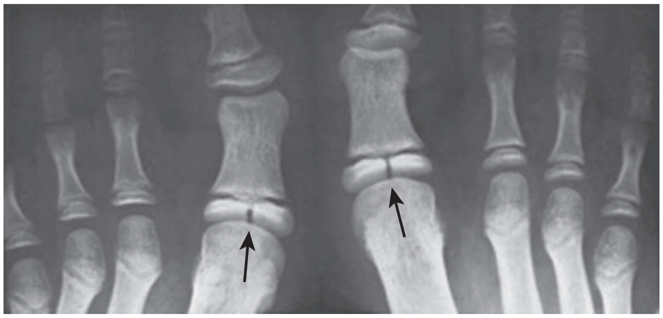
**e-Figure 128.21.** Accessory ossification center of the distal pole of the scaphoid *(arrow)* in an 11-year-old girl.



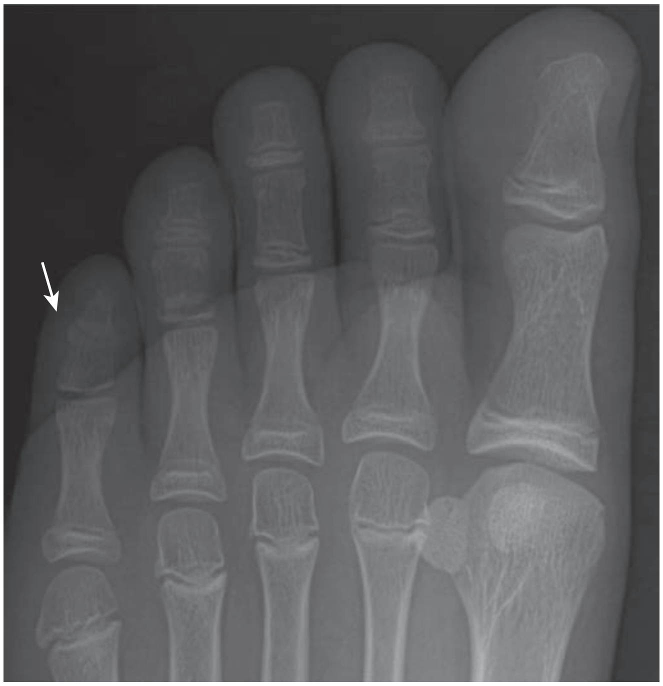
**e-Figure 128.22.** Irregular ossification of the pisiform *(arrow)* in a 12-year-old boy.



**e-Figure 128.24. Separate secondary epiphyseal ossicles *(arrow)* for the styloid in the distal epiphyseal cartilage of the ulna of an asymptomatic 11-year-old boy.** Ossicles of this type should not be mistaken for fracture fragments in cases of injury.



**e-Figure 128.26. Bifid epiphyses.** Symmetric fissures of the secondary ossification centers *(arrows)* in the proximal epiphyses of the proximal phalanges of the great toes of an asymptomatic 11-year-old boy. Radiolucent synchondroses between the segments of each center must not be mistaken for fracture lines.



**e-Figure 128.27.** Biphalangeal fifth toe *(arrow)* in a 13-year-old girl.

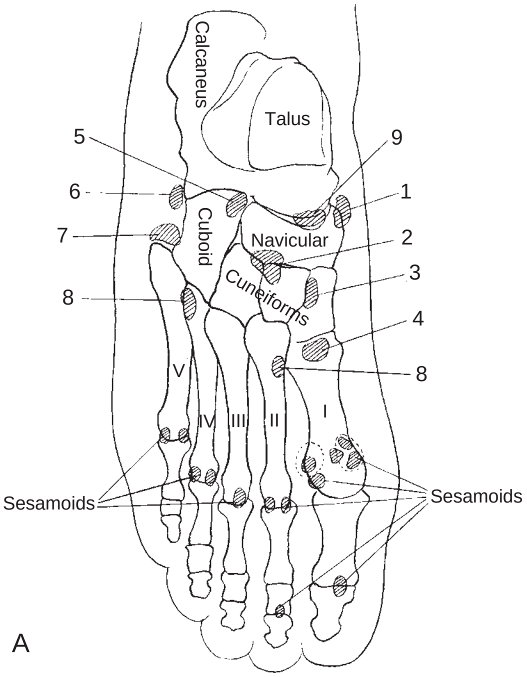


**Figure 128.20.** Normal supernumerary ossicles of the feet in ventrodorsal (A) and lateral (B) projections: *1,* os tibiale externum (accessory navicular); *2,* processus uncinatus; *3,* os intercuneiforme; *4,* pars peronea metatarsalia; *5,* os cuboideum secundarium; *6,* os peroneum; *7,* os vesalianum pedis; *8,* os intermetatarseum; *9,* os supratalare; *10,* talus accessorius; *11,* os sustentaculum; *12,* os trigonum tarsi; *13,* calcaneus secundarius.

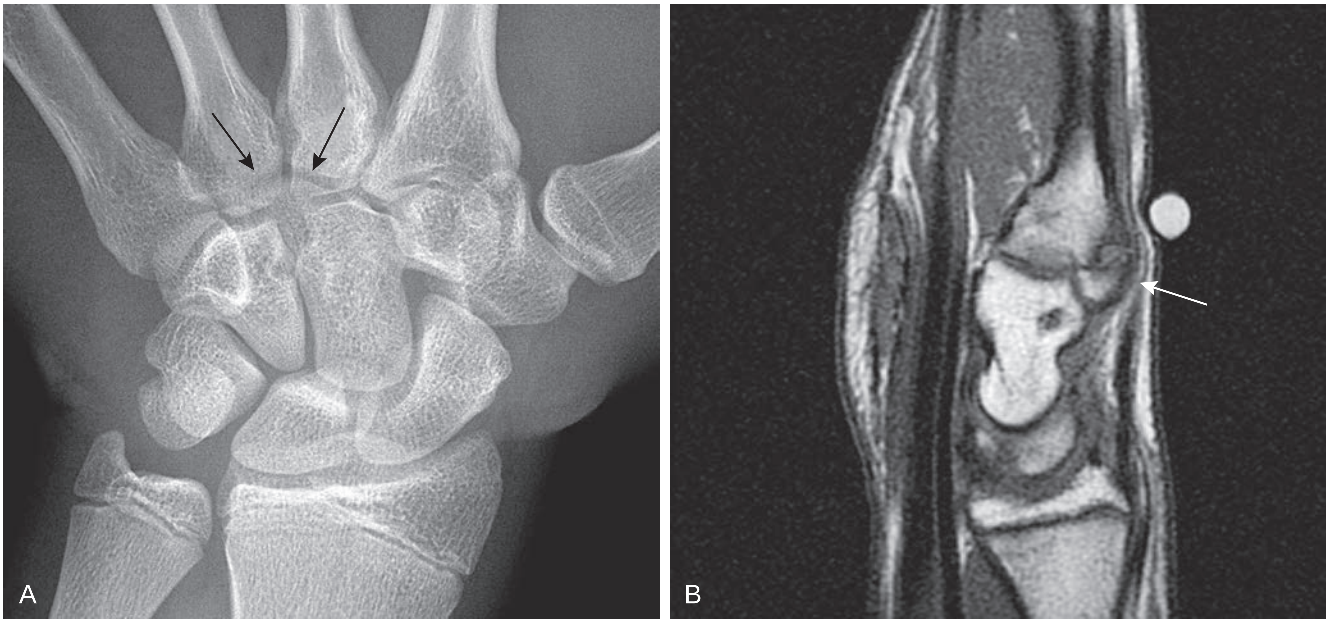

**Figure 128.23. Os styloideum (carpal boss) in a 14-year-old boy.** (A) Anteroposterior radiograph; the accessory bone is barely visible *(arrows)*. (B) Sagittal T1-weighted magnetic resonance (MR) image shows the accessory ossicle *(arrow)* at the dorsum of the carpometacarpal joint. Note that the ossicle causes a bump on the dorsum of the wrist.

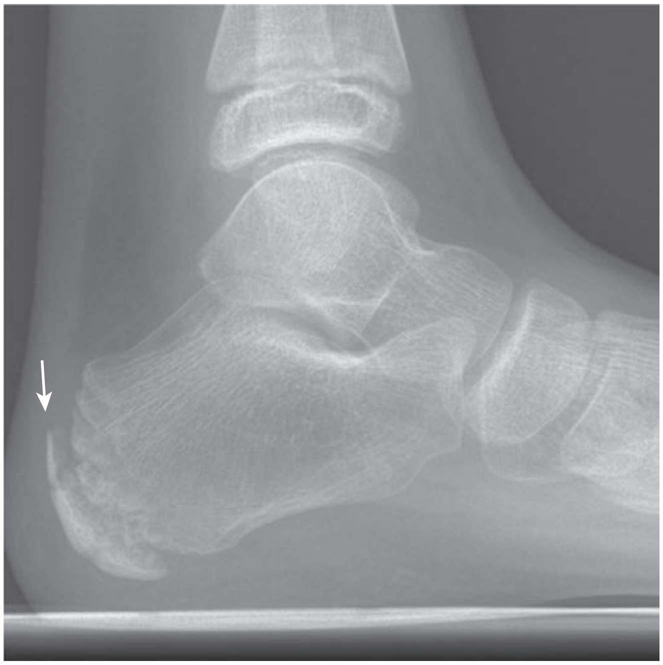
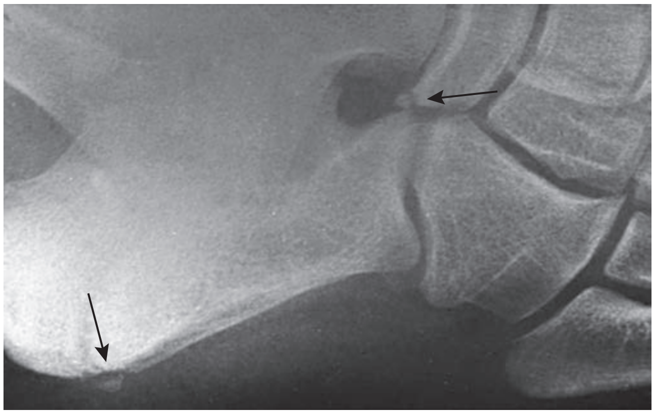
**Calcaneal Apophysis.** The calcaneal apophysis appears about the middle of the first decade. It often is fragmented and/or sclerotic well into the second decade until fusion with the body of the calcaneus is complete (e-Fig. 128.29). Calcaneal apophysitis (Sever disease) is a poorly understood cause of heel pain in children, and this diagnosis should not be made on the basis of radiographs alone.[26] MRI findings of apophyseal edema may suggest the diagnosis; however, Sever disease remains a clinical diagnosis.

**Calcaneus Secondarius.** The calcaneus secondarius (e-Fig. 128.30) may simulate an anterior process calcaneal fracture. The ossicle is located in between the anteromedial calcaneus, cuboid, talar



**e-Figure 128.29. Normal calcaneal apophysis.** Lateral radiograph shows a normal, sclerotic, slightly fragmented appearance of the calcaneal apophysis *(arrow)* in a 12-year-old boy.



**e-Figure 128.30. Calcaneus secundarius.** Small, round, smooth calcaneus secundarius *(arrow at right)* in the center of the space between the calcaneus, cuboid, navicular, and talus on lateral oblique projection in an asymptomatic 12-year-old boy. The posterior arrow points to a normal fragmentary calcaneal apophysis along the plantar aspect of the calcaneal tuberosity. Similar ossicles were present in the other foot.

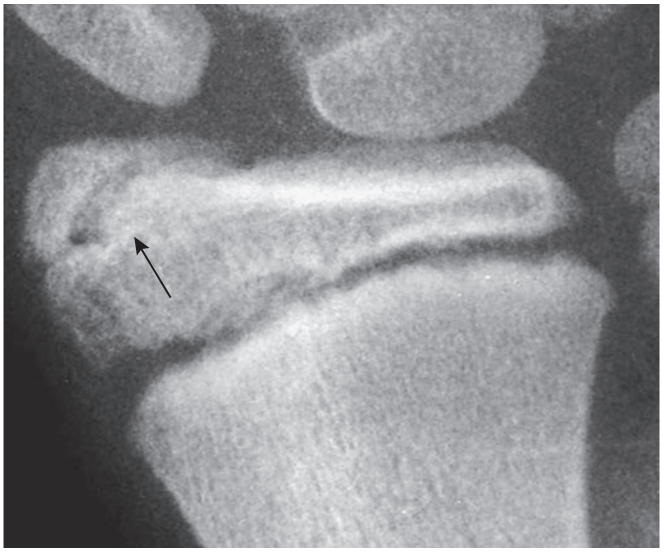


**Figure 128.25. Large accessory ossification center *(arrow)* in the styloid process of the radial epiphyseal ossification center of a healthy 13-year-old boy.** This may simulate a fracture fragment.

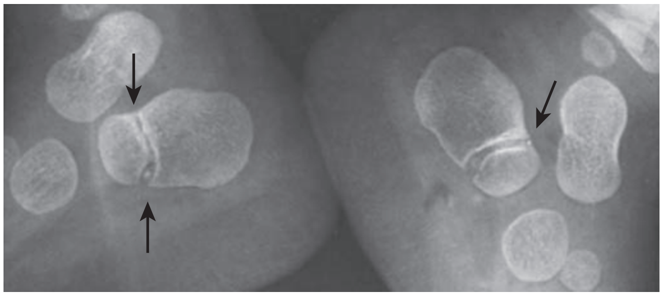

**Figure 128.28. Double ossification centers *(arrows)* in the body of the calcaneus on each side of a 20-month-old infant.** The infant had no known underlying disorder; radiographs were obtained because of an acute injury.

head, and navicular. It is rare and of no clinical significance other than possibly being mistaken for a fracture.

**Calcaneal Pseudocyst.** A pseudocystic triangular area of radiolucency is present in the anterior half of the calcaneal body. At this location, a deficiency of spongy bone is normal. The pseudocyst is of no clinical significance in itself; however, it must be differentiated from true bone cysts or intraosseous lipomas that can develop at this site but tend to have a more round shape. MRI or computed tomography (CT) is helpful for differentiating these lesions when radiographic features are equivocal.

**Os Trigonum.** There is a secondary ossification center within a posterior cartilaginous extension of the talus, which ossifies between 7 to 13 years and typically fuses with the talus within 1 year (Fig. 128.31). If this remains separate from the talus, as it does in approximately 15% of patients, it is referred to as an *os trigonum*.[27] This may mimic a fracture of the posterior process of the talus. Repetitive forced plantar flexion may cause a syndrome of posterior ankle impingement or "os trigonum syndrome." This syndrome occurs most commonly in ballet dancers, soccer players, and basketball players and may cause tendinopathy of the flexor hallucis longus.

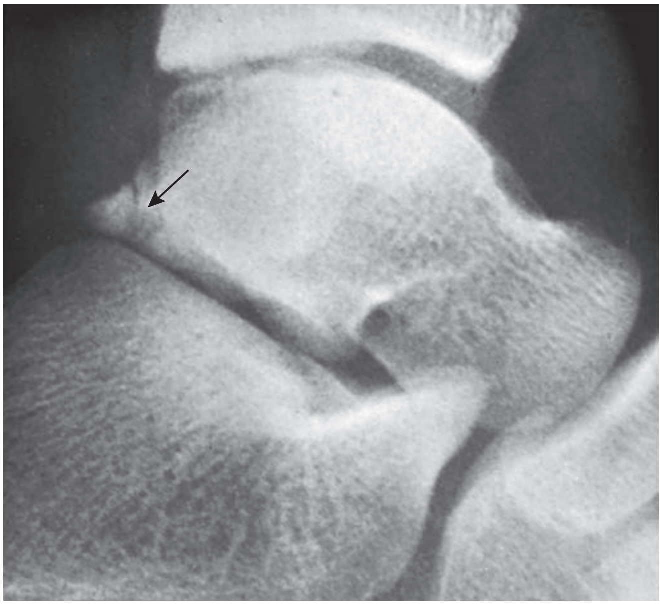

**Figure 128.31. Normal apophyseal ossification center *(arrow)* in the dorsal process of the talus in a healthy 11-year-old boy.** The radiolucent strip between the body of the talus and the ossification center is a normal synchondrosis, not a fracture line. When the synchondrosis persists after the normal age for its fusion with the body of the talus, the persistent ossification center is called the *os trigonum*.

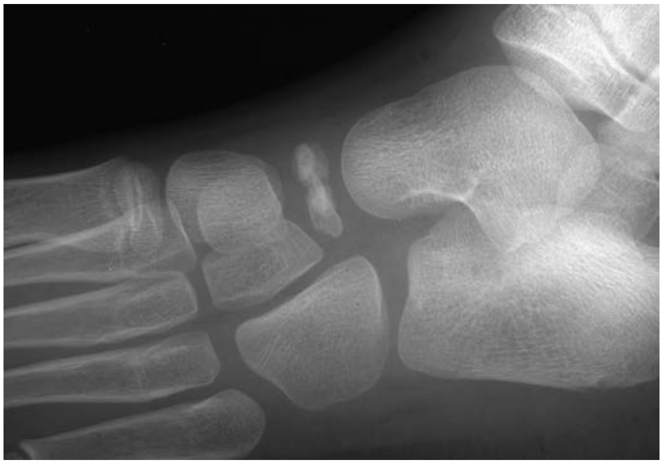

**Figure 128.33.** Irregular ossification of the navicular in a 2-year-old boy.

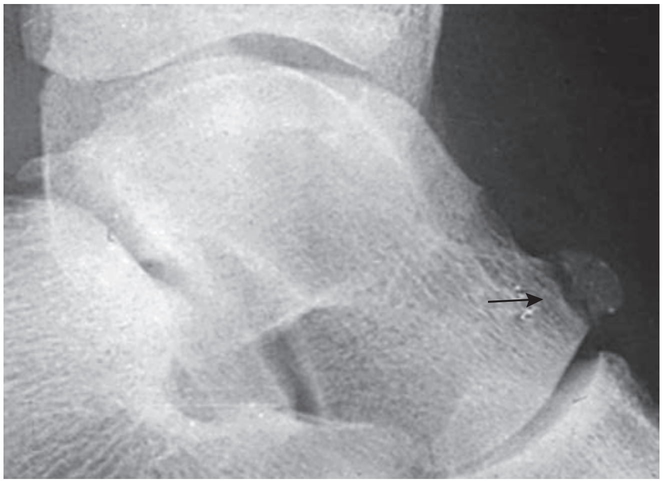
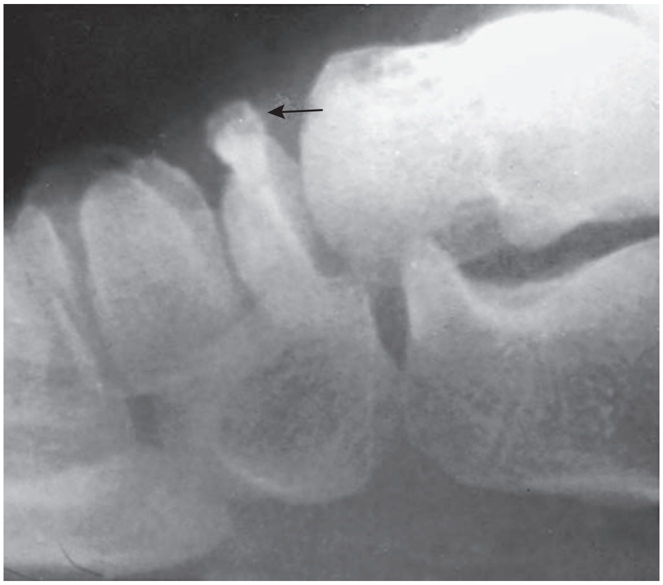
**Os Supratalare.** The os supratalare on the crest of the head of the talus may simulate injury or be simulated by injury (e-Fig. 128.32).

**Os Supranaviculare.** The ossification center for the navicular bone frequently is irregular and fragmentary up to about 5 years of age (Fig. 128.33). The os supranaviculare (e-Fig. 128.34) is an accessory ossicle along the dorsal navicular that may be seen after 5 years of age. These variants of navicular ossification have well-corticated margins and a characteristic ovoid to circular shape with or without associated sclerosis, which may superficially mimic Kohler disease. These accessory ossification centers must be differentiated from fractures.

**Accessory Navicular.** The accessory navicular is the best known and one of the most important accessory ossification variants in the foot. The accessory navicular is located along the medial aspect



**e-Figure 128.32.** Os supratalare *(arrow)* on the dorsal edge of the talus just proximal to the talonavicular joint in an asymptomatic 18-year-old girl.



**e-Figure 128.34.** Large supranavicular bone *(arrow)* partially fused with the main mass of the navicular itself and appears to be an accessory ossification center in the periphery of the navicular cartilage; similar changes were present in the other foot. The patient was an asymptomatic 8-year-old boy.

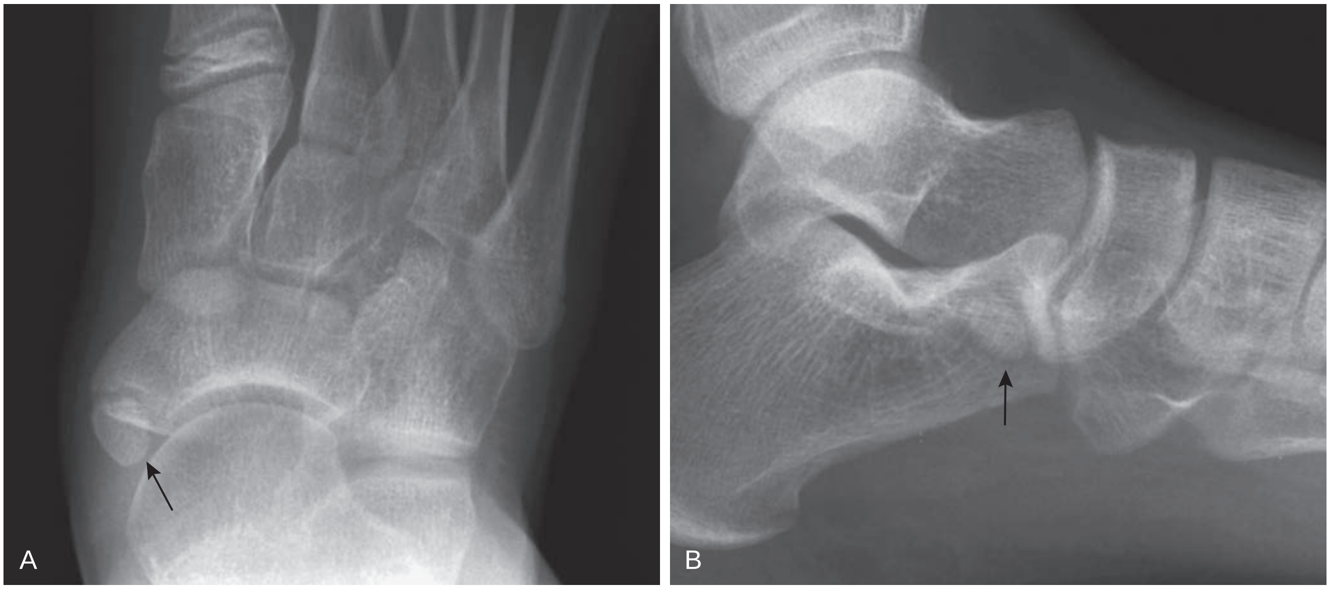


**Figure 128.36.** Type II accessory naviculars *(arrows)*. (A) An 11-year-old girl. (B) A 13-year-old girl.

of the navicular where the tibialis posterior inserts. They are seen in approximately 21% of patients, and 50% to 90% are bilateral.[28] When patients have symptoms related to their accessory navicular, it usually is related to painful flat foot in part as a result of tibialis posterior dysfunction.

The type I variant ("os tibiale externum" or "navicular secundarium") is a true round sesamoid bone measuring 2 to 6 mm that lies within the tibialis posterior tendon and is approximately 3 mm separate from the navicular bone (e-Fig. 128.35). Type I variants account for 10% to 15% of cases in children.

Type II variants ("prehallux" or "bifurcated hallux") are separated from the navicular by a cartilaginous or fibrocartilaginous bridge and represent an accessory ossification center for the tubercle of the navicular (Fig. 128.36). The ossicle is larger (9–12 mm), triangular or heart-shaped, and congruent with and closely apposed to the adjacent navicular. It is connected to the navicular by a synchondrosis. Symptoms generally develop in the second decade.

The type III variant is the cornuate navicular. The cornuate navicular represents medial and plantar elongation of the navicular bone without a separate ossicle, which sometimes may result from fusion of type II accessory navicular with the parent bone.

## Elbow

The six major ossification centers at the elbow ossify in an expected sequence—capitellum, radial head, internal (medial) epicondyle, trochlea, olecranon, and external (lateral) epicondyle. The sequence of ossification can be remembered with the acronym CRITOE (CRMTOL). If this acronym is too cumbersome to remember, a simpler and more relevant acronym to remember for chronologic appearance of elbow ossification centers is IT (Internal [medial] epicondyle followed by Trochlea) (Fig. 128.37). If an osseous density is seen in one area when an earlier-appearing center is lacking, a traumatic fragment is very likely the cause. The medial epicondyle appears earlier than the trochlea as a rule. Therefore if the medial epicondyle is absent but a trochlear ossification is present, a displaced medial epicondylar fracture should be suspected (e-Fig. 128.38; see also Fig. 142.27).

The ossification centers of the elbow can appear quite irregular during initial formation, particularly the trochlea (e-Fig. 128.39), which should not be confused with an osteochondrosis. The olecranon ossification center (Fig. 128.40) varies considerably in size and should be differentiated from an acute olecranon fracture (e-Fig. 128.41) by the shape of the individual ossifications and the nature of the margins. When the margins of the olecranon ossific densities are corticated, they are likely to be normal fragmentary accessory ossification centers, whereas noncorticated and linear ossific densities tend to represent sequelae from acute fracture.

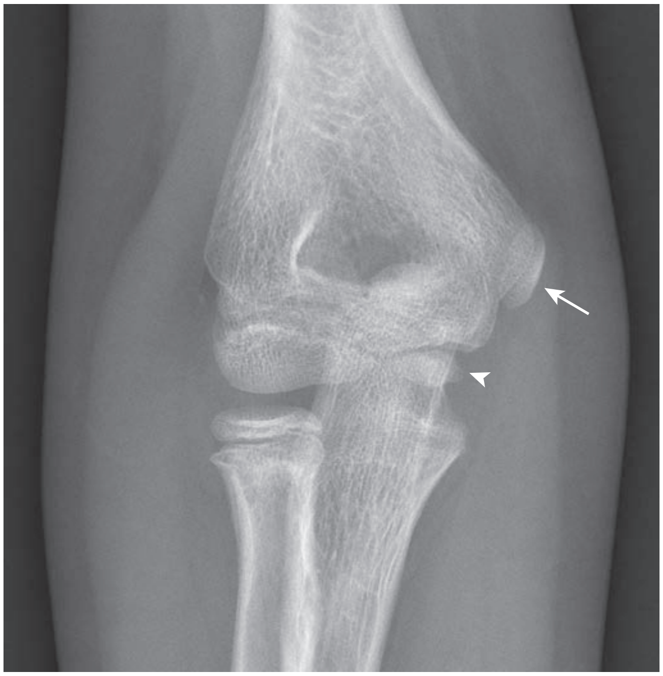

**Figure 128.37. Normal elbow in an 11-year-old boy.** As a rule, the medial (internal) epicondylar ossification center *(arrow)* should appear before the trochlear ossification center *(arrowhead)*. If only the trochlear ossification center is present, a medial epicondylar avulsion fracture should be suspected.

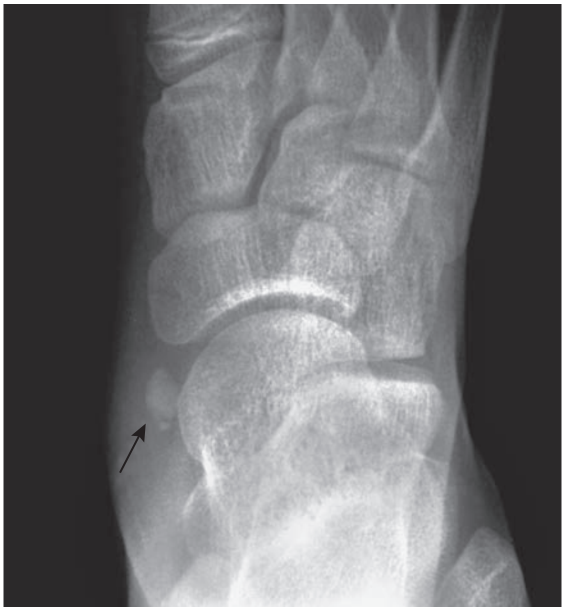
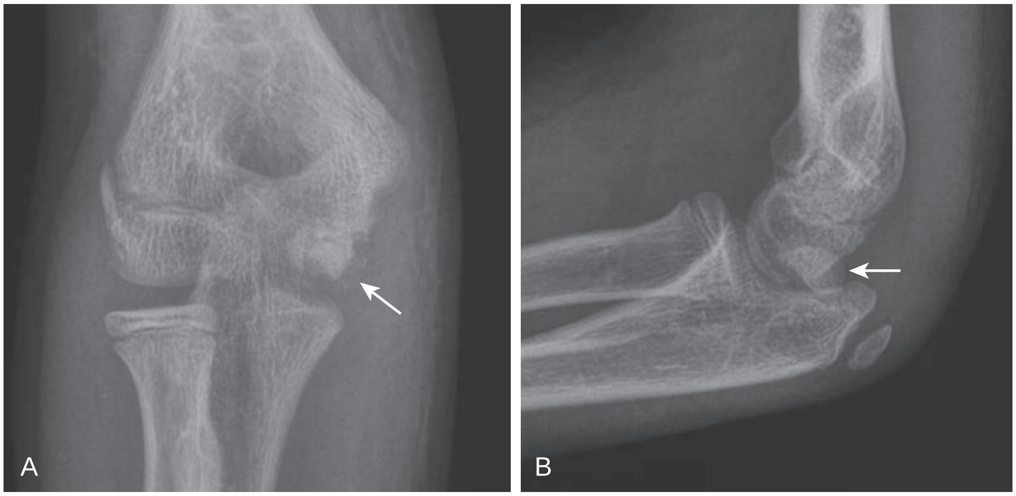
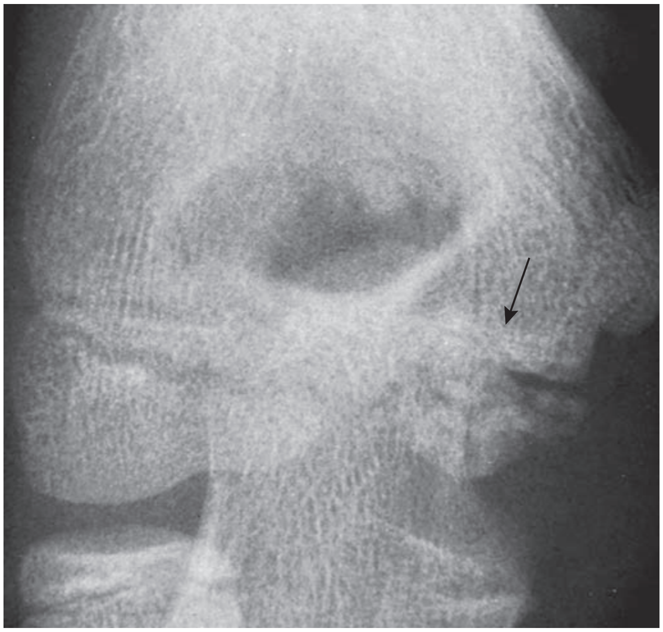
The lateral epicondyle does not fuse directly with the humeral shaft as the medial epicondyle does but fuses first with the adjacent capitellum; their fused mass then joins with the end of the humeral



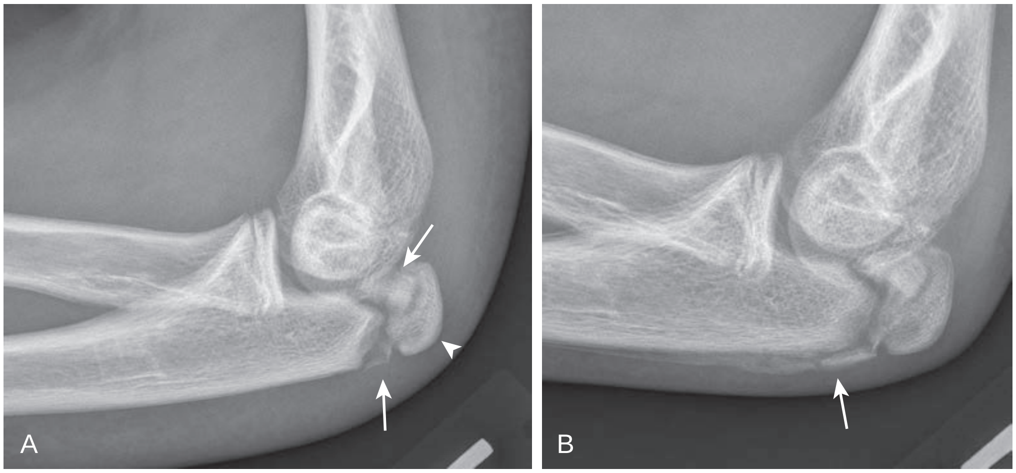
**e-Figure 128.35.** Type I accessory navicular *(arrow)* in a 10-year-old girl.



**e-Figure 128.38. Displaced medial epicondylar avulsion fracture.** (A) Frontal and (B) lateral radiographs show a displaced medial epicondylar avulsion fracture *(arrows)* mimicking trochlear ossification center in a 13-year-old boy.



**e-Figure 128.39. Irregular ossification center *(arrow)* of the trochlea of a healthy 13-year-old boy.** This irregular ossification of the trochlea persists throughout the growth period and always should be recognized as a normal variant; actually, it is the norm. The capitellum, in contrast, ossifies uniformly as it expands during the growth period.



**e-Figure 128.41. Olecranon fracture.** (A) An acute comminuted olecranon fracture involving the metaphyseal equivalent region *(arrows)* separate from the major olecranon ossification center *(arrowhead)* in a 12-year-old boy. (B) A subsequent film 2 weeks later demonstrates callus formation related to the healing fracture *(arrow)*.

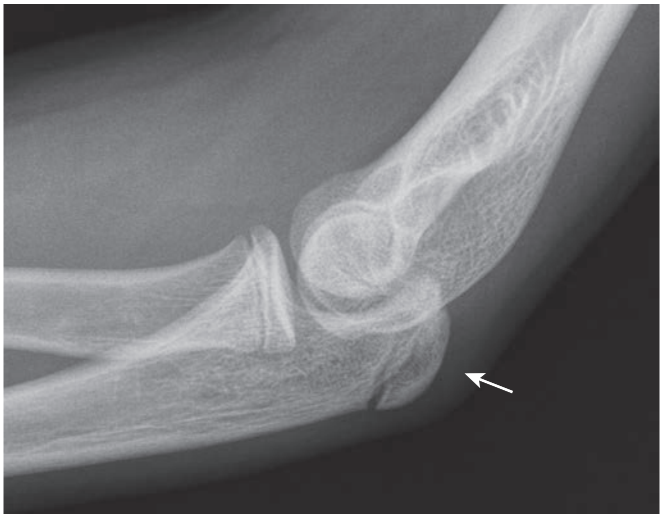


**Figure 128.40.** Normal smooth, corticated olecranon ossification center *(arrow)* in a 12-year-old boy.

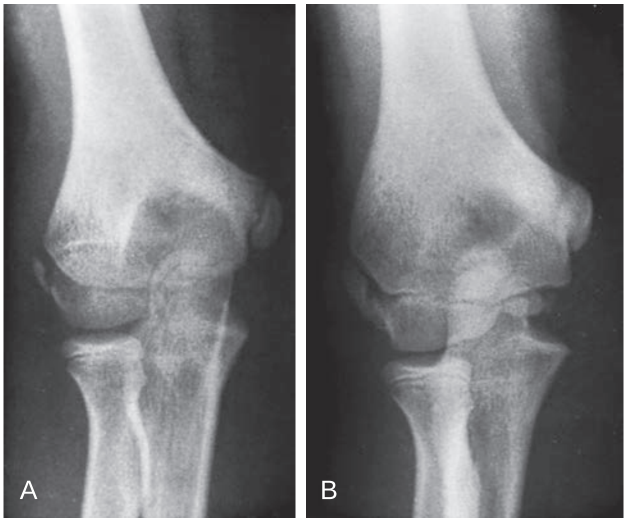

**Figure 128.42. Lateral epicondyle ossification center.** This center is independent of both the capitellum and the shaft at 11 years; (A) it is fusing with the capitellum at 12.5 years, (B) and these combined ossification centers will later fuse with the shaft. The medial epicondyle center is fusing directly with the shaft in (A) and (B). In (B), the trochlea is normally irregular.

shaft (Fig. 128.42). With early ossification, the lateral epicondylar ossification center appears as an irregular flake of bone, which is easily mistaken for an avulsion fragment. The medial epicondyle occasionally has an irregular, fragmentary appearance (Fig. 128.43). This finding must be differentiated from a medial epicondylar chondro-osseous avulsion fracture when widening or irregularity, or both, are present (e-Fig. 128.44).

## Supracondylar Process

The humeral supracondylar process is a vestigial structure that projects from the medial aspect of the anterior surface of the humeral shaft 5 to 7 cm proximal to the medial epicondyle (Figs. 128.45 and 128.46).[29] It occurs in 1% of individuals. The supracondylar process may be connected by the ligament of Struthers to the medial epicondyle. Portions of pronator teres and brachioradialis muscles may attach to the process, to the ligament of Struthers, or to both. Occasionally, median nerve neuralgia occurs as a result of entrapment or compression of the median nerve as it passes through this tunnel created by the supracondylar process, the ligament of Struthers, and associated structures.[30]

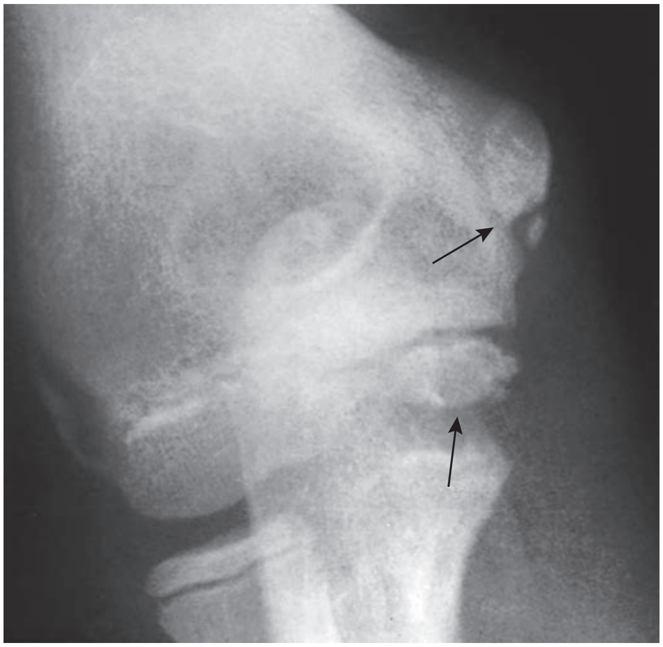

**Figure 128.43. Accessory ossification center *(proximal arrow)* at the lower pole of the medial epicondyle of a healthy 12-year-old boy that simulates a fracture fragment.** The distal arrow points to the normal irregular edges of the trochlear center of the humerus.

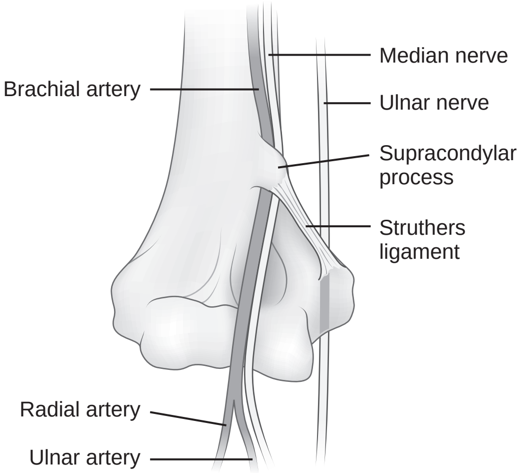

**Figure 128.45. Supracondylar process anatomy.** A drawing of the supracondylar process on the anterior surface of the humerus that shows the relationship of the process to the brachial artery and its branches and to the median nerve. *(From Spinner RJ, Lins RE, Jacobson SR, et al. Fractures of the supracondylar process of the humerus.* J Hand Surg [Am]. *1994;19:1038–1041.)*

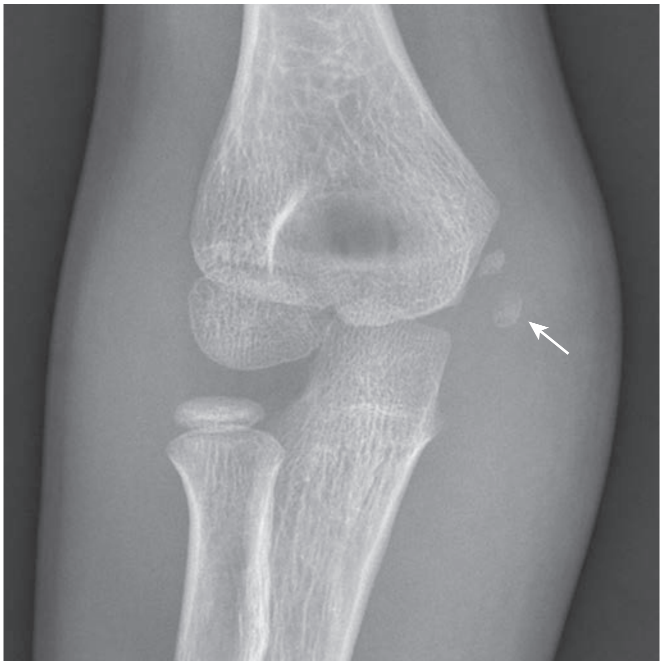
## Shoulder

**Proximal Humeral Epiphyseal Ossification.** At the upper end of the humerus, two and occasionally three secondary ossification centers can be observed. The first center (humeral head proper) to appear develops in the medial half of the epiphysis at about 2



**e-Figure 128.44. Medial epicondylar avulsion fracture.** Frontal radiograph shows a fragmentary medial epicondylar avulsion fracture *(arrow)* in an 8-year-old boy.

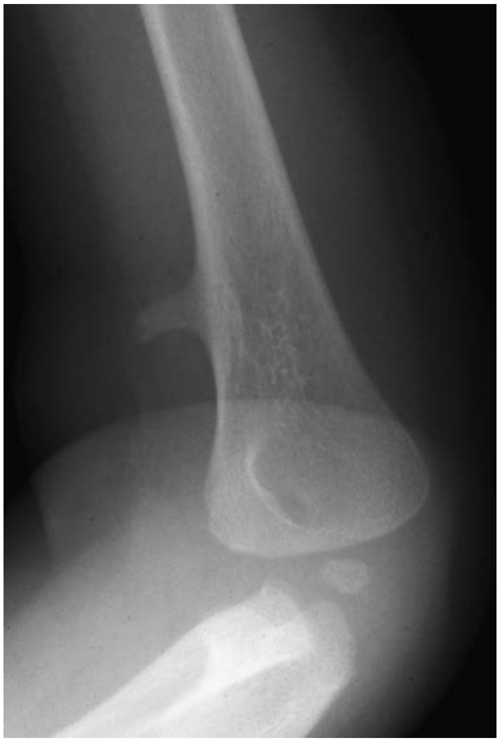


**Figure 128.46.** Supracondylar process of the distal humerus in a 21-month-old girl.

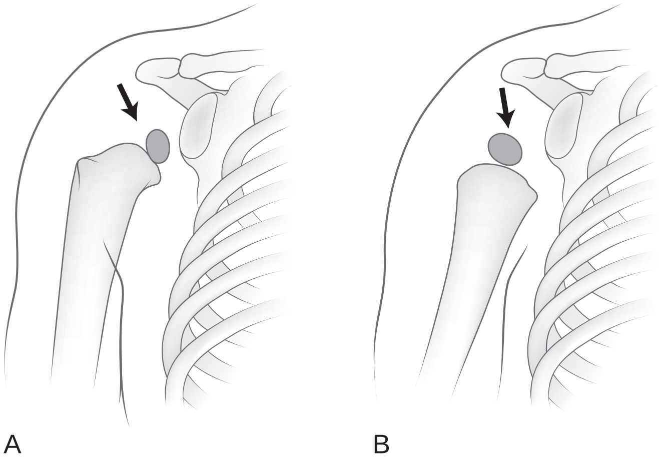

**Figure 128.47. Factitious shift in position *(arrows)* of the normally eccentric proximal ossification center of the humerus caused by rotation of the bone.** (A) In the neutral position the ossification center of the proximal humerus appears to be in the medial segment of the epiphysis. (B) With the humerus in internal rotation, the ossification center appears to be laterally displaced.

weeks of age; because of its eccentric location, it shifts to a factitious lateral position when the arm is internally rotated (Fig. 128.47). The second center appears laterally in the greater tuberosity during the second half of the first year. A rare third center occurs in the lesser tuberosity during the third year and fuses with the humeral head during the sixth to seventh years. This center may be seen in axillary views of the shoulder and may simulate a fracture fragment.

**Proximal Humeral Physis.** The proximal humeral physis is tented, with the apex above the pitched anterior and posterior segments.

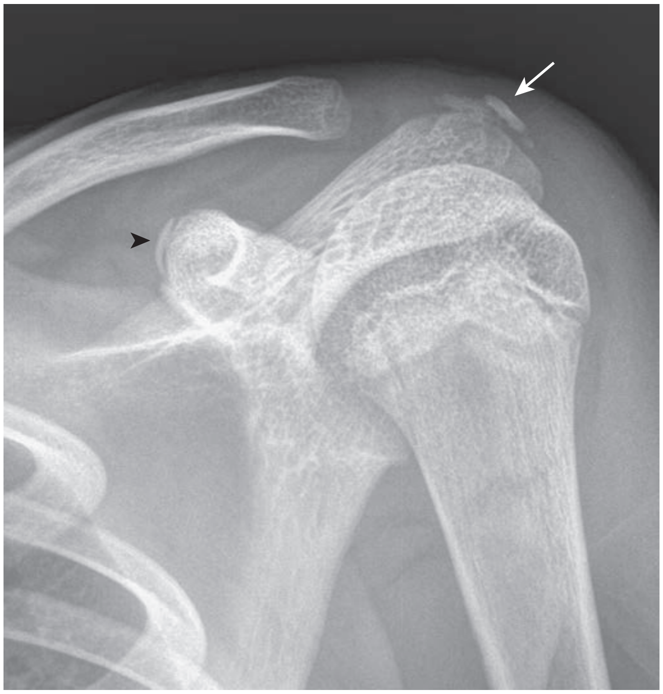

**Figure 128.52.** Normal acromial fragmentation *(arrow)* and coracoid apophysis *(arrowhead)*, which superficially may be mistaken for a fracture in this 12-year-old girl.

In rotated positions of the humerus, these segments are projected at different levels and may simulate fracture (e-Fig. 128.48). Offset of the epiphyseal ossification center relative to the lateral metaphyseal margin may simulate a Salter-Harris fracture.

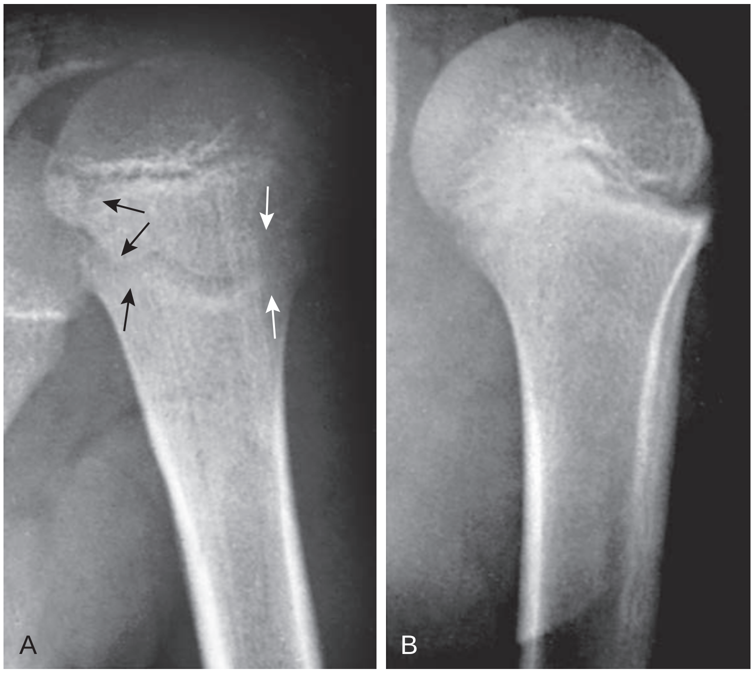
**Bicipital Groove.** The bicipital groove in the anterior surface of the humerus may simulate local bone destruction or production (e-Fig. 128.49).

**Muscular Insertions.** Local cortical thickening that resembles a periosteal reaction occurs frequently at sites of insertion of major muscles of the upper arm. This finding is most common at the site of the deltoid insertion at the lateral aspect of the humeral diaphysis (e-Fig. 128.50).

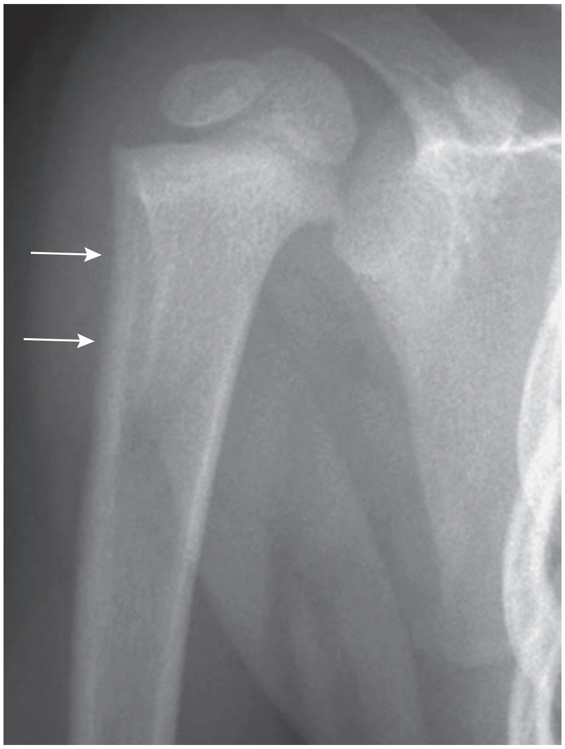
**Humeral Head Pseudocyst.** When the humeral head is well ossified, the region of the greater tuberosity appears relatively radiolucent and devoid of trabeculation.[31] This appearance may be mistaken for an underlying osseous lesion (e-Fig. 128.51).

**Acromion and Coracoid Process.** The acromion can have a fragmentary appearance during ossification, and superficially it may resemble an acromion fracture (Fig. 128.52). The acromion usually will fuse with the remainder of the scapula by around age 25 years. When the acromion persists as a separate secondary ossification center beyond 25 years, then it represents an os acromion. Because the acromion in children has a significant cartilaginous component that is radiolucent, the acromioclavicular (AC) joint may appear widened (e-Fig. 128.53). Therefore measurements developed for the AC joint in adult patients as a criterion for determining AC joint injury should not be used in children. The AC joint eventually will narrow as the acromion further ossifies. If AC joint pathology is a concern, comparison with the contralateral asymptomatic side may be helpful.

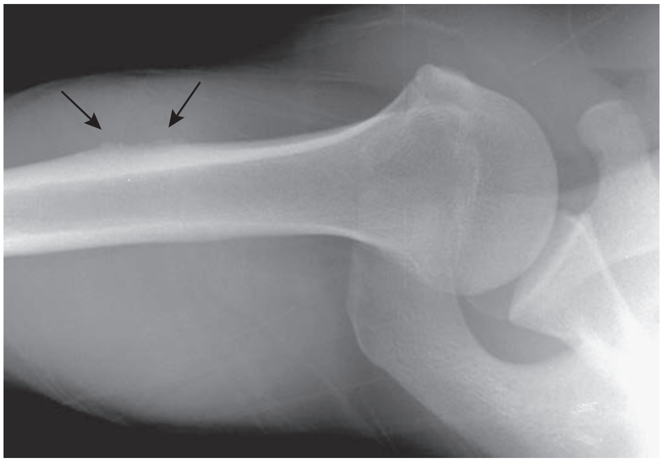
The coracoid process is the origin of the short head of the biceps tendon and coracobrachialis and is the insertion site of the pectoralis minor muscles. The coracoid process also is the origin



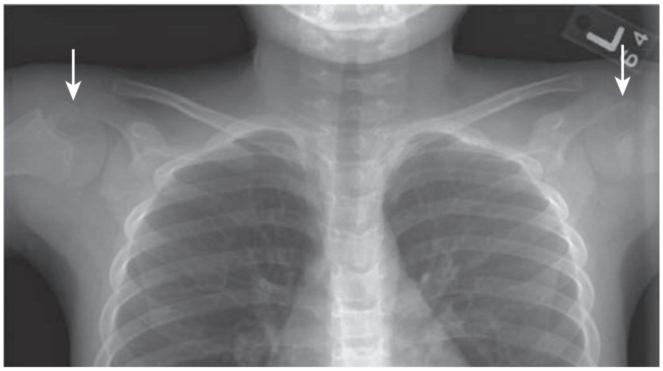
**e-Figure 128.48. Normal humeral neck.** (A) A false fracture *(arrows)* of the humeral neck on internal rotation to 90 degrees. (B) No fracture line is present in the anatomic position. The anterior pitch of the upper end of the humeral shaft is wider and deeper than the posterior, and it is the image of the segment below the posterior end of the shaft that casts the factitious fracture line.



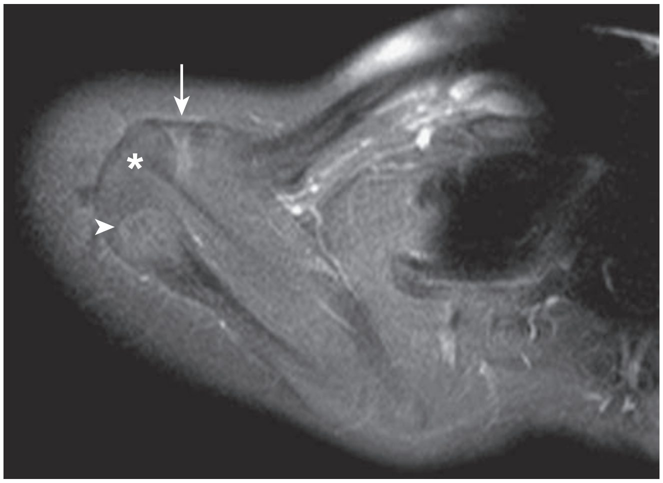
**e-Figure 128.49.** Pseudolesion of the proximal humeral metaphysis *(arrows)* due to a bicipital groove in a 16-month-old girl.



**e-Figure 128.50. Muscle insertion.** Irregularity of the anterior cortex of the proximal humeral diaphysis *(arrows)* due to muscle insertion in a 16-year-old boy. Similar findings were seen on the opposite side.



**e-Figure 128.51.** Bilateral humeral head pseudocysts *(arrows)* incidentally seen on the chest radiograph of a 7-year-old boy, with the left more prominent than the right.



**e-Figure 128.53. Normal acromion and acromioclavicular joint.** Postgadolinium T1 fat-saturated MR image shows that the acromion is mainly cartilaginous *(asterisk)* in this 5-year-old boy, which may cause the AC joint to appear artificially widened on radiography. The *arrow* indicates the AC joint, and the *arrowhead* indicates the metaphyseal equivalent of the bony acromion.

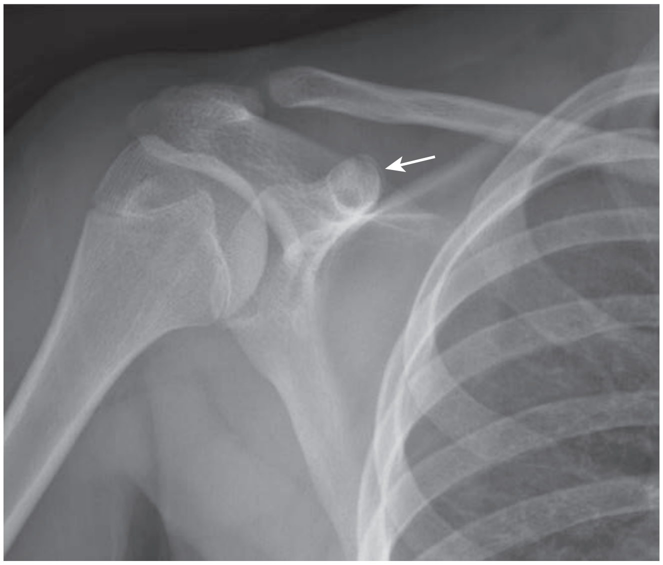


**Figure 128.54. Normal coracoid apophysis.** In this 15-year-old boy, the normal apophysis of the coracoid process *(arrow)* should not be mistaken for an avulsion injury.

and insertion site of various ligaments of the shoulder. The coracoid process apophysis has a complex ossification process with multiple different ossification centers that may develop at various stages and may superficially mimic a fracture (Fig. 128.54). In the beginning of the second decade, a normal lucency is present between the base of the coracoid process and the scapular body that should not be mistaken for a fracture. Later in the teenage years, the tip of the coracoid process may develop a separate ossification center that may superficially resemble an avulsion fracture.

## Pelvis

**Acetabulum.** Irregular ossification of the acetabular roof is a normal phenomenon during growth (e-Fig. 128.55). The regular smooth configuration of the roof develops from a confluence of individual bony foci near the end of the first decade.

**Accessory Ossification Centers.** Accessory centers of ossification may develop in cartilage in the spine of the ischium and also in the rim of the acetabulum (os acetabuli) just below the anterior inferior iliac spine (Fig. 128.56).[32] An os acetabulae should not be confused with an acetabular rim fracture. These acetabular ossification centers usually become visible between the 14th and 18th years, after which they fuse with the parent bone. Rarely, an os acetabuli persists as a separate ossicle. Although a normal variant, os acetabulae are associated with acetabular dysplasia and femoroacetabular impingement.[33] Accessory ossification centers also may form at the pubic symphysis and superior pubic ramus.

**Ischiopubic Synchondrosis.** Asymmetry of the ischiopubic synchondrosis is a very common normal variant and usually is an incidental finding unrelated to patient symptoms. Ossification of the ischiopubic synchondrosis is extremely variable in both velocity and pattern; fusion usually is complete by the teenage years.

The ischiopubic synchondrosis on the opposite side of the dominant leg usually is more prominent compared with the synchondrosis on the dominant leg.[34] Asymmetric ossification of the ischiopubic synchondrosis should be considered a physiologic process and is typically an incidental finding on radiographs. However, the ischiopubic synchondrosis represents fusion of two metaphyseal equivalent sites: (1) the ischial and (2) pubic component. Therefore it is a potential site for pathologies that may affect metaphyseal equivalent sites elsewhere such as osteomyelitis and trauma, typically stress changes (Fig. 128.57).

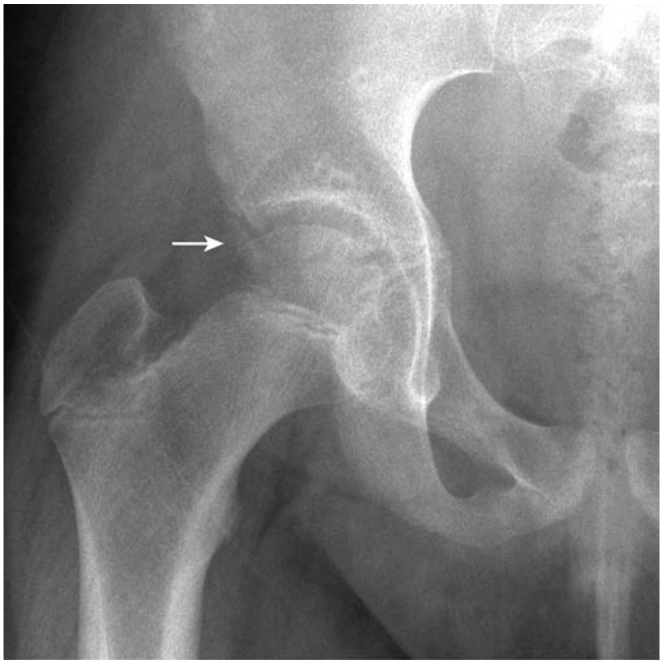

**Figure 128.56.** Os acetabulae *(arrow)* in a 10-year-old girl.

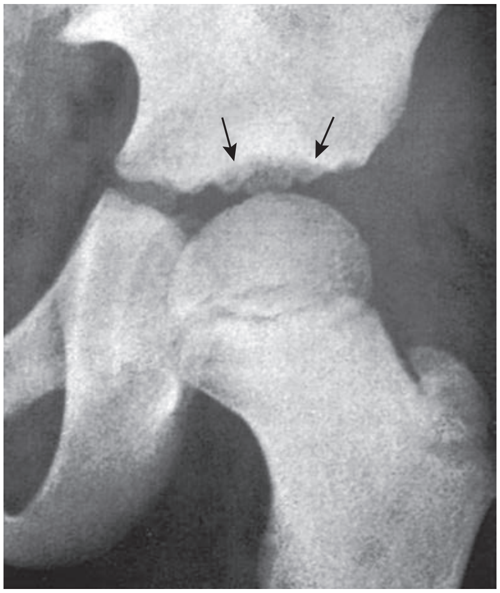
**Ischium.** Apophyseal irregularities along the posterolateral edge of the ischium also may be observed, usually during preadolescence (e-Fig. 128.58). This is the site of origin of the hamstring complex. The two sides may be unequally affected. During growth and before fusion of the body of the ischium, the ischial apophysis is scalelike at the inferior margin of the ischium.

The ischial spine, projecting posteriorly, usually is not visible on frontal radiographs of the pelvis. The lesser sciatic notch lies below it and sometimes appears as an indentation on the lateral margin of the ischium, at the region where the ischial irregularities are most common.

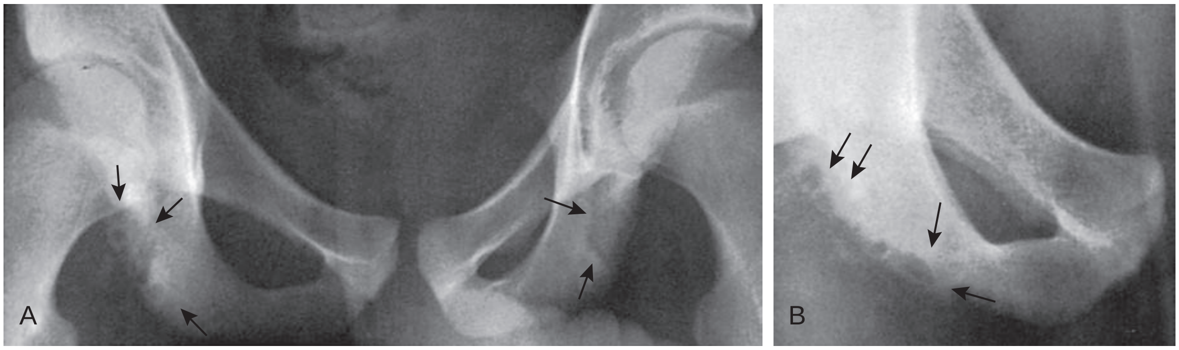
**Pubic Rami.** Delayed and irregular mineralization of the pubic rami may be present at birth, with subsequent mineralization from several ossification centers.[35] Vertical, radiolucent clefts occasionally noted as incidental findings in pelvis radiographs probably represent bars of nonossified cartilage between expanding ossification centers. The medial edges of the bodies of the pubic bones often are irregularly mineralized during the growth period.

## Hip

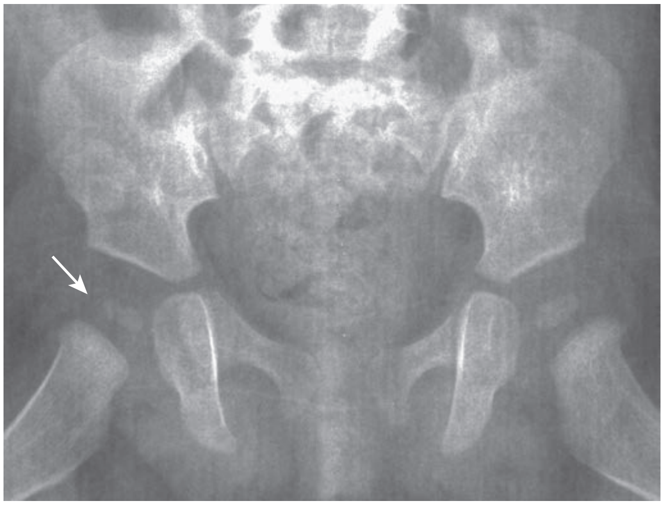
**Femoral Head Ossification.** A slight disparity in the timing of ossification, the size of the femoral head ossifications centers, or both is normal. In up to 30% of infants 3 to 6 months of age, a disparity of at least 2 mm exists between the two sides.[36] The ossification center for the head of the femur appears at about 4 months of age and enlarges with time. As ossification fills in the hemispheric cartilage of the head, the center may exhibit irregularities of form and density normally (e-Fig. 128.59).[37] Ossification may begin with coarse stippling and may progress, as the size increases, to irregularities along the margin. A bifid or split femoral head is a rare variant (Fig. 128.60) and may simulate Perthes disease. A bifid femoral head diagnosis as a normal variant should only be made after Perthes disease has been definitively excluded. A notch (separate from the fovea capitis) at the vertex of the



**e-Figure 128.55.** Normal irregular margins of the acetabulum *(arrows)* in a 6-year-old boy.



**e-Figure 128.58. Irregularities in both ischia in asymptomatic 12- and 11-year-old boys.** (A) The right ischium is irregularly rarefied at the tuberosity and slightly caudad into the ramus *(arrows)*. The tuberosity of the left ischium is evenly rarefied. (B) Bubbly rarefaction is present in the right tuberosity and caudad into the ramus *(arrows)*.



**e-Figure 128.59.** Normal, fragmentary appearance of the capital femoral epiphysis in a 4-month-old girl *(arrow)*.

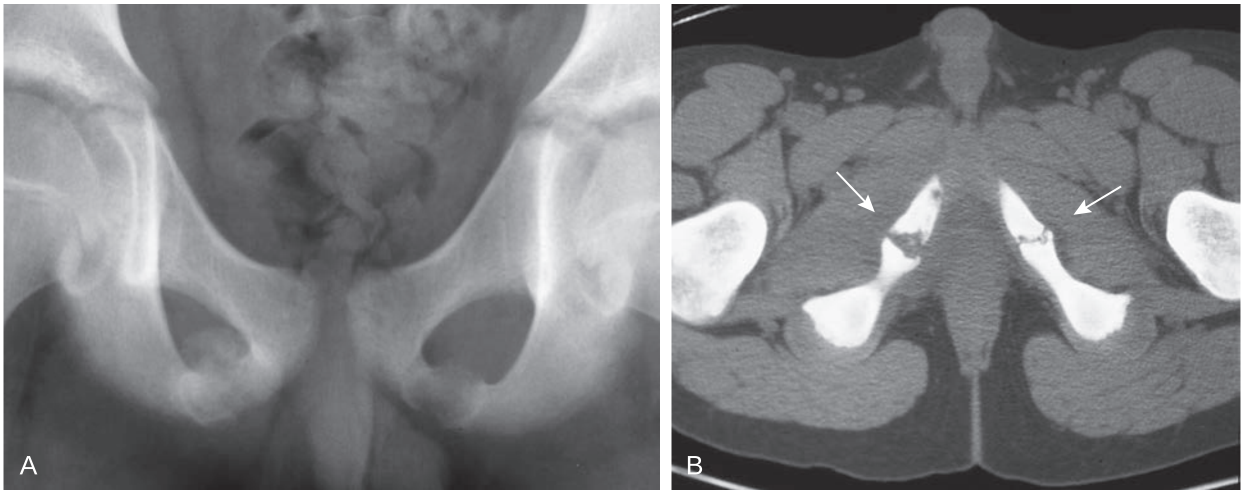


**Figure 128.57. Ischiopubic synchondrosis.** (A) Radiograph showing bilateral prominent ossification and the ischiopubic synchondroses in an 11-year-old male soccer player with right groin pain. Ossification of the ischiopubic synchondrosis is larger on the symptomatic side. (B) Irregularity of the ischiopubic synchondroses is seen on computed tomography *(arrows)*.

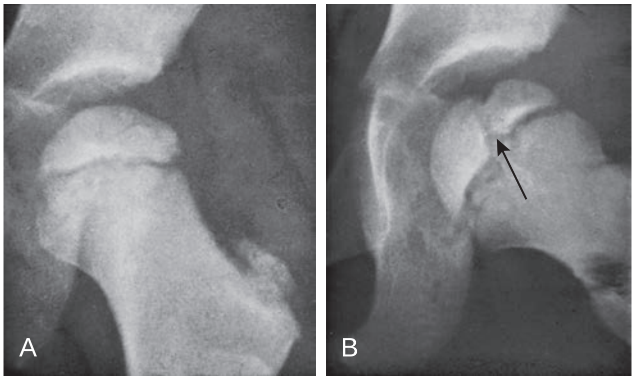

**Figure 128.60. Factitious splitting of the femoral head in an asymptomatic 4-year-old girl.** (A) In the frontal projection, the femoral head image is normal. (B) In the lateral, externally rotated position, the femoral head image is divided longitudinally into two unequal segments by a strip of decreased density *(arrow)* that represents the synchondrosis between the two ossification centers that developed one behind the other ventrodorsally.

femoral head also may be seen (e-Fig. 128.61). Before the ossification center has rounded out fully, some flattening of the contour may be observed where subsequently the fovea capitis can be recognized.

**Positional Coxa Valga.** External rotation of the femur increases the femoral neck-shaft angle and may factitiously suggest coxa valga (e-Fig. 128.62). With true coxa valga (Fig. 128.63), the greater trochanter projects laterally rather than being superimposed on the underlying femur, whereas with external rotation, the greater trochanter is rotated posteriorly and is superimposed along the femoral neck.

**Trochanters.** The centers for the greater and lesser trochanters frequently are irregularly mineralized and this is a normal finding during development (e-Fig. 128.64). Avulsions of the lesser trochanter related to the iliopsoas tendon insertion are uncommon, and thus comparison with the opposite, unaffected side may be helpful.

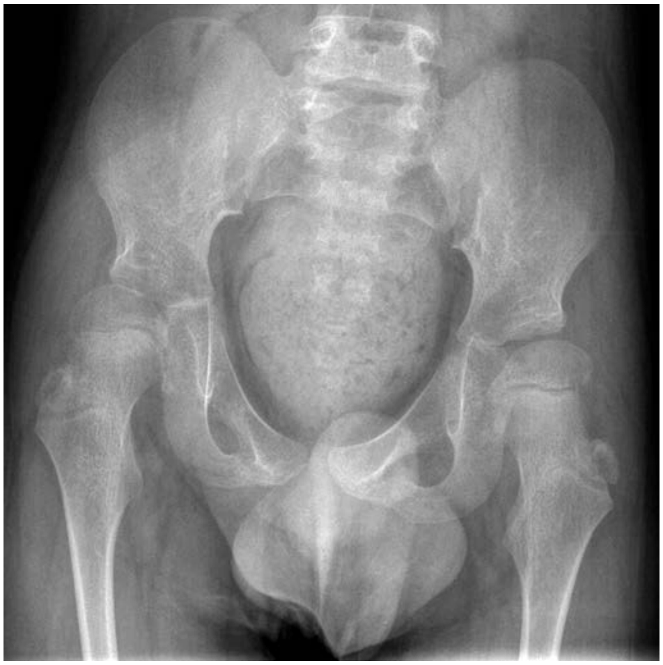

**Figure 128.63. Coxa valga.** An 11-year-old boy with cerebral palsy and coxa valga bilaterally with mild secondary developmental dysplasia of the hips.

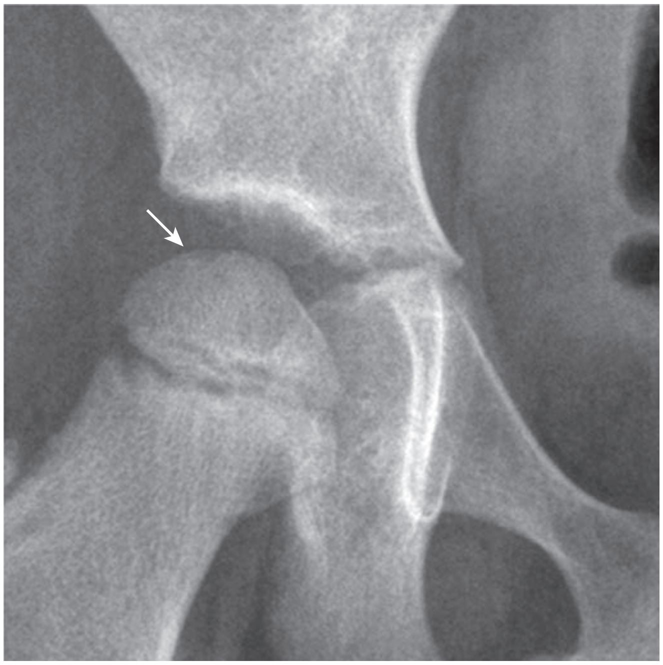
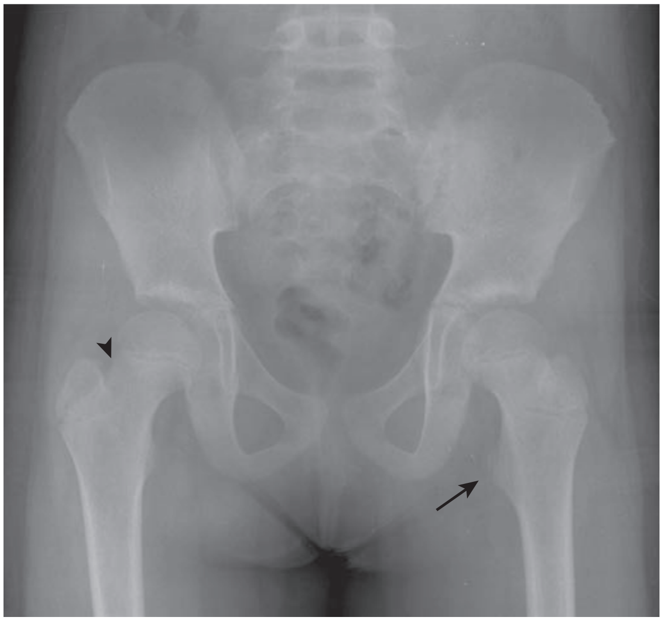
## Knee

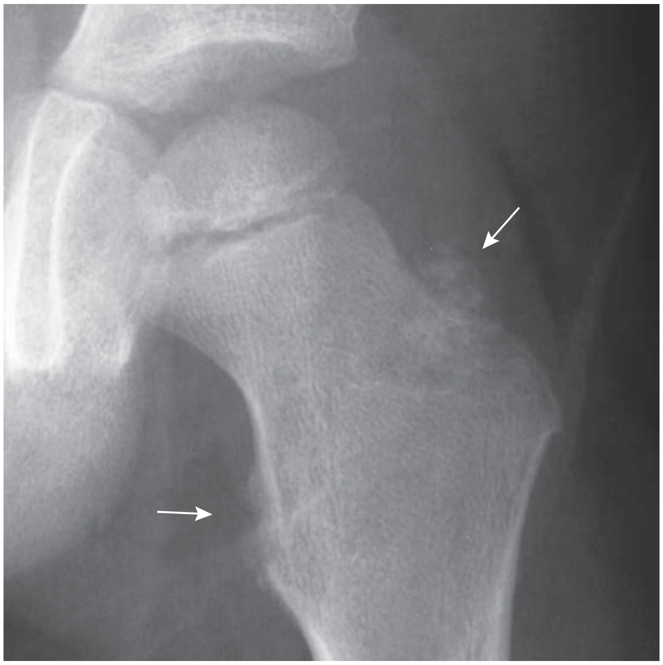
**Cortical Irregularity of the Distal Femoral Metaphysis (Avulsive Cortical Irregularity).** Irregularity of the cortex of the posteromedial distal femoral metaphysis (Fig. 128.65 and e-Figs. 128.66 and 128.67) is a common finding that easily can be mistaken a healing fracture or even an osteosarcoma.[38] Cystic cortical defects are common at this location, as are proliferative tuglike lesions, which probably are related to either the adductor magnus insertion or the origin of the medial head of the gastrocnemius muscle. When cystic, these lesions also have been termed *cortical desmoids* and may be difficult to differentiate from a nonossifying fibroma. The term "cortical desmoid" should be avoided as these irregularities are normal developmental variants.[39,40]



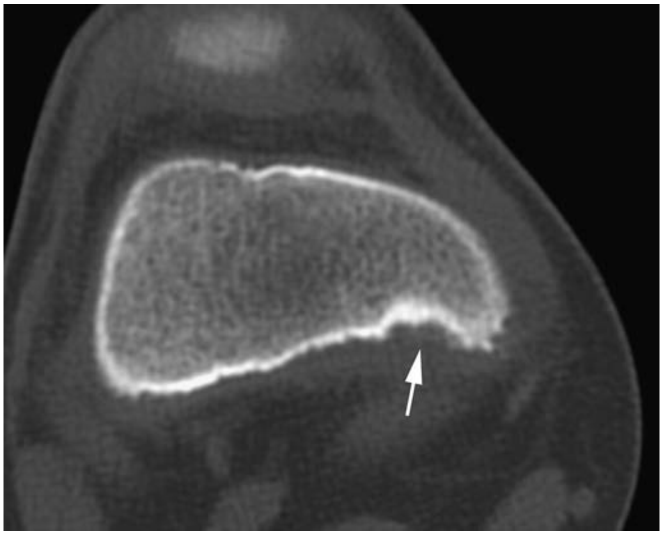
**e-Figure 128.61. Normal subchondral irregularity.** A 6-year-old girl with subchondral irregularity *(arrow)* of the weight-bearing portion of the capital femoral epiphysis, which is a normal finding.



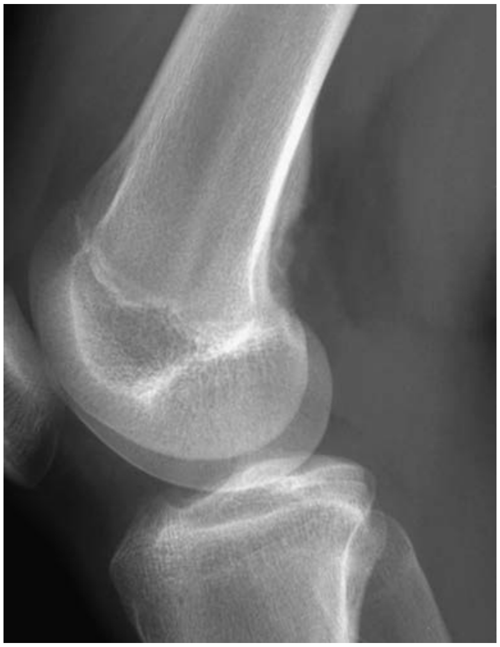
**e-Figure 128.62. Artifactual coxa valga in a 7-year-old girl with artifactual coxa valga.** On the left, external rotation will bring out the lesser trochanter *(arrow)* and cause overlap of the greater trochanter with the neck, which will cause factitious coxa valga. On the right, mild internal rotation causes accentuation of the femoral neck *(arrowhead)*. The more internally rotated the hip is, the more elongated the femoral neck will appear.



**e-Figure 128.64.** Normal trochanteric ossification irregularities *(arrows)* of the trochanteric ossification centers.



**e-Figure 128.66. Avulsive cortical irregularity.** CT scan shows an avulsive cortical irregularity *(arrow)* in an asymptomatic 6-year-old girl.



**e-Figure 128.67.** Avulsive cortical irregularity of the posteromedial distal femoral metaphysis in an adolescent.

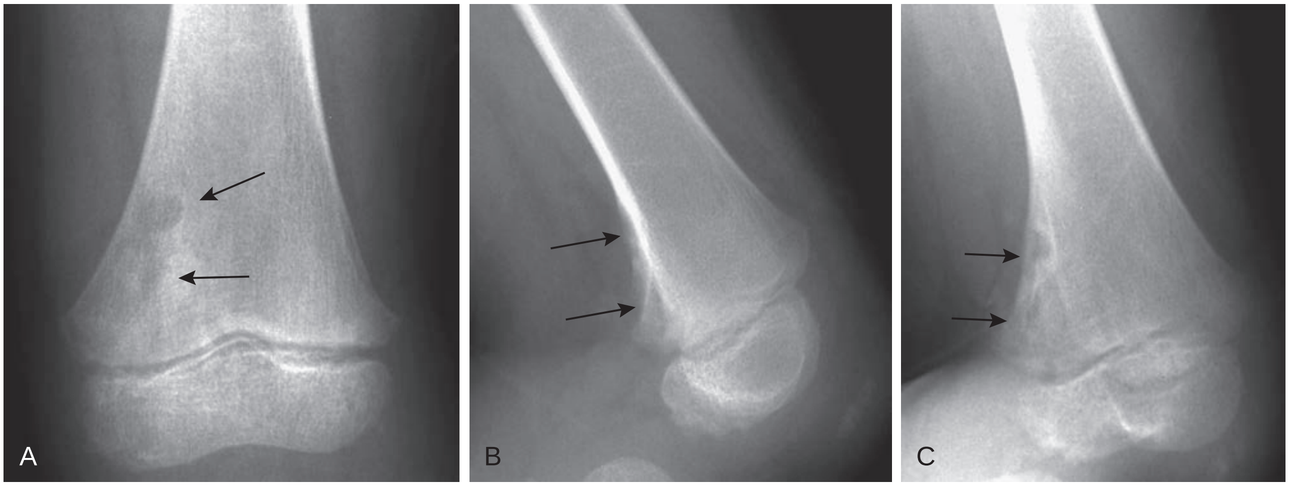


**Figure 128.65. Avulsive cortical irregularity of the distal femoral metaphysis in a 4-year-old girl.** The defect is posteromedial. (A) The anteroposterior view shows an ill-defined lucency *(arrows)*. (B) The lateral view shows irregularity *(arrows)* of the posterior margin of the distal femoral metaphysis. (C) An oblique view shows the cortical lucencies *(arrows)*.

**Irregular Ossification of the Distal Femoral Epiphysis.** The distal femoral epiphyseal ossification center growth in width occurs rapidly between the second and sixth years. As a result, the lateral and medial margins are commonly irregular and ragged (e-Fig. 128.68). In lateral projection, normal distal femoral ossification centers may have a rough, fringelike margin. Accessory ossification centers may persist at the margins of cartilage-bone junctions when ossification is almost complete. In older children, marginal mineralization of the femoral condyles is characteristically uneven and often is associated with independent ossification centers beyond the edge of the main bony mass.

Subchondral, fragmentary ossification of the femoral condyles may simulate osteochondritis dissecans (OCD). Caffey and colleagues found this variant in approximately 30% of healthy children when the knees were examined in tunnel and lateral projections (Fig. 128.69).[41] This variant is more common on the outer aspects of the condyles and tends to involve the non–weightbearing posterior surface, in contradistinction to OCD, which is more commonly located on the inner and weight-bearing aspects of the condyles. In addition, normal femoral condylar irregularities are seen in children younger than the usual age for OCD.

The normal variant is differentiated from OCD on MRI by its position in the outer posterior femoral condyles, intact overlying epiphyseal and articular cartilage, a large residual cartilage model, accessory ossification centers and spiculation, and absence of adjacent bone marrow edema (e-Fig. 128.70).[42] Additionally, the secondary physis of the epiphysis is typically disrupted in OCD but preserved in developmental irregular ossification.[43]

**Patella and Sesamoid Bones.** The patella, lying within the tendon of the quadriceps muscle, is the largest sesamoid bone of the body. Patellar ossification normally develops from several foci. Its edges may be irregular during childhood (e-Fig. 128.71). After fusion of the focal ossification centers, another center may develop in the superolateral portion of the bone and may persist as a distinct ossicle (Fig. 128.72). This common variant, known as *bipartite patella*, occurs in 1% to 6% of the population. Ninety percent of persons affected are male, and 40% have bilateral findings. Stress injury or acute fracture may occur at the synchondrosis between the superolateral ossicle and the patellar body, producing symptoms.[44] Bipartite patella may be related to aberrant traction by the vastus lateralis muscle, which inserts into the patella at its upper and outer quadrant. A bipartite patella is usually an incidental finding but may have an association with patellofemoral tracking abnormalities.[45]

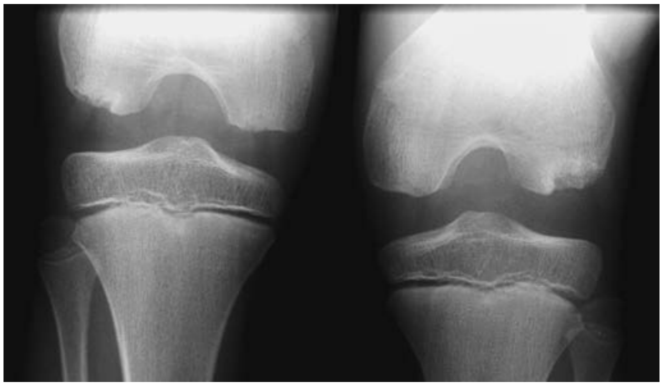

**Figure 128.69. Normal developmental irregularity of the posterior aspect of the femoral condyles seen on a notch view in a 10-year-old boy.** The defects are most prominent in the lateral condyles.

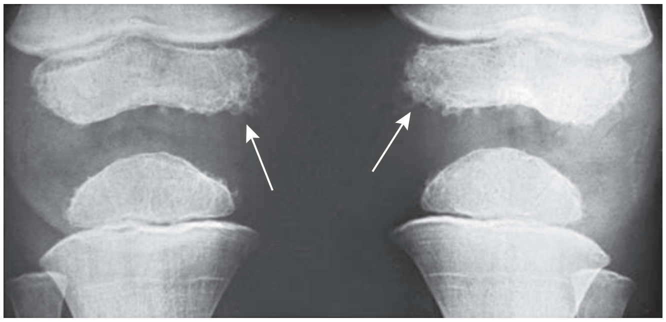
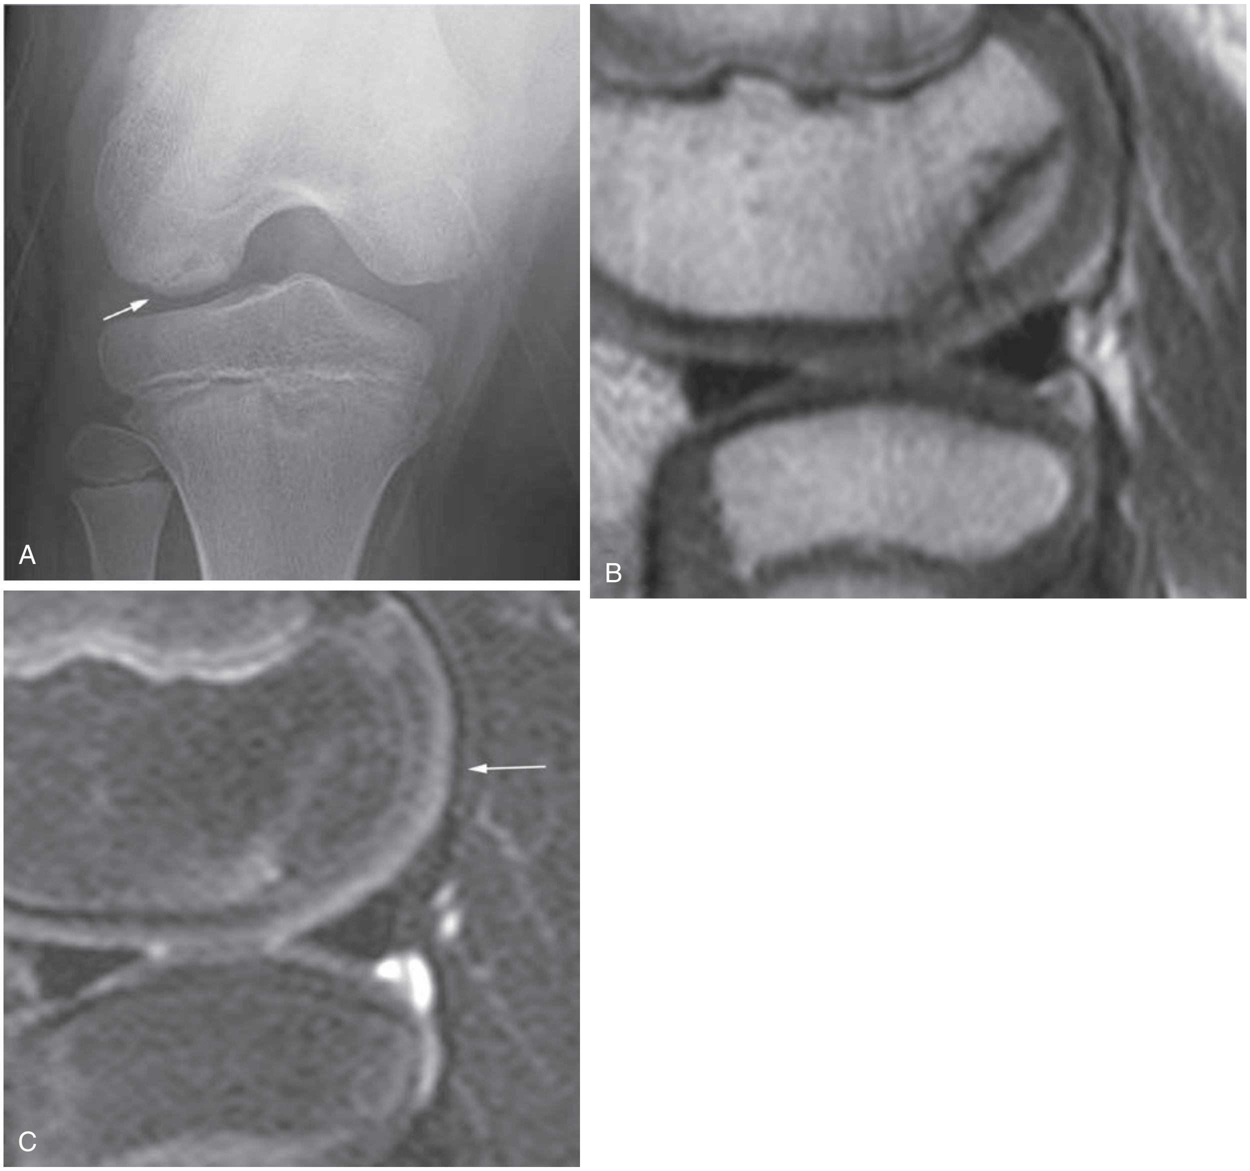
Irregular ossification of the lower pole of the patella is a common finding and may be difficult to differentiate from Sinding-Larsen-Johansson syndrome.[46] Also, it may be impossible to distinguish variation in ossification from an old traumatic avulsion. Acute patellar sleeve injuries will be symptomatic and have a linear nonsclerotic fracture fragment and accompanying soft tissue swelling.

Two other sesamoids of the knee occur as normal variants, the fabella and cyamella. The fabella (more common) forms in the tendon of the lateral head of the gastrocnemius muscle. The cyamella (less common) forms in the tendon of the popliteus muscle. A fabella is best seen on a lateral view (e-Fig. 128.73). The cyamella is found at the edge of the lateral condyle of the femur in the popliteal groove. Fabella syndrome is characterized by intermittent pain at the posterolateral knee accentuated by extension and localized tenderness over the fabella accentuated by compression.[47]

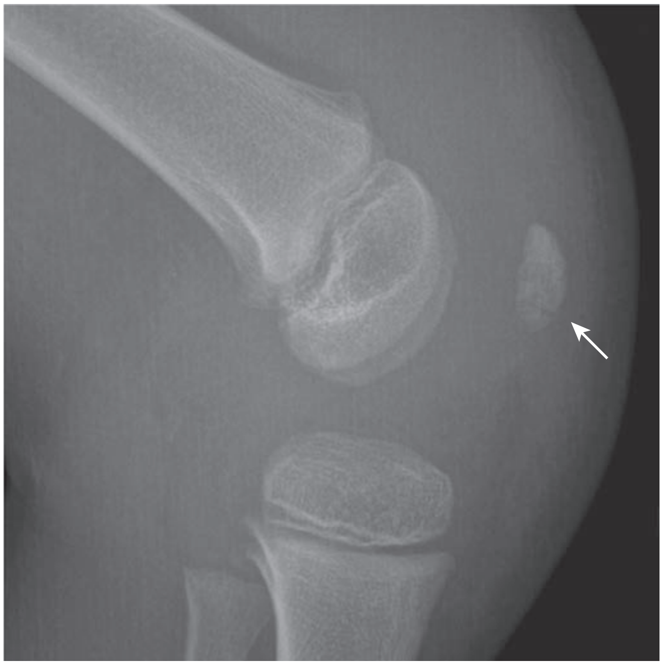
**Dorsal Defect of the Patella.** Dorsal defects of the patella may be seen along its superolateral aspect and usually are asymptomatic (Fig. 128.74). The dorsal defect of the patella is typically an



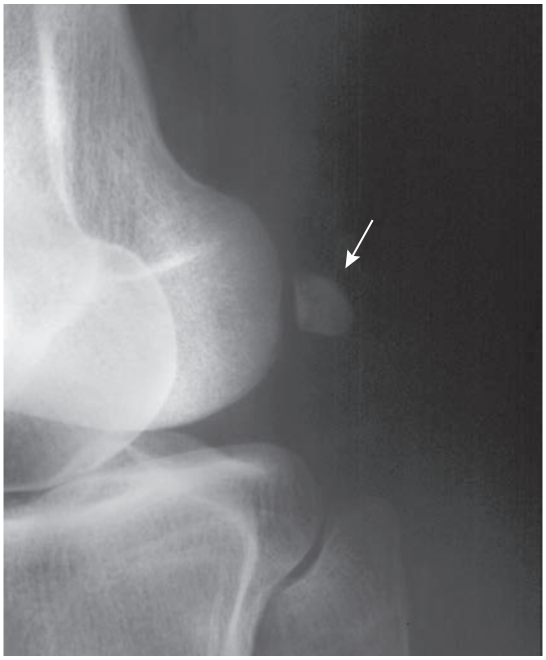
**e-Figure 128.68. Distal femoral epiphyseal irregularities.** Normal irregular mineralization on the margins of the ossification centers *(arrows)* in the distal epiphyses of the femurs of a 3-year-old boy.



**e-Figure 128.70. Normal lateral femoral condylar irregularities in a 10-year-old boy.** (A) Tunnel view shows subchondral irregularity of the lateral femoral condyle *(arrow)*. Proton density sagittal (B) and T2 fat saturation sagittal (C) MR images demonstrate subchondral irregularity with overlying intact epiphyseal and articular cartilage with absence of edema of the subchondral component of the irregularity *(arrow)*, indicating that this presentation is a normal variation as opposed to a developing osteochondral lesion.



**e-Figure 128.71. Normal patellar irregularity.** Lateral radiograph in a 5-year-old boy with a large knee effusion related to infection shows normal fragmentation and irregularity of the patellar bone *(arrow)* that should not be confused with pathology or fracture.



**e-Figure 128.73.** Fabella *(arrow)* in the lateral head of the gastrocnemius in its normal position, well separated from the femur itself.

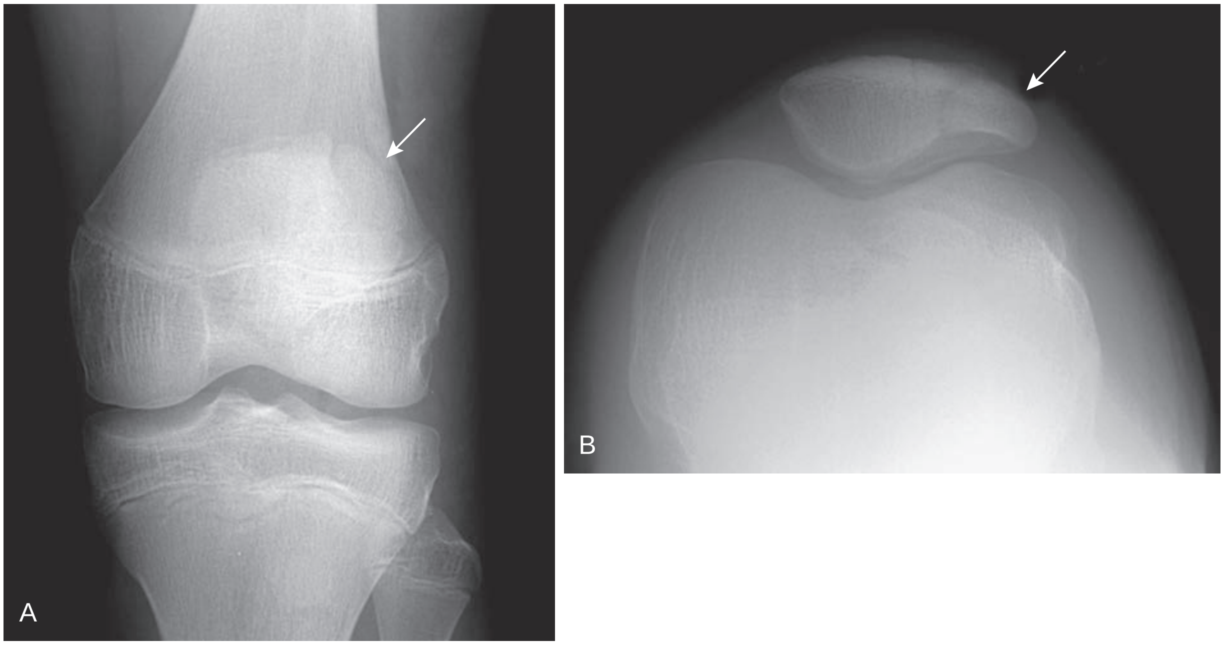


**Figure 128.72. Bipartite patella.** Anteroposterior (A) and axial (B) views of a bipartite patella in a 13-year-old boy. The accessory ossification center is superolateral *(arrows)*.

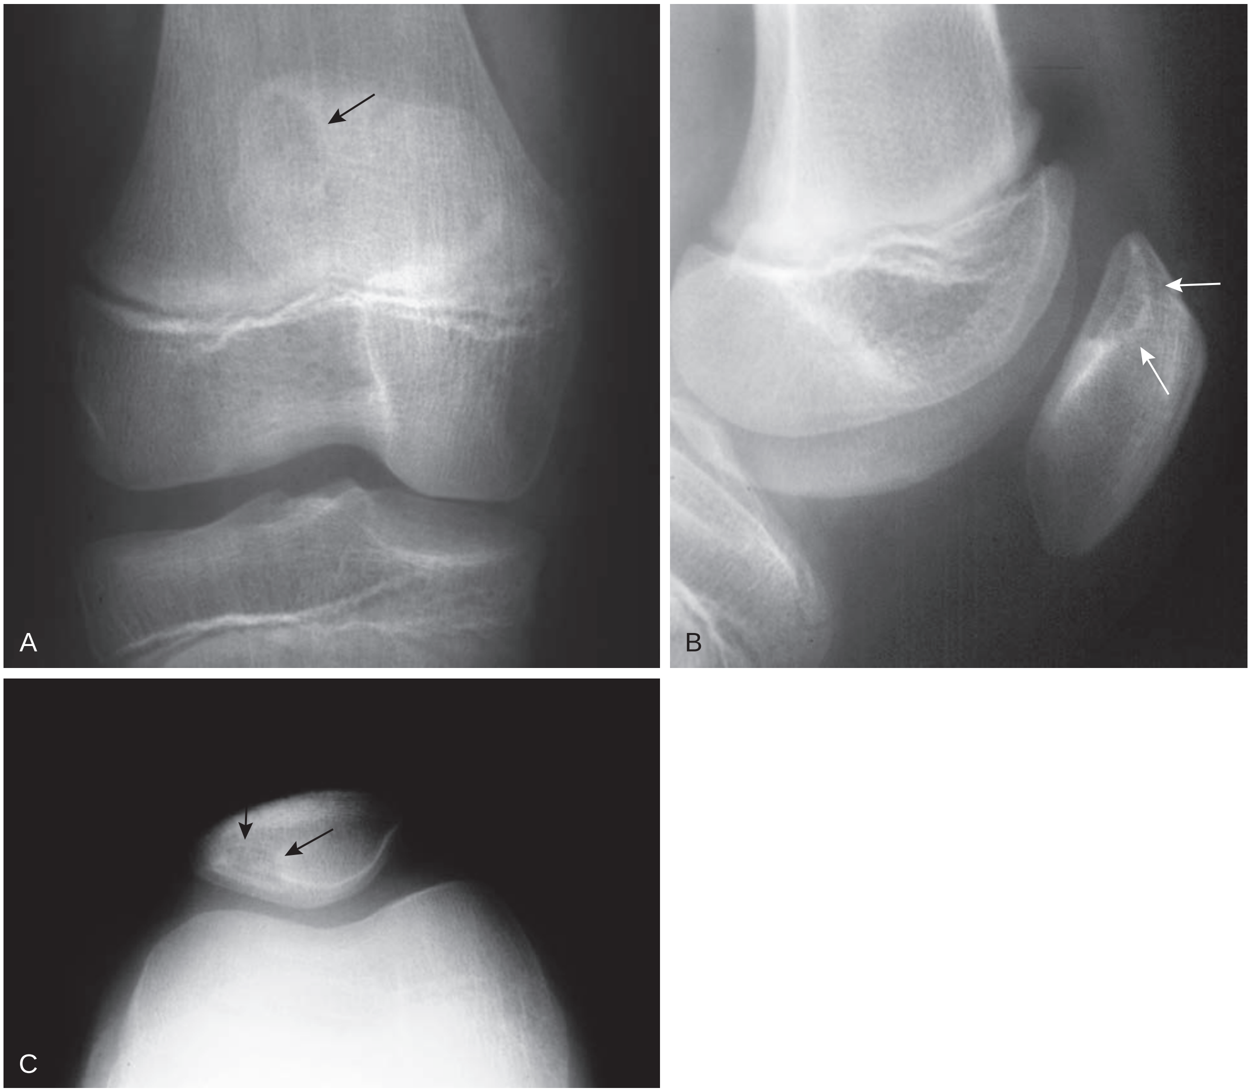

**Figure 128.74. Dorsal defect of the patella.** Anteroposterior (A), lateral (B), and axial (C) views of an 11-year-old girl shows the defect at the posterior aspect of the superolateral portion of the patella *(arrows)*.

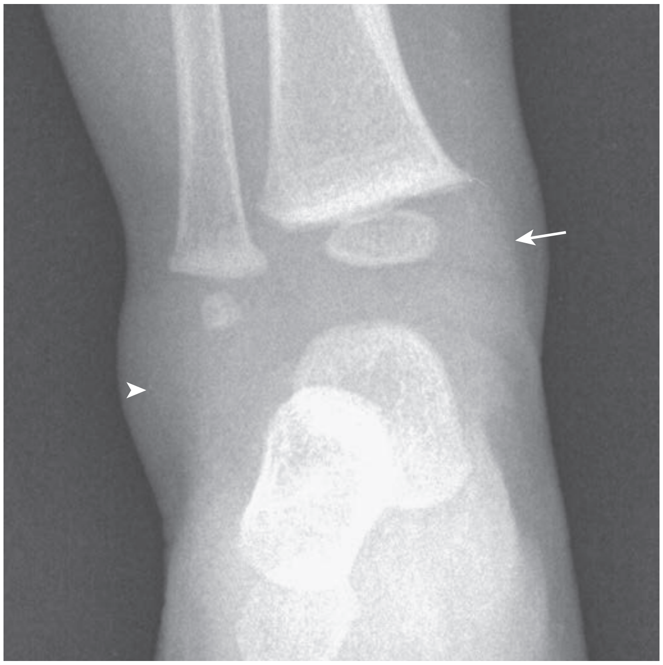

**Figure 128.76. Normal malleoli.** Medial *(arrow)* and lateral *(arrowhead)* cartilaginous epiphyses may superficially mimic ankle soft tissue swelling in this 9-month-old girl.

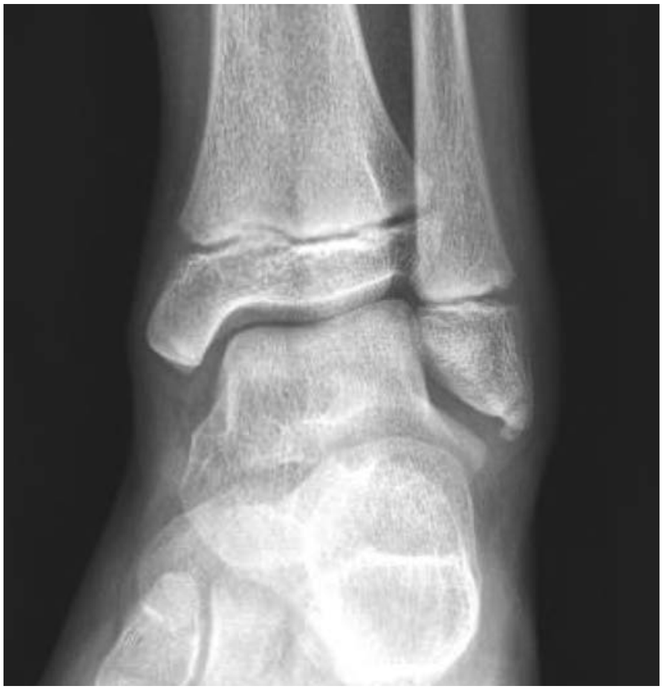

**Figure 128.78. Os subfibulare.** There is a well-corticated os subfibulare at the left lateral malleolus in this 11-year-old boy. This boy was asymptomatic in this ankle, having this radiograph done as a comparison for the contralateral side, which had a similar ossicle (not shown).

incidental finding on radiographs but may cause patellofemoral pain. On MRI, the overlying cartilage is typically intact. A dorsal defect of the patella may be seen concomitantly with a bipartite patella.[48] Dorsal patella defects should be differentiated from OCD of the patella, which usually affects the inferior aspect of the patella.

## Tibia and Fibula

**Tibial Tuberosity.** A steplike notched defect appears in the upper anterior border of the tibia in lateral projection before ossification proceeds in the cartilaginous anterior tibial tuberosity from the main proximal tibial ossification center. The tuberosity also may be ossified from multiple fragmentary accessory centers that, before union, may simulate avulsed fragments of bone. When ossification of the anterior tibial tuberosity is nearly complete, the radiolucent cartilage still separating the process from the shaft may appear as a notch or a horizontal strip (e-Fig. 128.75).

A fragmentary appearance of the tibial tuberosity is a normal finding in children. However, when accompanied by focal tenderness on palpation, edema in adjacent Hoffa's fat pad, and pretibial edema, a diagnosis of Osgood-Schlatter disease should be suggested.

**Irregular Ossification of the Medial and Lateral Malleoli.** The medial and lateral malleolus are initially cartilaginous and may superficially mimic soft tissue swelling (Fig. 128.76). Fragmentary ossification of both the medial and lateral malleoli is a normal finding in the skeletally immature and should not be confused with fracture.[49]

Separate accessory ossification centers are common in the cartilage of the medial malleolus (os subtibiale) and less common in the lateral malleolus (os subfibulare) (e-Fig. 128.77 and Fig. 128.78). At each location, the differential diagnosis is an avulsed fragment. Acute avulsed fragments will have an irregular shape and a sharp, noncorticated margin. A common pitfall is to mistake an acute avulsion fracture of the anterior talofibular ligament with an os subfibulare.

**Fibular Ossicle.** The provisional zone of calcification in the distal fibular metaphysis may be notched upward, and a tiny extra ossicle may develop in the notch. The notching is usually bilateral.

### KEY POINTS

- The spherical growth plate is responsible for epiphyseal ossification, and its physiology is similar to that of the physis.
- The subperiosteal metaphyseal bone collar should not be confused with classic metaphyseal lesions of child abuse.
- The ischiopubic synchondrosis can close asymmetrically and superficially mimic a fracture and a tumor. The irregular side is usually contralateral to the dominant foot.
- Epiphyseal ossification can be quite fragmentary in the femoral condyles and should not be mistaken for fractures.
- The acromion process is mainly cartilaginous, particularly in the first decade, and may cause pseudo-widening of the AC joint, superficially mimicking AC joint diastasis. Imaging the unaffected side may be helpful for comparison.
- Os acetabulae is a normal ossification center along the acetabular rim and should not be confused with acetabular rim fractures or anterior-inferior iliac spine avulsion fractures related to the rectus femoris origin.
- The medial epicondyle of the elbow appears before the trochlear ossification. If only a trochlear ossification is present, a displaced medial epicondylar avulsion fracture should be suspected.

# Imaging Techniques

Arthur B. Meyers and J. Herman Kan

Pediatric musculoskeletal radiology is a broad field that requires an understanding of normal growth and developmental variations, fracture patterns unique to the immature skeleton, skeletal dysplasias, and knowledge of unique tumor and tumor-like conditions. Advanced imaging has improved our ability to arrive at a precise diagnosis. However, it also has created the need for additional expertise within the field of pediatric imaging to determine how and when to properly use these tools to arrive at a diagnosis. This chapter provides a broad overview of the techniques available to evaluate the spectrum of pediatric musculoskeletal disorders.

## IMAGING TECHNIQUE OVERVIEW

### Radiography

Radiography remains the initial tool for the evaluation of trauma, developmental and congenital disorders, inflammatory arthritis, infection, and suspected bone neoplasms.

In the setting of acute trauma, nonarticular long bones should be imaged with at least two views (frontal and lateral). Osteoarticular regions should be imaged with three views (frontal, lateral, and oblique). Dedicated imaging of the digits is preferred rather than general imaging of an entire hand or foot when a patient has a single symptomatic digit. For alignment disorders, including scoliosis and foot deformities, weight-bearing views should be obtained routinely. In cases of suspected child abuse, a dedicated skeletal survey should be performed.[1]

In the setting of suspected infection, radiography should be performed before advanced imaging to exclude a fracture or bone tumor as the cause of symptoms. However, a normal radiograph should not preclude referral for magnetic resonance imaging (MRI) for suspected acute osteomyelitis.

For bone neoplasms, initial radiographs are typically better at delineating tumor matrix and pattern of bone destruction than MRI. MRI is used to evaluate tumor extent, evaluation of skip lesions, surgical planning, and tumor follow-up.

### Ultrasonography

Sonography is an especially useful tool when imaging children because it can usually be performed without sedation and avoids ionizing radiation. Common indications for musculoskeletal ultrasound in children include evaluation of dysplasias, soft tissue masses, foreign bodies, and pyogenic and nonpyogenic arthritis.[2] Other uses of musculoskeletal sonography are continually expanding for the assessment of muscles, tendons, ligaments, and peripheral nerves. In some cases ultrasound may be an alternative to or complementary to MRI.[3]

Sonographic evaluation of dysplasias includes developmental dysplasia of the hip (DDH), glenohumeral dysplasia related to brachial plexopathy, and selected congenital foot deformities. In DDH and glenohumeral dysplasia, ultrasound allows for detailed assessment of the femoral and humeral heads before their ossification, the shape of the acetabulum and glenoid, and the femoral head/acetabular and humeral head/glenoid relationships. In congenital foot deformities sonography can be used for static and dynamic visualization of unossified tarsal bones.[4]

Sonography is useful in distinguishing solid from cystic soft tissue lesions. Certain soft tissue lesions such as ganglia, synovial cysts, and some vascular anomalies may have a characteristic enough appearance to make a definite diagnosis. However, other lesions (including most solid masses) will have a nonspecific sonographic appearance. Caution is advised against differentiating benign and malignant soft tissue masses with ultrasound, as soft tissue malignancies may be well defined with a nonaggressive appearance.

Identification of the presence or absence of a joint effusion of any region is straightforward with sonography. However, the etiology is predicated on clinical history. It is not possible to differentiate pyogenic, nonpyogenic, and posttraumatic causes based on sonography alone.

### Computed Tomography

Roles for musculoskeletal computed tomography (CT) include the assessment of fractures, orthopedic hardware, lower extremity alignment disorders, and the evaluation of tumor matrix and tumor recurrence in the setting of an existing neoplasm or a resected neoplasm with hardware in place.

A low peak kilovoltage (kVp) technique may be used because of the inherent contrast of bone; however, when hardware is present a higher kVp, along with increased milliampere-second (mAs) and decreased pitch, may help minimize artifacts.[5] These methods need to be employed cautiously because they increase radiation dose. Multiplanar and sometimes volume-rendered reformats are typically performed for musculoskeletal CT applications.

Fracture assessment by CT is performed when there is clinical suspicion for a radiographically occult fracture or when additional characterization of fractures seen on radiographs is needed. CT can better define intraarticular components of fractures (providing precise measurements of fracture diastasis and articular step-off), identify additional fractures, and identify intraarticular bodies not visible on radiographs.

Alignment disorders that can be evaluated by CT include determination of acetabular and femoral version, tibial torsion, glenohumeral dysplasia, and patellofemoral tracking disorders. Patellofemoral tracking disorders usually are dynamic studies in which the knee is placed in varying degrees of flexion to evaluate lateral patellar dislocation.

### Magnetic Resonance Imaging

The volume and varying applications of musculoskeletal MRI in the pediatric population have grown because of the popularity of youth sports and subsequent injuries. In addition to imaging injuries, MRI plays a useful role in imaging congenital/developmental, infectious, inflammatory, metabolic, and oncologic conditions.

Four basic sequence types may be used for musculoskeletal MRI: an anatomy sequence (usually T1, proton density); a fluid-sensitive sequence (proton density with fat saturation, T2 with fat saturation, short-tau inversion recovery, and a fluid-weighted gradient echo sequence); a contrast sequence (postgadolinium T1 typically with fat saturation); and a susceptibility sequence (any gradient echo sequence).

The purpose of the anatomy sequence is to evaluate marrow replacement, trabecular anatomy, and ligamentous abnormality. In general, it is recommended to have a T1-weighted sequence without fat suppression in at least one plane to evaluate bone marrow. Proton density sequences without fat saturation are useful

## Abstract:

Pediatric musculoskeletal radiology requires an understanding of normal growth, developmental variations, fracture patterns unique to the immature skeleton, skeletal dys- plasias, and tumor and tumor-like conditions that arise in children. This chapter provides a broad overview of the techniques available to evaluate the spectrum of pediatric musculoskeletal disorders including: radiographs, ultrasound, computed tomography, magnetic resonance imaging, and nuclear imaging.

endocrine
hyperparathyroidism
hypoparathyroidism
renal osteodystrophy
hyperthyroidism
gonadal disorders

for evaluating trabecular anatomy and to evaluate ligamentous, labral, and cartilaginous anatomy.

Fluid-sensitive sequences are used to evaluate marrow edema, ligamentous anatomy, and cartilage. Spin echo fluid-sensitive sequences are superior to gradient echo sequences in the evaluation of pediatric cartilage. The primary and secondary physes, epiphyseal cartilage, and articular cartilage can be differentiated on spin echo sequences, whereas all types of cartilage have similar signal intensity on gradient echo sequences.

Gradient echo sequences are useful in the evaluation of entities that cause a susceptibility artifact allowing for detection of blood products, calcification or ossification (including ossified intraarticular bodies), and sites of prior surgery. Thin-slice gradient echo sequences can allow for detailed anatomic evaluation of small structures (e.g., ligamentous evaluation in the wrist). Three-dimensional fat-suppressed gradient echo sequences with dark bone and bright physeal cartilage can be reformatted to provide physeal maps in the setting of bone bars across the physis.

Postcontrast sequences are useful for determining tumor vascularity, detecting abscess in the setting of infection, and evaluating the synovium. Normal synovium will show thin enhancement, which should not be mistaken for pathology.[6] The relative thickness of the synovium as depicted by contrasted sequences is what is important in the setting of a joint effusion if pyogenic or nonpyogenic inflammatory arthritis is suspected. When initial precontrast images are entirely normal, postcontrast images have limited additional value.

Specialized sequences can be added to routine MRI protocols. For instance, a number of advanced sequences are available to assess articular cartilage. Two of the more commonly used are T2 relaxation time mapping and delayed gadolinium-enhanced MRI of cartilage (dGEMRIC).[7] Additionally, ultrashort echo time sequences can be used for qualitative and quantitative evaluation of many musculoskeletal structures, including articular cartilage, tendons, ligaments, and menisci.[8]

Technical innovations have made whole-body MRI possible. Indications for whole-body MRI in children are evolving and include many conditions involving the musculoskeletal system. Indications include fever of unknown origin without localizing symptoms, screening for tumors in children with cancer predisposition syndromes (e.g., Li–Fraumeni syndrome), assessment and follow-up of Langerhans cell histiocytosis, evaluation of benign tumor burden in children with neurofibromatosis type 1, evaluation of generalized vascular malformations, osteonecrosis, chronic recurrent multifocal osteomyelitis, and myopathies.[9]

In general, girls who are older than 6 years and boys who are older than 8 years are able to undergo MRI without the need for sedation. Sedation should be handled by a dedicated and qualified team.

## Nuclear Imaging

Skeletal scintigraphy, typically using technetium-99m methylene-diphosphonate, has a higher sensitivity than skeletal radiography for bone pathology that exhibits osteoblastic activity, including fractures, tumors, and infection. Images obtained after injection of this compound reflect a combination of pathophysiologic functions (blood flow and bone turnover) but are nonspecific and do not provide exceptional anatomic detail. Images therefore should be interpreted in the context of the patient's clinical presentation and relevant radiologic findings. Structures adjacent to open physes are difficult to assess because the high uptake in the physes may mask the activity associated with an adjacent pathologic lesion. Single-photon emission CT helps in localization of such lesions by improving spatial resolution of activity in contiguous and overlapping structures.

Indications for skeletal scintigraphy are varied and include investigation of bone pain, diagnosis of early and chronic osteomyelitis, osteonecrosis, and occult trauma, including nonaccidental trauma and stress fractures. CT and MRI have usurped skeletal scintigraphy in many clinical settings; however, bone scanning remains a very useful imaging tool.[10]

Positron emission tomography (PET) imaging with fluorine-18-deoxyglucose (FDG) offers improved spatial resolution and greater sensitivity for detection of aggressive bone neoplasms. FDG-PET is particularly effective in detecting an active tumor. Because of its high sensitivity, increased signal on PET is nonspecific. The fusion of PET with CT or MRI allows for better spatial localization of lesions and improves the characterization of lesions. PET also is an effective method of determining response of malignant bone tumors to therapy.

# 130 Prenatal Musculoskeletal Imaging

Christopher I. Cassady

## OVERVIEW

Evaluation of the fetal skeleton is one of the more challenging aspects of prenatal imaging for a variety of reasons. It is such a rapidly changing system in gestation that ossification varies in extent and distribution from week to week; ultrasonography, the primary fetal imaging modality, does not clearly demonstrate the full morphology of a bone because of lack of sound penetration; and many skeletal pathologies that become increasingly obvious with growth are, at best, subtle in the fetus. Still, techniques are available to overcome some of these barriers, and these include evaluation of bone contour abnormalities and proportions by using magnetic resonance imaging (MRI), and rarely, computed tomography (CT) in addition to ultrasound. Musculoskeletal abnormalities in the fetus are diagnosable in the following categories:

1. Generalized skeletal dysplasias
2. Nongeneralized anomalies of segment length, number, or shape
3. Primary anomalies of the spine
4. Neuromuscular disorders, including clubfoot
5. Tumors

## SKELETAL DYSPLASIAS

***Etiology.*** Dysplasias are often the result of genetic mutations that encode for proteins important to development of the growth plate.[1,2] Current clinical application of "skeletal dysplasia testing panels" is, however, very limited. Both the range of included mutations and the sensitivities of their detection are expected to increase with time. Furthermore, the discovery of cell-free fetal DNA in maternal plasma may lead to noninvasive techniques such as capture sequencing for the prenatal diagnosis of some skeletal dysplasias.[3] In utero testing in sporadic cases remains controversial.[4]

***Imaging.*** More than 430 dysplasias have been described in the literature. Only a small percentage is considered diagnosable in utero with imaging.[3–5] Because of the lack of specificity of many of the findings, efforts at ultrasonographic prenatal evaluation have focused on identification of cases in which the neonates are not expected to survive, typically because of an abnormally constricted chest (Box 130.1).[6–9] Most of these criteria correlate limb length with survival, but emphasis is also placed on measures predicting lethal pulmonary hypoplasia.[10–13] Other findings that may be detected in association with lethality and that increase diagnostic certainty are polyhydramnios and nonimmune hydrops fetalis.[7] It is important to avoid making a diagnosis of lethality in borderline cases and to use criteria in combination for the most accurate discrimination. The fetus with intrauterine growth retardation should not be assigned a diagnosis of generalized skeletal dysplasia on the basis of proportionate but short bones. Questionable cases in either category deserve follow-up ultrasonography for interval growth.

Three dysplasias constitute the vast majority of lethal cases: (1) thanatophoric dysplasia, (2) achondrogenesis, and (3) osteogenesis imperfecta type II. A familiarity with their ultrasonographic features is therefore essential (Box 130.2).[14,15]

Certain morphologic findings on ultrasonography suggest particular diagnoses in the setting of a suspected dysplasia. Multiple long bone fractures are very likely from osteogenesis imperfecta or hypophosphatasia, and rib fractures are rarely seen with other diagnoses (Fig. 130.1). Kleeblattschädel, or cloverleaf skull, may be present in several of the acrocephalosyndactyly syndromes (Apert, Carpenter, Crouzon, and Pfeiffer syndromes), campomelic dysplasia, osteocraniostenosis, and thanatophoric dysplasia type II (Fig. 130.2). Hypoplastic scapular bodies are a feature of campomelic dysplasia and Antley-Bixler syndrome.[16] However, many findings (e.g., platyspondyly, short ribs) are not specific and must be considered in relation to other features (abnormal mineralization, solid organ malformations) to arrive at a more narrow differential diagnosis (e-Fig. 130.3 and Fig. 130.4).[17] Three-dimensional ultrasonography can be very helpful when an appropriate volume of fluid is present around the fetus to display the morphology of specific segments, including the face, hands, and feet.[18,19]

Fetal MRI has not been pursued routinely in the evaluation of fetal dysplasia because of the difficulty in imaging the signal-poor ossified skeleton. However, it may have a role in quantification of fetal lung volumes in cases in which ultrasonography has limitations.[20,21] It has also been used successfully to make the diagnosis of dysplasias that primarily involve the epiphyses, taking advantage of the high water content T2-weighted signal characteristics of cartilage (e-Fig. 130.5).[22] Finally, fetal magnetic resonance imaging (MRI) specifically for temporal lobe malformation evaluation has been used when an FGFR3 mutation expression (such as thanatophoric dysplasia) is suspected.[23]

The use of ionizing radiation is generally avoided during pregnancy unless the need to make a diagnosis is critical to patient care, though low-dose CT techniques have been used effectively to reconstruct highly detailed three-dimensional models of the fetal skeleton (Fig. 130.6).[24–27] The features described are compared with an atlas of postmortem radiographs in identified syndromes to aid diagnosis.[28] This strategy can be offered at radiation doses of 3 to 5 millisievert with superb resolution of individual skeletal components.[29]

***Treatment and Follow-up.*** When a lethal skeletal dysplasia is detected using ultrasonography, the parents and fetal care team can make informed decisions about the continuation of the pregnancy and the circumstances of delivery. An opportunity exists for neonatal hospice care coordination, when appropriate. Even though ultrasonography is reliable at separating lethal dysplasias from nonlethal dysplasias, neonatal physical examination and radiographs, appropriate genetic testing, and autopsy, if relevant, are crucial in arriving at a specific diagnosis for accurate family counseling.[30]

## ANOMALIES OF SEGMENT LENGTH, NUMBER, OR SHAPE

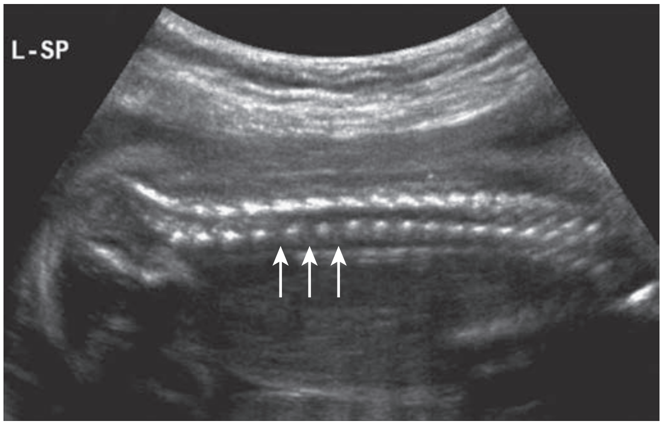
***Etiology.*** Limb reductions may be caused by a variety of insults. Some cases of terminal transverse limb defects (TTLD) are from amputation, such as in the amniotic band sequence spectrum. Although the initiating event in this sequence has not been incontrovertibly established, the most commonly supported theory is that a tear is made in the amnion, exposing the fetus to the more adhesive chorion with subsequent loss of tissue or the development of a constrictive band.[31] In other cases of TTLD, primary vascular insults including coagulation abnormalities are blamed. Teratogens (e.g., thalidomide) are highly associated in some instances of phocomelia, in which a proximal segment is

## Abstract:

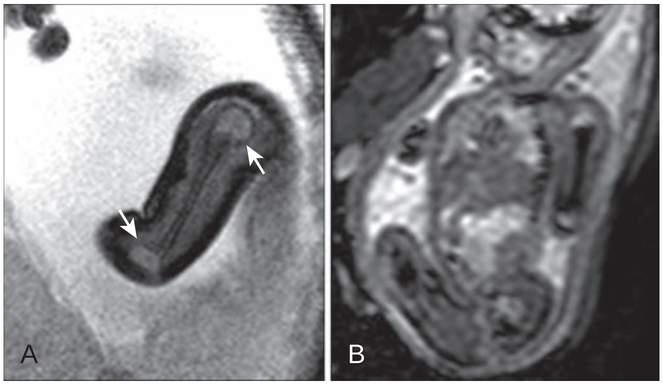
Evaluation of the fetal skeleton is a challenge in prenatal imaging for a variety of reasons: the fetal skeleton changes rapidly in gestation such that ossification varies in extent and distribution from week to week; ultrasonography, the primary fetal imaging modality, does not demonstrate the full morphology of a bone because of a lack of sound penetration; and many skeletal pathologies that become increasingly obvious with growth are, at best, subtle in the fetus. Techniques are available to overcome some of these barriers, and these include evaluation of bone contour abnormalities and proportions by using magnetic resonance imaging (MRI), and rarely, computed tomography (CT) in addition to ultrasound. This chapter discusses the appropriate imaging evaluation and work up for fetal musculoskeletal abnormalities, with particular emphasis on common dysplasias; abnormalities of the extremities to include limb reductions, overgrowth and malposition; spinal bone malformation; and soft tissue tumors.

## Keywords:

fetal skeleton
fetal skeletal dysplasia
fetal imaging
fetal limb anomaly
fetal spine
fetal teratoma



**e-Figure 130.3. Platyspondyly.** Disc spaces *(arrows)* are wider than the ossification centers for the vertebral bodies.



**e-Figure 130.5. MRI evaluation of fetal bones.** (A) Sagittal steady-state free precession gradient-recalled echo image at 33 weeks' gestation. The higher-signal cartilage *(arrows)* is distinct from the ossified diaphysis in the humerus. (B) Coronal gradient-recalled echo-planar imaging at 27 weeks. Echo-planar imaging is more reliable for bone morphology than other sequences at younger gestational ages.

### BOX 130.1 Proposed Ultrasonography Criteria for Lethal Dysplasia

- Micromelias >4 standard deviation behind expected lengths
- Femur length >5 mm below 2 standard deviation in second and third trimesters
- Femur length/abdominal circumference ratio <0.16
- Thoracic/abdominal circumference ratio <0.6
- Thoracic circumference < lower limit of the 95% confidence interval for gestational age
- Chest to trunk ratio <0.32

### BOX 130.2 Imaging Features of the Most Common Lethal Dysplasias*

**THANATOPHORIC DYSPLASIA**

- “Telephone receiver” shaped femurs
- Depressed nasal bridge, macrocephaly
- Platyspondyly
- Short ribs
- Trident hand
- Clover leaf skull in type II
- Oversulcation of the inferomedial temporal lobes

**ACHONDROGENESIS**

- Deficient vertebral ossification, ± calvarial
- Short, flared ribs ± fractures
- Hydrops (25% of cases)
- Micrognathia, midface hypoplasia

**OSTEOGENESIS IMPERFECTA TYPE II**

- Multiple long bone fractures
- Hourglass-shaped thorax (from fractures), normal rib lengths (two-thirds of the way around chest)
- Increased conspicuity of brain anatomy on ultrasound (decreased mineralization)
- Skull deformity with pressure

*All have marked micromelia.

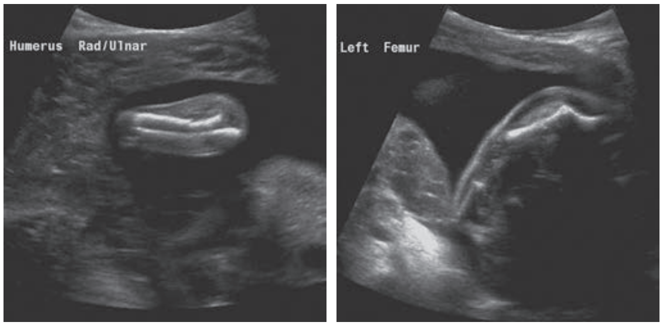


**Figure 130.1. Long bone fractures in a fetus with severe micromelia.** Diagnosis is osteogenesis imperfecta type II.

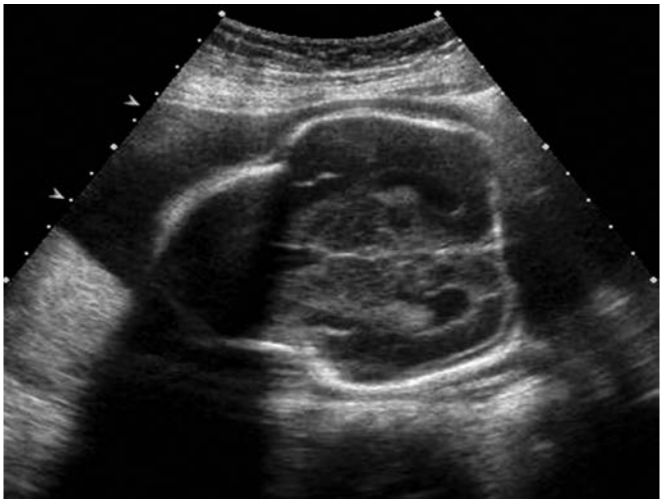

**Figure 130.2. Kleeblattschädel, or cloverleaf skull (pancraniosynostosis).** In the setting of a lethal bone dysplasia, the differential diagnosis includes thanatophoric dysplasia type II, campomelic dysplasia, and osteocraniostenosis.

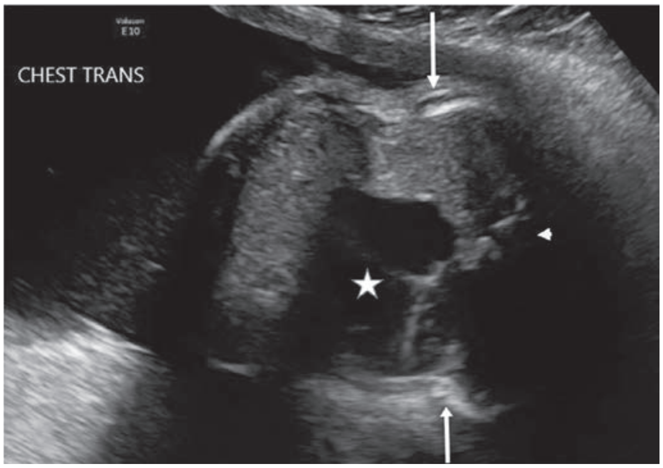

**Figure 130.4. Short ribs.** The ribs *(arrows)* are less than the normal 70% around the chest and are curved inward, with the heart *(star)* bulging outside the bony chest and the liver protuberant ventrally due to the chest:abdomen disproportion. *Arrowhead* indicates the spine on this transverse image.

missing, though phocomelia can be chromosomal or associated with specific syndromes (e.g., thrombocytopenia-absent radius).[32–35] Proximal focal femoral deficiency is a particular, generally isolated form of reduction that affects the femoral head and neck but may include fibular aplasia or hypoplasia. It can be unilateral or bilateral (Fig. 130.7).

Overgrowth is typically syndromic, as with hemihypertrophy in Beckwith-Wiedemann syndrome, or the soft tissue bulk of Proteus, Klippel-Trenaunay-Weber or CLOVES syndromes.[36,37] An increased number of segments over normal typically affects only the fingers or toes, and is often chromosomal though isolated cases can be familial and benign. Bowing of a long bone can affect one bone or several, but in either case genetic associations (dysplasias, neurofibromatosis) should be investigated. Posteromedial bowing of the tibia and fibula is a unique case.[38,39]

***Imaging.*** Limb reduction anomalies may be subtle if isolated or very distal (e.g., fingers/toes). Ultrasonography can often characterize the shape of the affected limb sufficiently well for diagnosis. Associated findings may include edema of the extremity distal to a constricting band (Fig. 130.8 and Video 130.1). Cine ultrasound sequences can capture the abnormal motion that is a consequence of subluxation or dislocation if the affected segment involves a joint. Random isolated or multiple defects are more likely secondary to amniotic band sequence than are symmetric defects, which tend to be related to chromosomal abnormalities or syndromes (Fig. 130.9).[40] As amniotic bands can cause defects

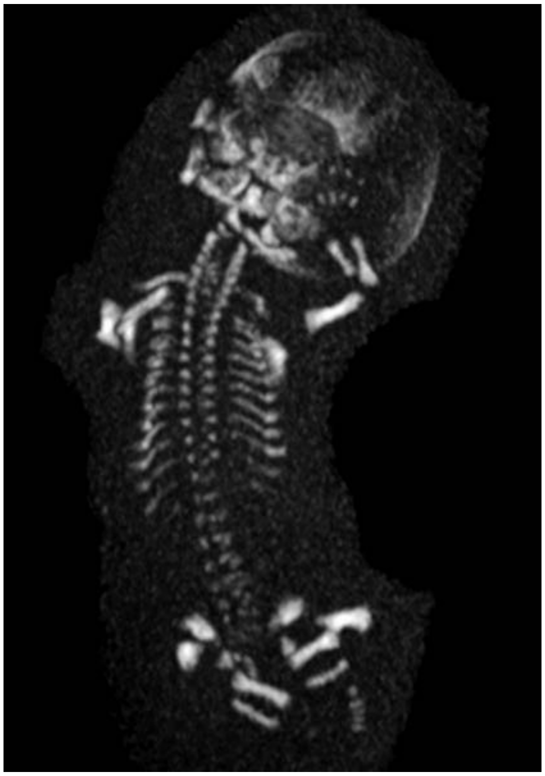

**Figure 130.6. Thanatophoric dysplasia type I.** Three-dimensional volume set acquisitions allow reconstructed CT projections in any plane. Radiation dose to the 21-week fetus was 3.9 millisievert. Gene testing confirmed an *FGFR* mutation. *(Courtesy of Teresa Victoria, MD.)*

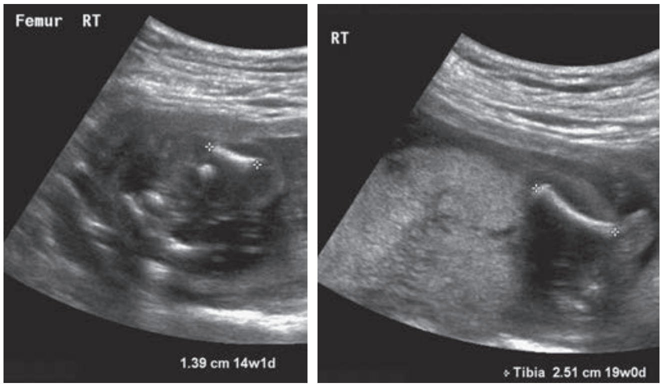

**Figure 130.7. Proximal focal femoral deficiency with fibular aplasia.** Fetus at 20 weeks' gestational age shows a short femur associated with a single long bone in the distal leg.

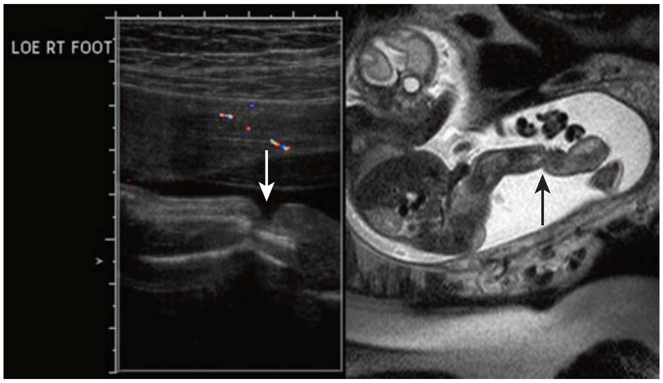

**Figure 130.8. Amniotic band syndrome.** Ultrasound and sagittal T2-weighted single-shot fast spin echo images show focal constriction of both soft tissue and bone *(arrows)* at the distal leg, with edema of the ankle and foot.

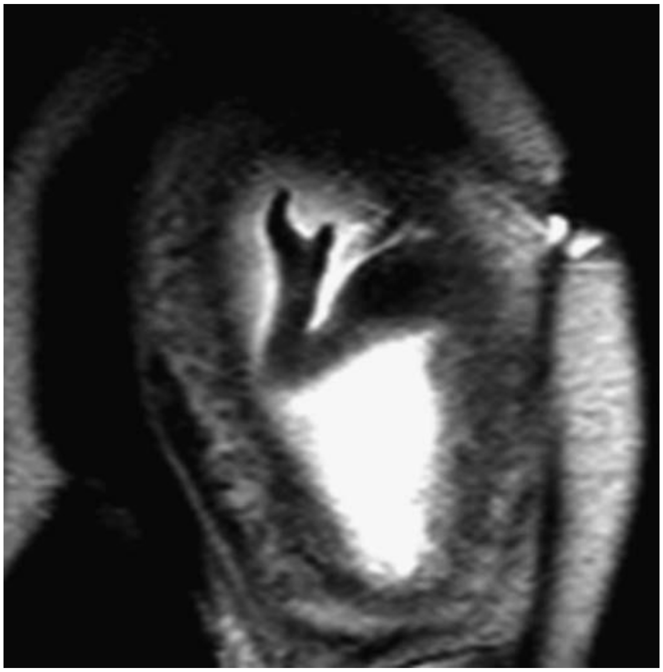

**Figure 130.9. Brachmann-DeLange syndrome.** This 30-week fetus had bilateral ectrodactyly (split hand-foot malformations), with only two digits of the hand. The contralateral hand had a similar appearance *(not shown)*.

in any body part, a thorough evaluation of the entire fetus is indicated. Umbilical cord involvement is often overlooked but has consequences because of the risk of cord occlusion.[41]

Recognition of overgrowth necessitates an evaluation of the types of tissue that are involved, including vascularity and fat, and therefore Doppler interrogation and MR may prove useful.[42] In cases where polydactyly is discovered, a careful search for other fetal anomalies that might give a clue to a genetic association is warranted.[43]

***Treatment and Follow-up.*** Successful cases of fetoscopic lysis of amniotic bands have been reported when it has been thought that release could improve blood flow to and consequent growth of an affected limb segment.[44] Otherwise, plastic surgery consultation is sought for limb salvage after delivery of the fetus.

## PRIMARY ANOMALIES OF THE SPINE

***Etiology.*** Primary anomalies of the spine typically manifest as an unusual curvature. Care must be taken to ensure that this finding is a fixed abnormality and not positional or merely the result of a lack of space (e.g., in anhydramnios). Fixed kypho/scoliosis is abnormal and may be the result of tethering, as with limb–body wall complex (Fig. 130.10), a severe and lethal form of amniotic band sequence; rib fusions, as in Jarcho-Levin syndrome (Fig. 130.11); or fetal akinesia or hypokinesia.[45] Often, the finding is subtle and secondary to segmentation anomalies of the spine (Fig. 130.12). Complex spinal anomalies can be seen with neural

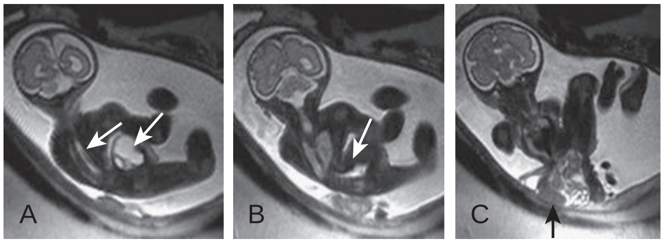

**Figure 130.10. Limb–body wall complex.** (A–C) Contiguous oblique coronal SS-FSE T2-weighted images. Multiple images had shown fixed scoliosis and contortion in a fetus with extrusion of abdominal contents adherent to the amnion *(black arrow)*. *White arrows* indicate the spinal canal in this fetus, who also has a closed neural tube defect.

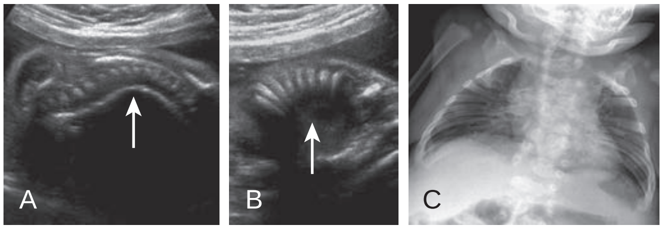

**Figure 130.11. Jarcho-Levin syndrome (spondylocostal dysostosis).** (A and B) Fixed scoliosis associated with thoracic restriction, with ribs fanning out from a central fusion. (C) Typical chest appearance with rib deformities and vertebral segmentation anomalies.

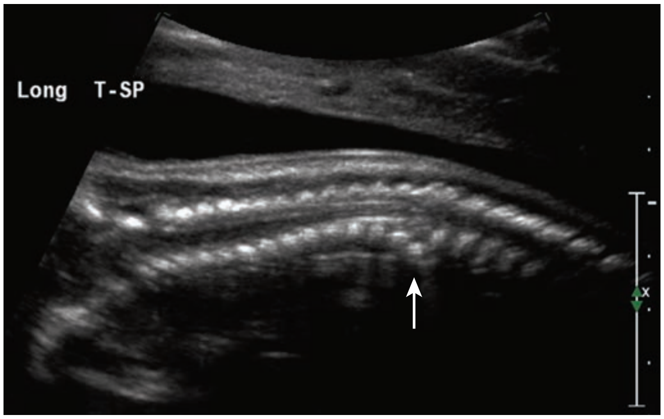

**Figure 130.12. Vertebral segmentation anomaly.** Focal interruption in the continuity of vertebral body ossification centers, signifying a segmentation anomaly (hemivertebra, *arrow*).

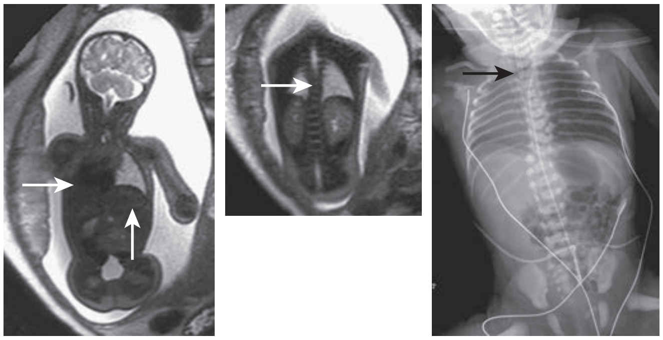

**Figure 130.13. VACTERL association (*v*ertebral anomaly, *a*norectal atresia, *c*ardiac lesion, *t*racheo*e*sophageal fistula, *r*enal anomaly, *l*imb defect).** Coronal T2-weighted single-shot fast spin echo MR images show a right-sided heart *(horizontal arrow on left image),* absence of fluid in the stomach *(vertical arrow on left image),* and thoracic scoliosis from hemivertebrae *(arrow on middle image)*. Subsequent neonatal radiograph also shows the right heart and vertebral segmentation anomalies. Note that the Repogle tube is in the proximal esophageal pouch *(black arrow)* due to esophageal atresia.

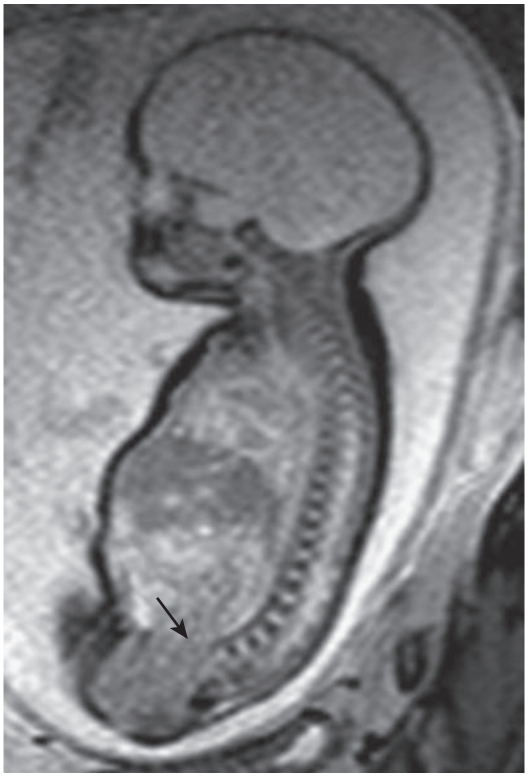

**Figure 130.14. Caudal regression sequence.** Sagittal gradient-recalled echo MR image at 31 weeks' gestation. The spine terminates abruptly *(arrow)* without a sacrum.

tube defects and with the Currarino triad, which is a heritable complex of anomalous sacrum, presacral mass, and anorectal malformation.[46] Absence of the sacrum, with variable involvement of the more proximal spine, occurs in caudal regression syndrome, which is significantly associated with elevated glucose levels in the fetus of a mother with diabetes.[47] The most common spinal anomaly in the fetus involves the dysraphism of posterior elements in a neural tube defect.

***Imaging.*** A spinal anomaly may be an isolated fetal finding, but it does prompt a careful search for associated syndromic abnormalities, including the various components of the VACTERL association (***v***ertebral anomaly, ***a***norectal atresia, ***c***ardiac lesion, ***t***racheo***e***sophageal fistula, ***r***enal anomaly, ***l***imb defect) (Fig. 130.13). The presence of an anal dimple can be confirmed on ultrasonography, where attention is also directed specifically to the size of the stomach and morphology of the radial ray segments. Devoted echocardiography is recommended in suspicious cases. MRI has been used to examine for a transiently distended esophageal pouch proximal to an atresia, using repetitive dynamic T2-weighted sequences in the sagittal midline.[48] The multiplanar capabilities of MRI may be advantageous in sorting out the components of complex spinal anomalies (Fig. 130.14).

***Treatment and Follow-up.*** Correlation with imaging and physical examination after delivery is critical to confirm the suspected anomaly and guide therapy. Because both ultrasonography and MRI have limitations in the evaluation of the spine, prenatal imaging findings may not be straightforward, and it should not be assumed that the most complete diagnosis has been described antenatally.

## NEUROMUSCULAR DISORDERS

***Etiology.*** Several conditions that cause generalized hypotonia in the fetus and neonate are heritable: the most important from the point of view of obstetric management is congenital myotonic dystrophy. This is an autosomal dominant muscular disease in which expansion of abnormal genomic repeats inserted during cell division will be greater in an affected child than in the carrier parent. Milder cases in adults often go undiagnosed, and a carrier mother may not display obvious manifestations of muscular insufficiency until administered respiratory-depressant anesthetics, to which these patients are exquisitely sensitive. Sudden death from cardiac conduction abnormalities during sedation has also been reported.[49] Therefore if myotonic dystrophy is suspected as part of the differential diagnosis in a fetus, maternal genetic testing should be performed and a careful anesthetic strategy planned for the delivery.[50,51]

Most of the time, a specific diagnosis is difficult to establish for a fetus with any combination of limited movement, fixed position of the extremities, or multiple contractures. An unsatisfactory term, *arthrogryposis multiplex congenita*, has been used to describe this combination, with muscular, neurologic, and connective tissue disorders all showing similar manifestations. Differential considerations include multiple pterygium syndrome, in which skin webs tend to tether the limbs at the joints and restrict fetal movement. The major cause of arthrogryposis is fetal akinesia sequence, which has been associated with Pena-Shokeir syndrome (pseudotrisomy 18), nemaline rod myopathy, and maternal myasthenia gravis.[52–54]

"Clubfoot" is a term used generically to describe abnormal foot position relative to the leg; the more accurate term is *talipes*, the most common presentation of which is fixed plantar flexion with internal rotation at the ankle (talipes equinovarus, or clubfoot), though several forms of talipes (combinations of calcaneo- or equino- varus/valgus) are described (see also Chapter 133).[55] If unilateral, it is often an isolated finding with a low likelihood of syndromic association. Bilateral clubfoot, however, is typically secondary to spinal cord abnormalities such as meningomyelocele; anhydramnios or oligohydramnios, as with fetal renal or bladder obstruction; fetal akinesia; or genetic anomalies. Rocker-bottom foot (congenital vertical talus, or rigid flatfoot) is nearly always bilateral and is highly associated with aneuploidy (trisomies 9, 13, or 18), though most cases are related to neurologic disorders such as myelomeningocele (Fig. 130.15).[56]

***Imaging.*** Most fetuses move during ultrasonography, and assessment of fetal posture and movement is an essential part of determining fetal well-being.[57,58] Those that do not move as expected may be sleeping, which can be confirmed by later reimaging. True movement limitation should be determined as generalized versus focal. An effort should be made to look for tethering, constricting bands, or a neural axis lesion, and muscle bulk should be assessed. Polyhydramnios is likely if the fetus is not swallowing; a lack of breathing movements will result in a small chest and pulmonary hypoplasia. Fetal MRI may be indicated to evaluate the neural axis for a cause of generalized hypotonia or contractures and can help measure lung volumes. Alterations on MRI of muscular contour, thickness, and signal have suggested atrophy from neuromuscular disease.[59]

Clubfoot is diagnosed on ultrasonography or MRI when the foot is seen in a coronal long axis orientation on the same image in which the bones of the leg are also seen in coronal plane (Fig. 130.16). Care should be taken to ensure that this is a fixed position over time; spontaneous flexion at the ankle suggests the finding is positional.

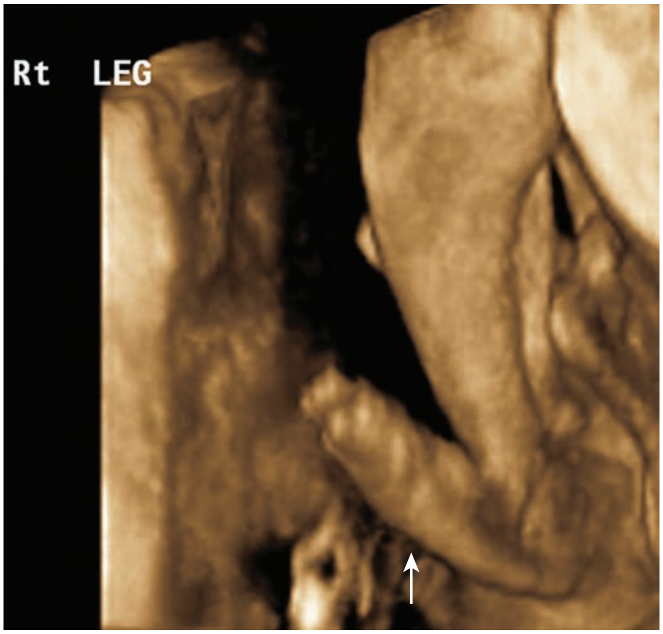

**Figure 130.15. Congenital vertical talus (rocker-bottom foot).** Three-dimensional ultrasound reconstruction using surface rendering shows inferior convexity of the plantar aspect of the foot *(arrow)* and upturned toes.

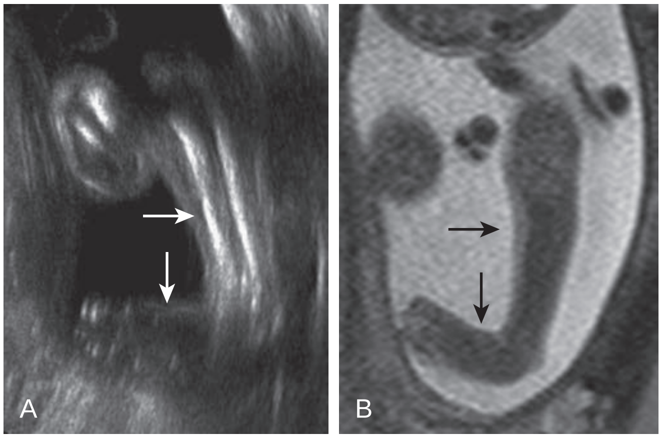

**Figure 130.16. Congenital clubfoot.** Ultrasonography (A) and T2-weighted MR (B) images show the foot in a coronal long axis orientation *(vertical arrows)* on the same image that the tibia and fibula are seen in a coronal orientation *(horizontal arrows)*.

***Treatment and Follow-up.*** Neonatal treatments for hypotonia, arthrogryposis, or both are supportive. No fetal treatments are described, though testing for myotonic dystrophy should be undertaken in appropriate cases to avoid maternal complications. Treatment for clubfoot is generally started in the first days of life, and surgery depends on the success of manipulation and casting.[60]

## TUMORS

***Etiology.*** Tumors of the fetal musculoskeletal system are extraordinarily rare, except for sacrococcygeal teratoma (SCT). Still, this entity is uncommon, with a reported incidence of only 1 per 40,000.[61] SCT is thought to arise from primitive cells associated with the fetal coccyx, which must be removed in entirety at excision

### BOX 130.3 Altman Classification of Sacrococcygeal Teratoma

**Type 1:** Tumor primarily external to the pelvis
**Type 2:** Tumor predominantly external but with a substantial intrapelvic component
**Type 3:** Tumor predominantly within pelvis/abdomen with a smaller external component
**Type 4:** Tumor entirely within pelvis/abdomen without an external component

to prevent recurrence. The Altman classification of SCT applies to the fetus but may change during gestation (Box 130.3).[62]

***Imaging.*** As with teratoma anywhere in the fetal body, tumors are characteristically mixed cystic and solid, with arterial vessels identifiable in the solid components. Ultrasonography is excellent for identifying the abnormal mass at the pelvis and involvement of superficial soft tissue just dorsal to the anus, which is invariably displaced ventrally when an external tumor component is present. Color Doppler interrogation is used to assess the vascularity of the tumor. Because of tumoral vascular shunting, a fetus may develop signs of high cardiac output failure, with subsequent typical findings of hydrops fetalis. Close-interval follow-up with serial ultrasonography for the signs of developing cardiac dysfunction and hydrops is indicated in a fetus with SCT if intervention is to be considered.[63] Because pelvic bones may interfere with clear visualization of the deep structures on ultrasonography, MRI is advantageous for better definition of the extent of a lesion, its relationship to the bladder and rectum, and calculating a tumor–body weight ratio that some institutions use for prognosis (Fig. 130.17).[64] Both single-shot T2- and T1-weighted sequences for meconium–rectal position and hemorrhage are helpful. Fetal MRI can supplant neonatal MRI for preoperative planning in some cases. Although much more rare, neuroblastoma in the low pelvis has been reported to mimic the appearance of SCT.[65]

Rhabdomyoma, rhabdomyosarcoma, fibrosarcoma, or myofibroma (myofibromatosis) are extraordinarily rare in the fetus. These are characteristically solid masses with some internal heterogeneity that grow on serial examination; they are typically found in the fetal neck or pelvis but may be in the extremities, retroperitoneum, or chest wall.[66–72] They may be confused with vascular tumors such as a kaposiform hemangioendothelioma, although the latter are typically more infiltrative. Lymphatic malformation may also be infiltrative and multicompartmental with both solid appearing (microcystic) and cystic (macrocystic) components. The differential diagnosis for solid tumors includes teratoma (which is more common, generally has some cysts, and might be distinguished by a fat component) and potentially neuroblastoma. Either of these tumors can contain calcifications.

***Treatment and Follow-up.*** Before viability, should a fetus develop cardiac failure and hydrops fetalis, in utero surgical resection of SCT has been offered in some centers as an alternative to inevitable demise. The procedure involves a hysterotomy with partial delivery of the fetus, tumor resection, and return of the fetus to the uterus with myometrial closure. A significant complication is preterm labor, and efforts are therefore being directed toward less invasive surgeries.[73,74] This is clearly a rare circumstance but has been successfully managed. After the age of viability, a fetus in distress could be delivered for further ex utero treatment options.

Treatment for SCT in the neonate is complete surgical excision of the tumor; the risk of malignancy is lowest with fetal or neonatal presentation and therapy.[75] Recurrence rates are negligible as long as the coccyx is also removed with the tumor.[76]

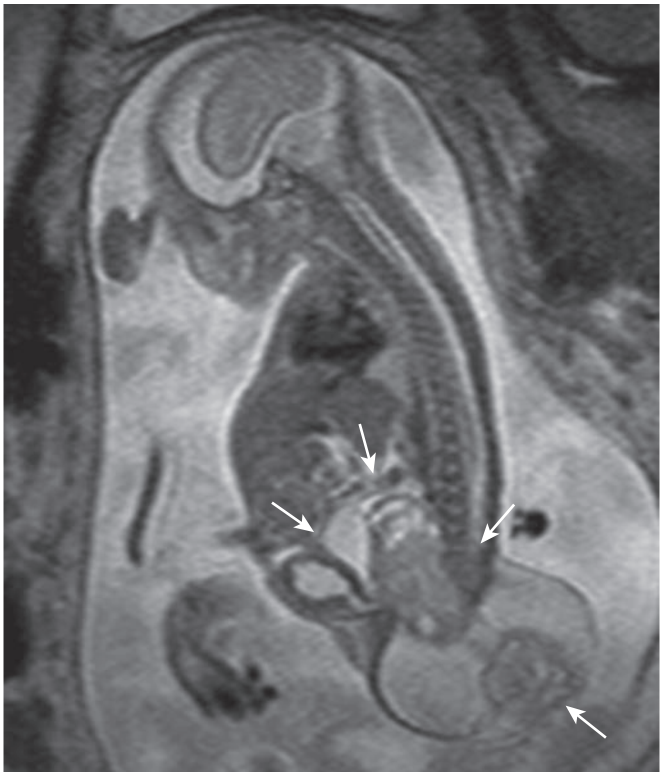

**Figure 130.17. Sacrococcygeal teratoma.** Mixed cystic-solid mass *(arrows)* in the fetal pelvis between the bladder and the spine with internal and external components.

## KEY POINTS

- Marked thoracic restriction portends lethality in cases of skeletal dysplasia.
- The majority of lethal skeletal dysplasias are one of three diagnoses: thanatophoric dysplasia, achondrogenesis, or osteogenesis imperfecta type II.
- Thorough evaluation of the fetus and its environment, including the umbilical cord, is indicated when a limb defect is detected.
- Fetal posture should be assessed for fixed or abnormal positions.
- Fetal musculoskeletal tumors are rare; SCT is the most common and can cause fetal cardiac high-output failure due to arterial shunting.

# Congenital Anomalies of Bone

J. Herman Kan and Tal Laor

Regardless of origin, abnormal limb development tends to fall into patterns that can be recognized clinically and radiographically (Fig. 131.1). Most classification systems of congenital malformations are based on osseous structures, but it is well recognized that anomalous conditions of surrounding soft tissues are certain to be present. Congenital malformations of the extremity can be generally classified as dysplastic or absent (amelia).

Congenital deficiencies are more common than acquired amputations in children. Frantz and O'Rahilly developed a system of classification that is still commonly used to evaluate congenital anomalies of the extremities.[1] Each malformation is defined by the part that is deficient. For example, the fibula is deficient in fibular hemimelia. The abnormality is considered terminal if the deformity extends to the distal aspect of the extremity; it is intercalary if the limb distal to the deformity is normal. For example, in fibular hemimelia, if the foot is abnormal, the deficiency is terminal, and if the foot is normal, it is intercalary. Likewise, a defect may be classified as longitudinal (paraxial) or transverse. The malformation is paraxial if only the fibular side is affected. If both the tibia and the fibula are affected, the deformity is considered transverse.

The cause of reduction malformations is known in only a small number of cases. A few abnormalities are heritable, but most are sporadic. Environmental factors are implicated infrequently. Medications, such as thalidomide, induced malformations that were reduction deformities, ranging from severe amelias to mild muscular hypoplasia.[2] Most malformations were on the radial or tibial side, and the upper limbs were affected more often than were the lower extremities. Infrequently, excess deformities such as polydactyly were observed.

## EXTREMITY DEFICIENCIES

### Proximal Femoral Focal Deficiency

***Etiology.*** Proximal femoral focal deficiency (PFFD) refers to abnormalities that range from mild shortening and hypoplasia of the femur to severe deficiency of the bone and dysplasia of the acetabulum. The defect is thought to be a result of altered proliferation and maturation of the chondrocytes of the proximal femoral physis in utero, which in turn results in underdevelopment of the ipsilateral acetabulum. A child with PFFD usually presents in infancy with a short extremity and an unstable hip.[3] A well-formed acetabulum implies the presence of a femoral head, which might be cartilaginous and therefore is not apparent radiographically early in life. Most cases are sporadic; however, the combination of bilateral femoral deficiencies and abnormal facies (the femoral hypoplasia–unusual facies syndrome) is thought to be an autosomal-dominant disorder.

PFFD should be distinguished from developmental dysplasia of the hip, infantile coxa vara, and congenitally short femur. In the setting of developmental dysplasia of the hip, proximal femoral neck and head hypoplasia may be present. The subtrochanteric region of the femur is normal and distal congenital anomalies are absent, and the deformities at the level of the acetabulum are more severe than the deformities at the level of the femoral head and neck. Children with infantile coxa vara have varus configuration of the femoral head and neck, with a normal subtrochanteric region and distal bones, and the femur is normal in length. Unlike PFFD, infantile coxa vara is discovered after weight bearing occurs.[4] A congenitally short femur may be unilateral or bilateral and often is associated with reduction defects elsewhere in the same limb. Most cases are sporadic, but several external factors have been implicated in more complex deformities. Known causes include drugs (such as thalidomide), trauma, irradiation, infection, and focal ischemia.[5] Unlike patients with PFFD, patients with a congenitally short femur have a stable hip.

***Imaging.*** The most commonly used classification for PFFD was proposed by Aitken (Fig. 131.2).[6] The least severe type is class A, which refers to an adequate or only mildly dysplastic proximal femur and acetabulum. The femoral head is present but separated from the shortened distal femoral segment. With age, a fibrous connection between the head and the distal femoral segment ossifies—usually, not completely. A subtrochanteric varus deformity invariably is present. Class C deformities have a residual acetabulum present (Fig. 131.3). In the most severe form, class D, most of the femur and the ipsilateral acetabulum are absent. PFFD classification may change over time with osseous maturation.[7]

PFFD is associated with other ipsilateral deformities, including fibular hemimelia (in more than 50% of affected children), shortening of the tibia, equinovalgus deformity of the foot (more often than equinovarus deformity), and deficiency of the lateral rays of the foot. PFFD is bilateral in 15% of affected children.[8]

Sonography can be used to delineate radiographically inapparent structures at an early age. If a cartilaginous femoral head and its connection to the femoral shaft can be shown, the stability of the hip joint is likely greater than is implied from radiographs. Sonography with dynamic stress maneuvers of the affected hip is helpful to determine the presence of coexisting ligamentous laxity and hip subluxation. Similar to sonography, magnetic resonance imaging (MRI) is useful for defining the anatomy of the hip joint and associated deformities of the limb,[9] allowing for appropriate early classification of the deformity. Although the acetabulum might appear developed, even the least severe forms of PFFD are associated with acetabular deficiency. In contrast to the predominantly anterior deficiency of developmental acetabular dysplasia, the acetabulum in PFFD usually has an insufficient posterior wall. Most of the muscles about the affected hip are hypoplastic when compared with a contralateral normal side, with the exception of the sartorius muscle, which often is hypertrophied. This situation results in the characteristic flexion deformity of the hip and knee. MRI also defines the anatomy of soft tissues that can guide surgical exposure and preparation of the limb stump for fitting of a prosthesis.

***Treatment and Follow-up.*** Therapy for children with PFFD is based on the severity of the deficiency and projection of growth and final limb length discrepancy at maturity. Objectives for treatment are to maximize the length of the extremity, to promote stability of the hip, knee, and ankle, and to optimize anatomic alignment. Mild deformities may not require surgery. Stabilization of the upper femoral defect is controversial and usually is indicated if a deformity is progressive. Children with severe deformities

## Abstract:

Objective: To describe common and uncommon congenital deformities of the bone and classification systems when applicable.

Methods: Review of the relevant current literature, and include relevant illustrations and examples.

Results: Congenital deformities of bone are rare. By understanding the underlying embryologic and pathophysiologic basis of these entities and their pertinent classification systems, accurate and succinct description and delineation of these deformities can be achieved.

## Keywords:

radiography
embryology
congenital deformities

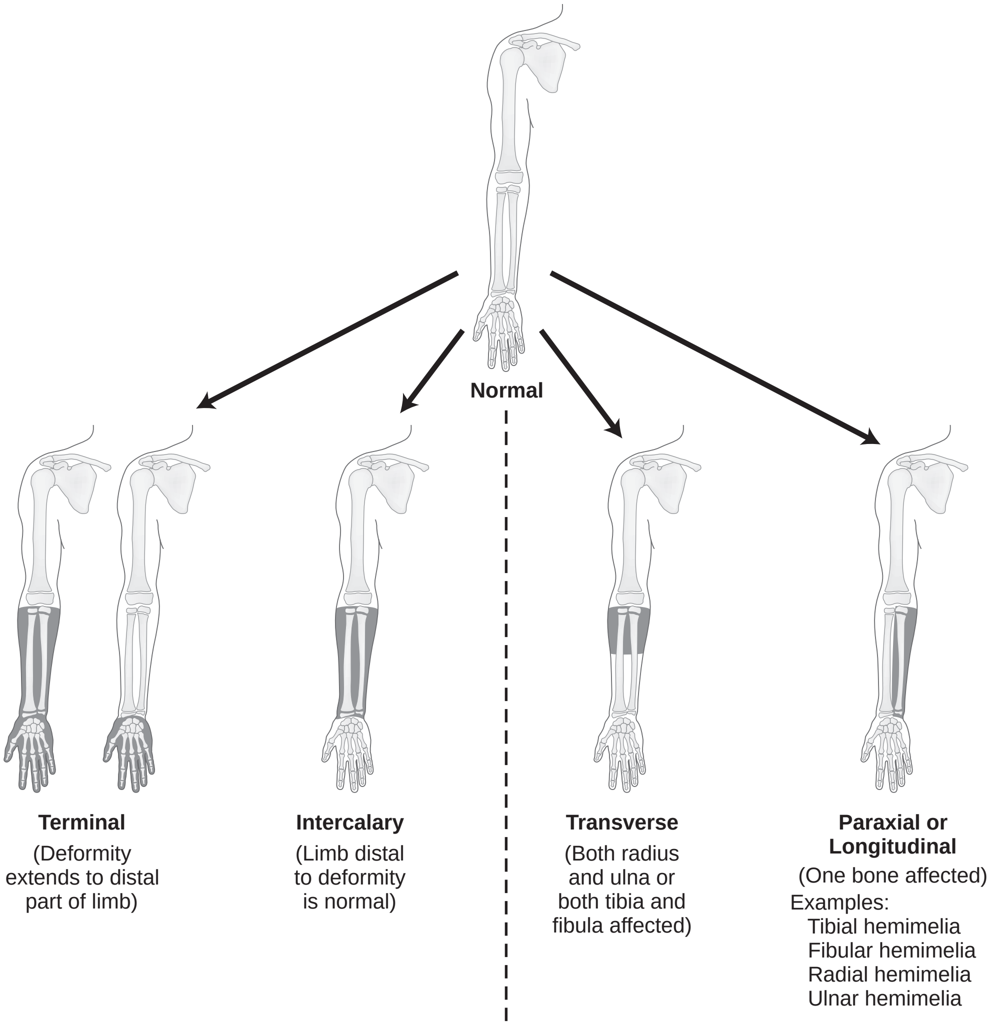

**Figure 131.1. Skeletal deformities of the limbs.** The shaded, blackened areas indicate deficient parts.

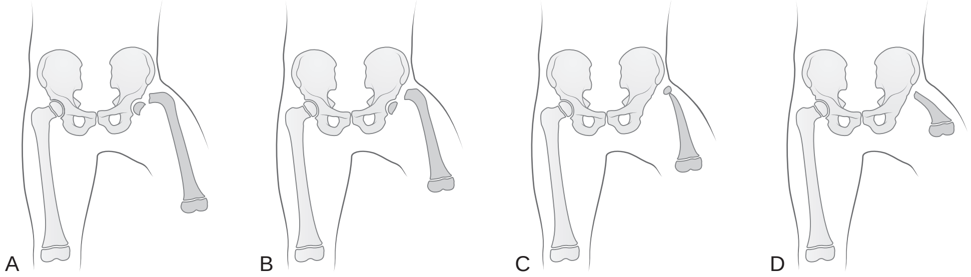

**Figure 131.2. Aitken classification of proximal femoral focal deficiency.** (A) Class A, mildly dysplastic proximal femur with coxa vara and a normal acetabulum. (B) Class B, no osseous connection between the femoral head and shaft, with mild to moderate acetabular dysplasia. (C) Class C, absent or small femoral head with tapered proximal femoral configuration with severely dysplastic acetabulum. (D) Class D, absent proximal femur and absent acetabulum.

benefit from amputation of the foot and fusion of the knee. Van Ness rotationplasty of the tibia, in which the foot is rotated 180 degrees (so that the toes face posteriorly and the ankle now serves as a knee joint), allows the ankle and foot to control a distal prosthesis.[10] Intact sensory feedback from the foot provides proprioceptive control of the knee. Thus it is imperative to assess the morphology of the proximal femur and acetabulum, the cartilaginous epiphyses of the knee, and the supporting soft tissue structures. For example, instability of the knee can result from absence of the anterior cruciate ligament. In the rare case of bilateral PFFD, amputation is contraindicated and therapy is based on extension prostheses that enhance the child's height.

## Fibular Hemimelia

***Etiology.*** Fibular hemimelia is the most common hemimelia and the most common congenital anomaly of the fibula. It also has been referred to as *congenital short tibia with absent fibula syndrome*. Unilateral absence is more frequent than bilateral deformity. A band of strong connective tissue may replace all or most of the

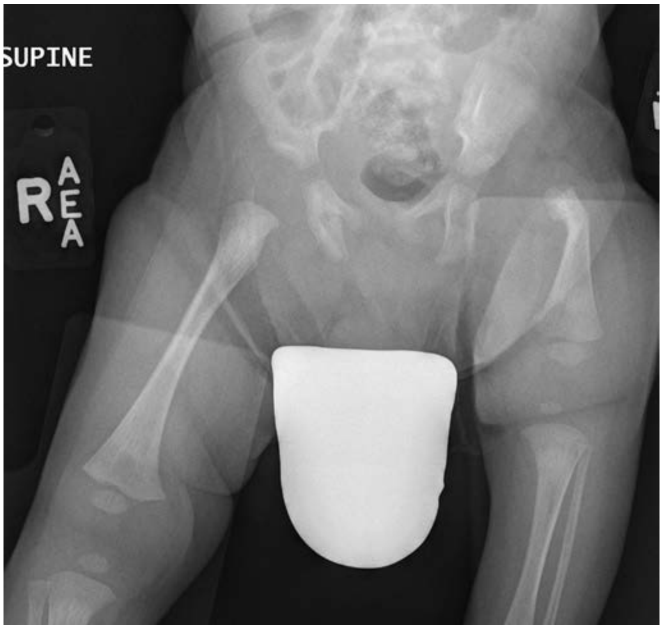

**Figure 131.3. Aitken type C proximal femoral focal deficiency of the left hip in a 4-week-old boy.** The femur is substantially short and the left acetabulum is severely dysplastic. Mild developmental dysplasia of the right acetabulum is present.

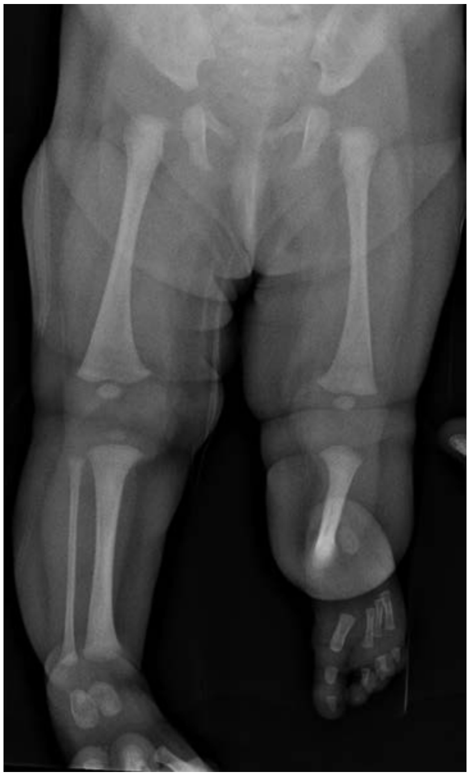

**Figure 131.4. Left fibular hemimelia in a 2-month-old girl.** The left fibula is absent, and the tibia is shortened. The left femur is short, and there are only four digits in the left foot. The left talus is not seen.

fibula.[11] Fibular hemimelia is associated with a short, bowed tibia; absence of lateral rays of the foot; tarsal abnormalities (particularly coalitions); ball and socket ankle deformity; and femoral shortening or deficiency in 15% of patients. Clubfoot or equinovalgus may be seen in up to 39% of patients with fibular hemimelia.[12] Other associations include small, subluxated, or dislocated patellae; hypoplastic femoral condyles; and ligamentous deficiencies of the knee.[11]

***Imaging.*** Fibular hemimelia ranges from mild deficiency of the proximal end of the bone to complete absence accompanied by multiple malformations of neighboring structures (Fig. 131.4). Standing anteroposterior (AP) lower extremity radiographs inclusive of the unaffected side are helpful for evaluation of the degree of fibular deficiency, alignment abnormalities, and presence of additional lower extremity deficiencies. MRI can document associated abnormalities, particularly if surgery is contemplated, including ligamentous deficiencies of the knee.

***Treatment and Follow-up.*** The talipes equinovalgus deformity of the foot and severe shortening of the limb associated with fibular hemimelia result in poor function of the limb. Children with extensive abnormalities involving the fibula, ipsilateral tibia, femur, and foot benefit the most from early amputation of the foot and often the more proximal structures.[13] If the deformity is less severe, lengthening of the affected side, realignment of the tibiotalar articulation, and epiphysiodesis of the contralateral limb often are undertaken. Attempts at lengthening a severely dysplastic limb often are unsatisfactory.

## Tibial Hemimelia

***Etiology.*** Most cases of tibial hemimelia are sporadic, although reported forms (particularly bilateral deformities) display an autosomal-dominant inheritance pattern. There are various classification schemes for tibial hemimelia, all of which describe the various degrees of dysplasia.[14]

***Imaging.*** Radiography of tibial hemimelia (Fig. 131.5) ranges from absence of a portion of the distal tibia to complete absence with multiple malformations of neighboring structures. Complete

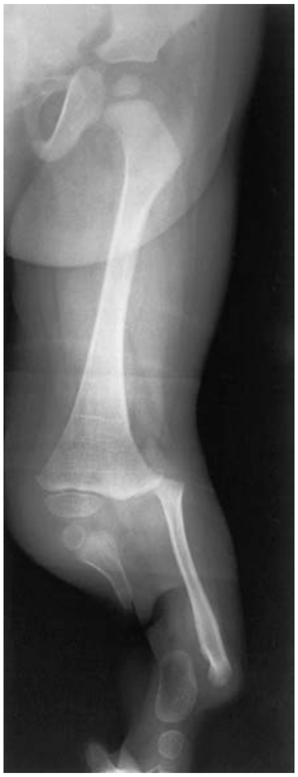

**Figure 131.5. Tibial hemimelia in a 2-year-old girl.** A dysplastic proximal tibial remnant is evident. The fibula is short and subluxed laterally, and multiple tarsal bones are absent.

absence of the tibia may mimic fibular hemimelia, particularly if there is relative overgrowth of the distal portion of the fibula. A differentiating feature between these two entities is that the fibula in the setting of tibial hemimelia always will be laterally located with respect to the knee or ankle joint. Conversely, the tibia in the setting of fibular hemimelia usually will be concentrically located with respect to the knee or ankle joint. With weight bearing, the fibula will usually override the distal femur and talus.[7]

MRI can document associated abnormalities, including associated muscular and ligamentous deficiencies, which is important if surgery is contemplated. MRI may identify a cartilaginous tibial remnant that may not be apparent on radiography and which is necessary for accurate classification.[14]

***Treatment and Follow-up.*** Treatment of tibial hemimelia varies with the severity of the deformity. A knee disarticulation is recommended for complete tibial absence. Brown pioneered centralization of the fibula with a Syme amputation of the foot in children with complete tibial hemimelia.[15] This approach produces adequate results in the rare cases in which the quadriceps muscles are well developed. When the quadriceps mechanism is abnormal, the patella often is absent. MRI can be used to assess deficiencies preoperatively, allowing the clinician to discern who will function better with primary knee disarticulation (most patients) rather than knee reconstruction.

## Radial Longitudinal Deficiency

***Etiology.*** Conditions associated with radial longitudinal deficiency (also referred to as *radial dysplasia* or *radial clubhand*) are listed in Box 131.1.[16] Usually the entire limb is involved to some degree, which often results in joint dysfunction of the shoulder, elbow, wrist, carpus, and small joints of the hand. Muscular deficiencies are proportionate to the degree of skeletal abnormality. Neurovascular abnormalities include an absent radial artery and superficial radial nerve.

**BOX 131.1** Conditions Associated With Radial Longitudinal Deficiency (Dysplasia)

**SYNDROMES ASSOCIATED WITH CONGENITAL HEART DISEASE**

*VACTERL,* Vertebral, anal, cardiac, tracheal, esophageal, renal, limb.
*Modified from Goldberg MJ, Bartoshevsky LE. Congenital hand anomaly: etiology and associated malformations.* Hand Clin. *1985;1:405–415.*

Whether radial deficiency is isolated or is associated with a syndrome, the primary malformation is likely the result of a vascular abnormality occurring before embryonic differentiation of mesenchyme into muscle and bone.[17] Most cases are sporadic, but some autosomal-dominant and autosomal-recessive inheritance patterns are reported. Other cases are likely the result of various environmental insults from viruses, chemicals, radiation, and drugs during limb bud development.

***Imaging.*** Congenital radial longitudinal deficiency ranges from hypoplasia of the thumb to various degrees of radial hypoplasia. Complete radial absence is the most common longitudinal deficiency. This deformity usually is accompanied by radial and volar deviation of the hand, which results in part from unopposed pull by the flexor carpi radialis and brachioradialis muscles.

In most cases of radial aplasia or complete radial longitudinal deficiency, the forearm is bowed with convexity to the radial side and the distal ulna is prominent (Fig. 131.6). The forearm is short (usually approximately two-thirds the length of the normal contralateral side) and remains proportionately so throughout growth. Often, only the capitate, hamate, triquetral bones, and the metacarpals and phalanges of the four ulnar rays are present and normal. The trapezium, scaphoid, and first ray often are deformed or absent. If a remnant of the radius is present proximally, it usually is fused to the ulna, which is curved, shortened, and thickened. Bilateral deficiency occurs in approximately 50% of affected children.[16] The degree of deformity of the hand is related to the severity of deficiency of the forearm.

***Treatment and Follow-up.*** Treatment of a radial longitudinal deficiency begins with serial casting and splinting intended to improve radial deviation by stretching the soft tissues. This is often followed by surgical centralization of the hand over the ulna to improve function and appearance.[18] Thumb reconstruction and pollicization of the index finger often are indicated.

## Ulnar Longitudinal Deficiency

***Etiology.*** Deficiency that occurs along the ulnar or postaxial border of the upper extremity is known as *ulnar longitudinal deficiency* (also referred to as *ulnar dysplasia* or *ulnar clubhand*). It is a relatively uncommon disorder that occurs much less frequently than radial

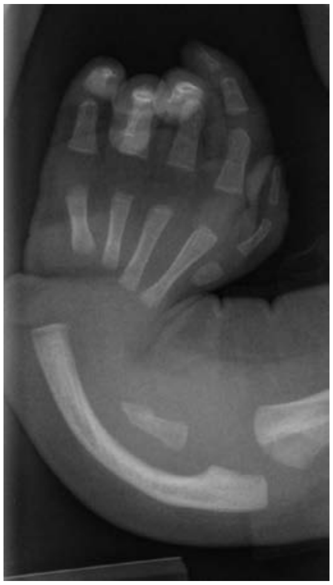

**Figure 131.6. Radial longitudinal deficiency in a 1-month-old boy.** There is a rudimentary proximal radius associated with a short and bowed ulna. The thumb is hypoplastic.

longitudinal deficiency. Approximately 48% of cases have anomalies of the contralateral limb.[19] Most cases are sporadic, but associations with many other syndromes have been reported, most commonly Brachmann-de Lange syndrome.[20]

***Imaging.*** Coexisting abnormalities almost always are present in the carpal, metacarpal, and phalangeal rays (e-Fig. 131.7). The pisiform is always absent, and the hamate frequently is not detected. Syndactyly, carpal fusion, and radiohumeral fusion are frequent. The forearm is shortened and bowed, with a concavity to the ulnar side. The hand is deviated in an ulnar direction, and elbow abnormalities are common. Hypoplasia of the shoulder girdle and the upper arm can coexist with ulnar deficiencies. Anomalies of the contralateral upper limb and the lower limbs (such as PFFD) have been reported.

***Treatment and Follow-up.*** Treatment for ulnar deficiency includes early serial casting to correct ulnar deviation of the hand. Surgical treatment is reserved for cases with significant limitation of function.[21] Forearm instability and associated hand deformities must be addressed.

## GENERALIZED ANOMALIES

### Congenital Constriction Bands

***Etiology.*** Constriction bands are thought to result from intrauterine rupture of the amnion and subsequent mechanical constriction of fetal limbs.[22] Various body parts become entangled in the amnion as it separates from the chorion. In some instances, adjacent structures are pulled together by the bands and ultimately become fused, producing a soft tissue syndactyly. Bony syndactyly is very rare. The earlier the amnion ruptures, the more severe are the malformations. Limb abnormalities range from slight soft tissue grooves to transverse intrauterine amputations. Acrosyndactyly, craniofacial and visceral anomalies, and fetal death are part of the spectrum of congenital constriction band syndrome. Sporadic congenital constriction band syndrome is estimated to occur at an incidence of 1 : 1,200 to 1 : 15,000 births. An alternative explanation is the intrinsic theory, which suggests that an inherent defect leads to bands during limb embryogenesis.[22]

***Imaging.*** Radiography may underestimate the degree of soft tissue compromise, and associated anomalous vascular anatomy may not be recognized. Typical conventional radiographic findings include a tethered appearance of fingers with a characteristic tight distal waist with soft tissue syndactyly (Fig. 131.8). MRI can be used to evaluate the depth of the constriction band, the degree of resultant lymphedema, and the integrity of the involved musculature.

***Treatment and Follow-up.*** Surgical treatment usually is cosmetic, although it may be used to relieve massive edema distal to a constriction band or improve neurovascular function. Intervention for acrosyndactyly may result in partial correction of the deformity and improved longitudinal growth.

### Arthrogryposis

***Etiology.*** Arthrogryposis multiplex congenita is a descriptive term used loosely to refer to conditions that result in congenital contractures involving two or more joints, such as those that limit intrauterine movement.[23] The earlier in gestation that movement is limited and the longer the restriction lasts, the more severe will be the contractures at birth. Normal in utero motion is necessary for normal development of joints.

Arthrogryposis may result from abnormal muscles (such as myopathies), abnormal nerve function or innervation, abnormal connective tissues, or mechanical limitation of movement (such as oligohydramnios or multiple fetuses). Other possible causes include genetic defects, mutagenic agents, mitotic abnormalities, and toxic chemicals or drugs (Box 131.2).

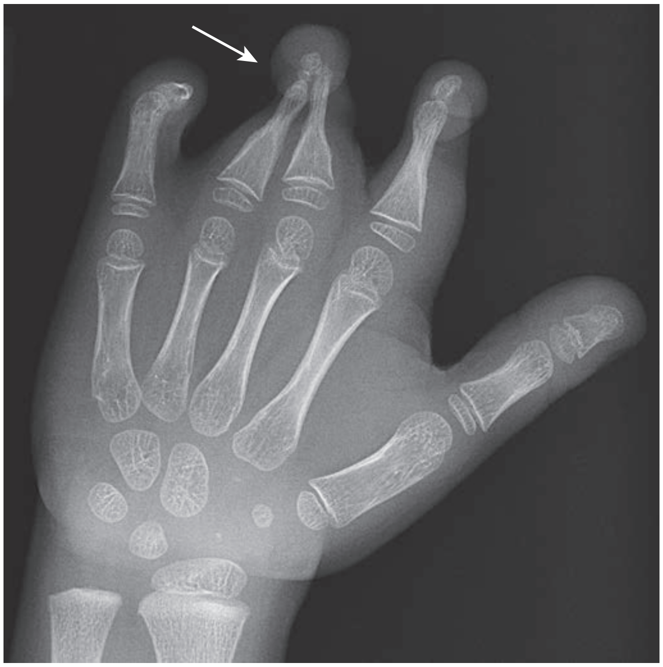

**Figure 131.8. Constriction bands in a 3-year-old girl.** Radiograph of the hand shows a “tight waist” appearance *(arrow)* and multiple distal digital amputations.

**BOX 131.2** Causes of Arthrogryposis: Causes of Limited Fetal Joint Mobility

**NEUROLOGIC**

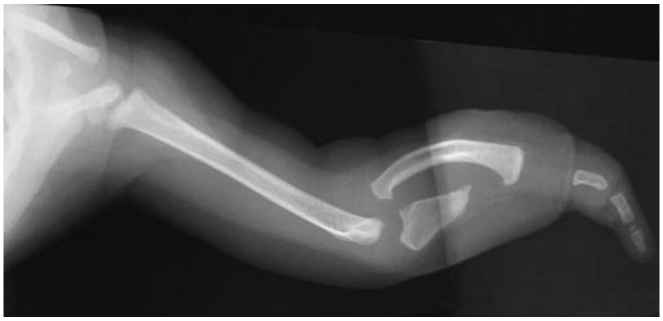
- Diabetes mellitus
- Hyperthermia
- Infection
- Drug use and abuse

*Modified from Jones K.* Smith’s Recognizable Patterns of Human Malformation. *5th ed. Philadelphia: WB Saunders; 1997.*



**e-Figure 131.7. Ulnar deficiency.** Partial formation of the proximal ulna is present, with aplasia of the distal portion. The radius is bowed, and only a single digit of the hand is present. The humerus is normal.

***Imaging.*** Contractures that are present at birth often are symmetric, can involve upper and lower extremities, and most commonly affect the distal parts of limbs. Long bone bowing deformities, joint subluxation or dislocation, and clubfoot alignment frequently coexist. Rigid joints and hypotonia contribute to frequent perinatal fractures. Soft tissue dimples may be seen over the affected joints, and muscle mass is decreased in affected limbs (e-Fig. 131.9). Affected muscles are partially or completely replaced by fatty or fibrous tissue. In many children, scoliosis develops. MRI can assess joint integrity when surgery to maximize joint function is planned.

***Treatment and Follow-up.*** The long-term prognosis for most children with arthrogryposis is good. However, children with associated central nervous system abnormalities usually have a limited life span. A neuromuscular workup is recommended for all children with arthrogryposis. Early therapy includes manipulation and possibly surgery to increase range of motion.[24]

## FUSION DEFORMITIES

### Tarsal Coalition

***Etiology.*** Tarsal coalition is a congenital failure of segmentation of the primitive mesenchyme that results in the union of two or more tarsal bones. A preadolescent or adolescent child with pain in the midfoot and hindfoot that is associated with lack of motion in the subtalar region should be suspected of having a tarsal coalition. Prevalence in the US population is approximately 1% or less. At least 50% of patients with coalitions have bilateral findings.[25] An autosomal-dominant inheritance pattern with a high level of penetrance is reported, although the coalition need not involve the same joint. Although it typically presents during the second decade of life, tarsal coalition may not manifest until adulthood.

Tarsal coalition is defined on the basis of anatomic location and completeness of ossification. A complete ossific bar forms a synostosis, a cartilaginous bar forms a synchondrosis, and a fibrous union is termed a *syndesmosis*. The most common fusions are talocalcaneal and calcaneonavicular. The middle facet is the most common location for a talocalcaneal coalition. Talocalcaneal coalitions often may extend posteriorly, with involvement of the junction of the middle and posterior facet. Talonavicular (e-Fig. 131.10), calcaneocuboid, and cubonavicular coalitions are much less common. Synostoses can occur between other bones of the foot but frequently are associated with other limb abnormalities, such as fibular hemimelia or short femur, or disorders such as Apert syndrome.

Symptoms from a tarsal coalition present with advancing ossification. Pain with activity usually is the presenting symptom. The child may have a peroneal spastic flatfoot, which involves pain and rigid valgus deformity of the hindfoot and forefoot, along with peroneal muscle spasm. This condition is not a true spasticity but reflects peroneal shortening to adjust for heel valgus and to maintain a less painful position for the subtalar joint.

***Imaging.*** Weight-bearing views of the foot are recommended to accurately evaluate longitudinal alignment of the foot, as pes planus is associated with tarsal coalitions. A 45-degree lateral oblique radiograph of the foot directly shows a calcaneonavicular coalition. The secondary radiographic features of calcaneonavicular coalitions visible on a lateral radiograph include pes planus, anteater sign (Fig. 131.11), and talar beak sign (e-Fig. 131.12).[26] A reverse anteater sign is seen on the AP view of the foot and is defined as diminished AP height of the lateral portion of the navicular (compared with the medial navicular), with the navicular extending far lateral with respect to the talar head.

Radiographic features of talocalcaneal coalitions include the C sign (Fig. 131.13A), talar beak, an ovoid, enlarged sustentaculum tali (see Fig. 131.13A), and broadened lateral process of the talus.[26]

The talar beak associated with tarsal coalitions is a dorsal extension of the talar head (see e-Fig. 131.12). A talar beak should not be confused with a talar ridge. The talar ridge represents bony proliferation related to the insertion of the anterior tibiotalar capsule and is located along the more proximal dorsal talar neck rather than at the distal talar head.[26]

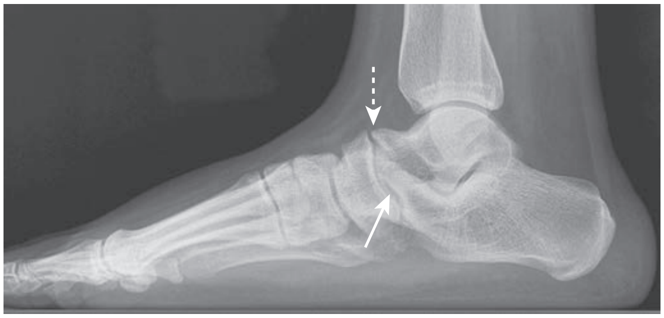


**Figure 131.11. Calcaneonavicular coalition in a child with the anteater sign *(arrow)* and talar beak *(dotted arrow)*.** Elongation of the anterior calcaneus resembling the nose of an anteater is present.

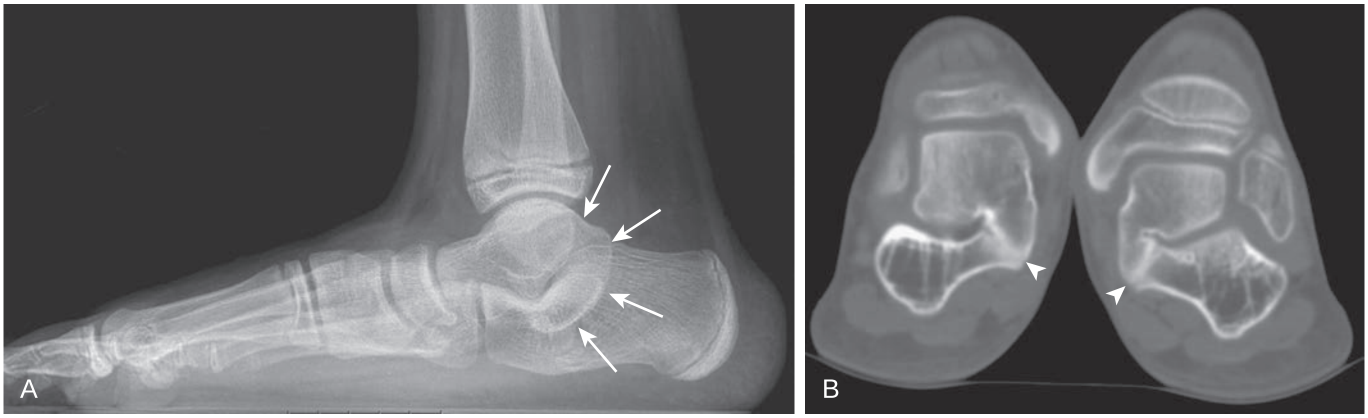

**Figure 131.13. Talocalcaneal coalition.** (A) Lateral radiograph demonstrates the C sign *(arrows)*, ovoid, elongated sustentaculum tali, and pes planus. (B) Coronal reformatted CT image in a different patient demonstrates bilateral middle facet subtalar coalitions *(arrowheads)*.

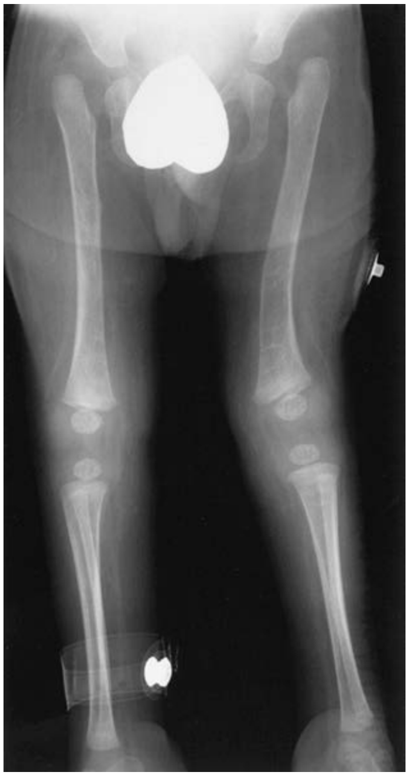
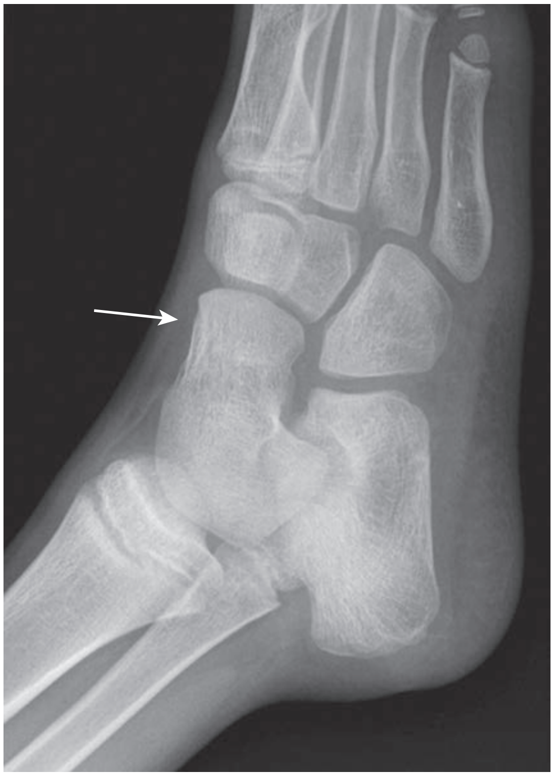
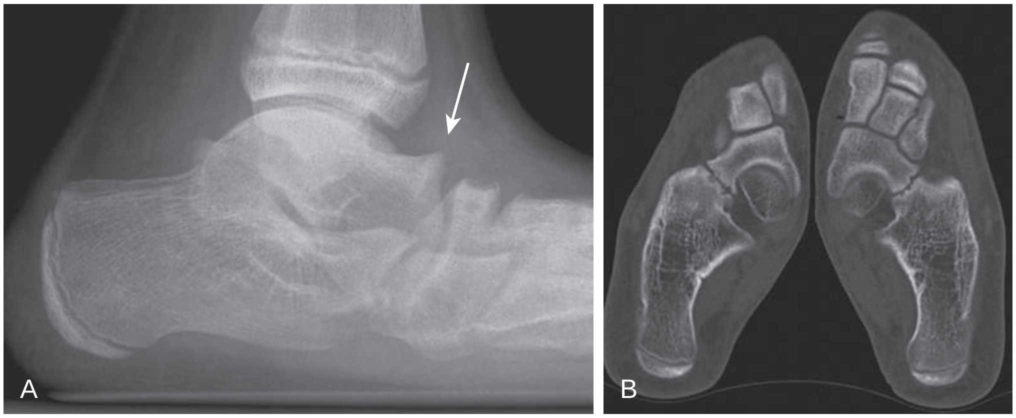


**e-Figure 131.9. Arthrogryposis.** Radiograph of the lower extremities of a child with arthrogryposis shows that the bones are gracile and demineralized, and muscle mass is reduced. The proximal femora are dislocated, and the acetabula are dysplastic. Femoral bowing on the left is the result of previous fractures.



**e-Figure 131.10.** Talonavicular coalition *(arrow)*.



**e-Figure 131.12. Calcaneonavicular coalition.** (A) Lateral radiograph demonstrates a talar beak *(arrow)* at the distal end of a shortened talar neck in a child with a calcaneonavicular coalition. (B) CT reconstructions demonstrate bilateral calcaneonavicular coalitions.

A ball-and-socket articulation of the distal tibia and talus is an uncommon association with tarsal coalition. This configuration at the ankle joint is nonspecific and may be associated with congenital long bone deficiencies, as well as tarsal coalitions.[27]

Computed tomography (CT) and MRI help to define the nature and cross-sectional area of a fusion. CT is more cost-effective if the clinical suspicion for coalition is high (Fig. 131.13B). If other causes of pain and limited hindfoot mobility are considered, then MRI may be indicated. MRI may directly show bony, cartilaginous, and fibrous unions. Bone marrow edema often is noted adjacent to the fused articulation (Fig. 131.14).

***Treatment and Follow-up.*** Casting and nonsteroidal antiinflammatory medications often are the initial treatment for symptomatic children. Steroid injections and physical therapy also may be used. If symptoms are not relieved and no degenerative changes have occurred, then surgical resection of the abnormal tarsal bridging often is attempted.[25] Regrowth of a calcaneonavicular coalition can be halted by interposition of the extensor digitorum brevis tendon. Fat frequently is interposed after resection of a subtalar coalition. Subtalar fusion or triple arthrodesis may be indicated in refractory cases.

## Carpal Fusion

Isolated fusion of the carpal bones is a normal variant that is seen in approximately 0.1% of the white population and approximately 1.6% of the African American population (e-Fig. 131.15).[28] Carpal fusion is seen most frequently between the lunate and triquetrum. Fusion between bones of the proximal and distal carpal rows usually is associated with a syndrome. Fusions also may be acquired, as in juvenile idiopathic arthritis or after trauma.

## Syndactyly

Fusion between adjacent digits resulting from intrauterine failure to separate is termed *syndactyly*. These fusions may involve only soft tissue (simple syndactyly), or they also may involve bone (complex syndactyly). If the entire length of the digit is involved, syndactyly is termed *complete*, and if only a partial length is bridged, it is incomplete. Fusion may be unilateral or bilateral and usually involves the second, third, and fourth digits. Syndactyly may be isolated or may be associated with congenital disorders such as Poland, Apert (Fig. 131.16), and Carpenter syndromes. Poland syndrome includes symbrachydactyly (brachydactyly and syndactyly) and ipsilateral chest wall anomalies, most commonly pectoralis muscle hypoplasia or aplasia. Apert syndrome includes syndactyly, craniosynostosis, and facial bone anomalies. Carpenter syndrome includes polysyndactyly, craniosynostosis, and facial bone anomalies. Syndactyly is thought to have an autosomal-dominant inheritance pattern.[29] Surgery is performed early in life to improve function and appearance when the hand is involved. Surgery is rarely indicated for the foot.

## Symphalangism

Symphalangism is an uncommon autosomal-dominant disorder of fusion of the interphalangeal joints of the hands and feet (Fig. 131.17). Proximal interphalangeal joint fusion is more common than distal interphalangeal joint fusion.[30] The anomaly is usually bilateral, and the little finger and little toe are affected most often. Fusion may not be recognized radiographically until later in childhood. Despite the radiographic appearance of the digits, seldom is disability or loss of function reported. Symphalangism may be associated with other skeletal abnormalities, various digit deformities (e.g., brachydactyly, clinodactyly, and camptodactyly), radioulnar fusion, hip dislocation, tarsal coalition, and spinal anomalies.

## Radioulnar Synostosis

***Etiology.*** Congenital radioulnar synostosis anomaly is due to failure of longitudinal segmentation between the radius and the ulna.[31] In utero, cartilaginous anlagen of the humerus, radius, and ulna are connected. Normal separation progresses from the distal end of the forearm to the proximal end. An insult to segmentation during early in utero development can lead to bony or fibrous synostosis. Radioulnar synostosis is associated with disorders such as Apert and Carpenter syndromes, as well as with other upper

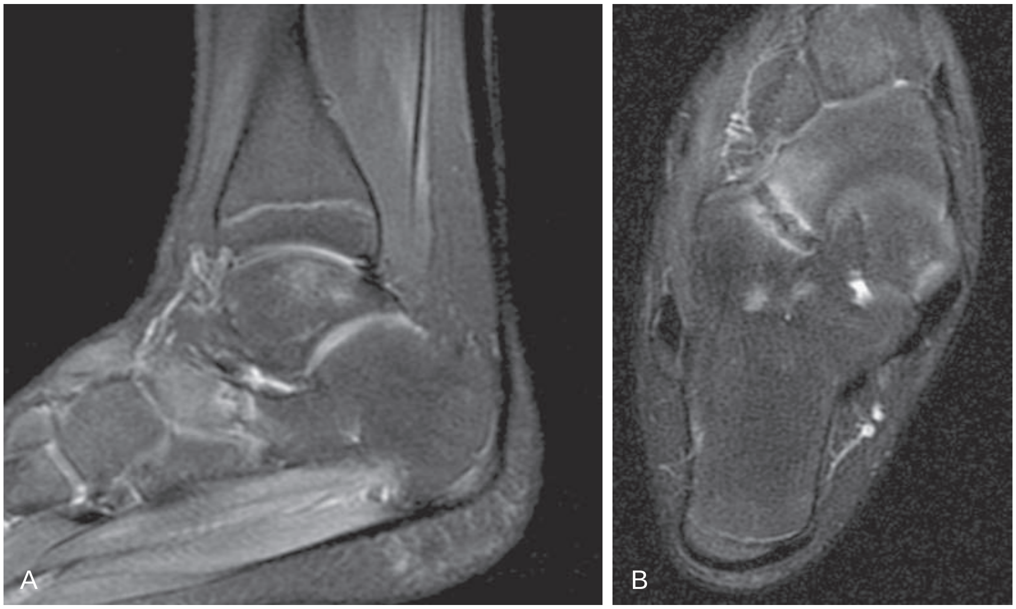


**Figure 131.14. Calcaneonavicular coalition in a 12-year-old girl.** Short Tau inversion recovery sagittal (A) and T2 fat-saturated axial magnetic resonance (MR) (B) images demonstrate marrow edema on both sides of a fibrous coalition.

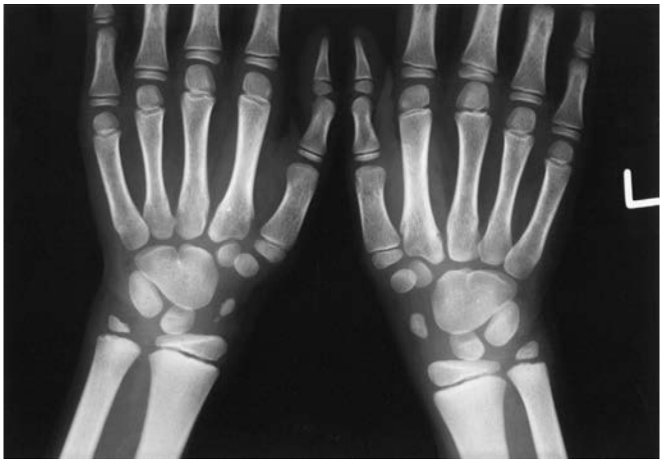

**e-Figure 131.15. Carpal fusion.** There is fusion of the hamate and capitate bones bilaterally.

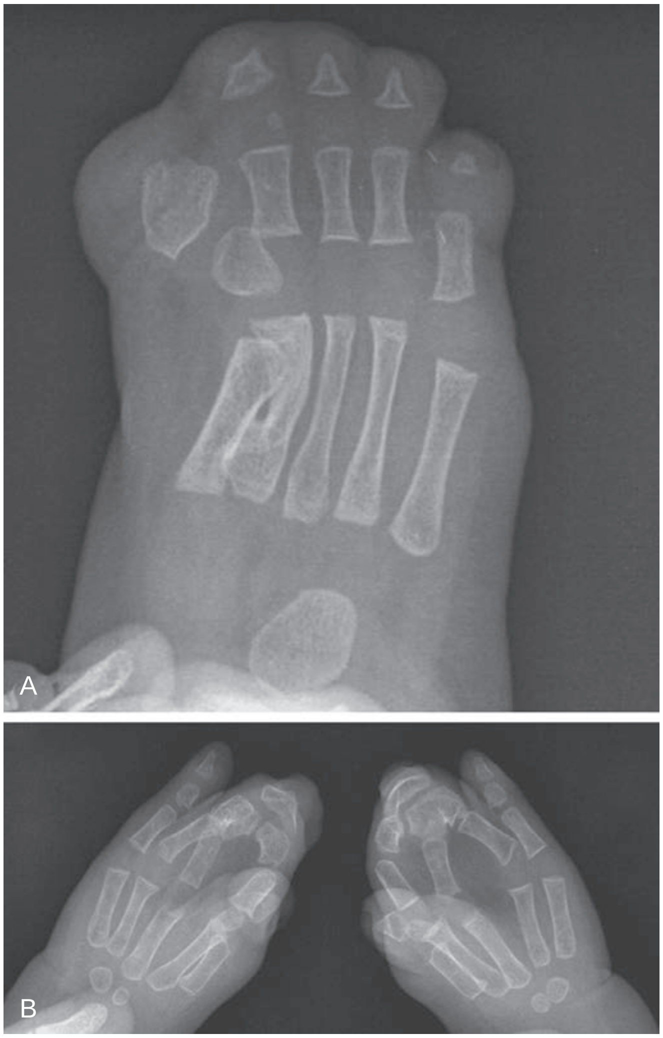

**Figure 131.16. Apert syndrome in a 1-year-old.** (A) Frontal view of the foot shows syndactyly of the digits. Hypoplasia of many bones of the foot is seen with absent middle phalanges. The first and second metatarsals are partially fused. (B) Frontal radiograph of both hands of the same child shows syndactyly, synostosis, and symphalangism bilaterally.

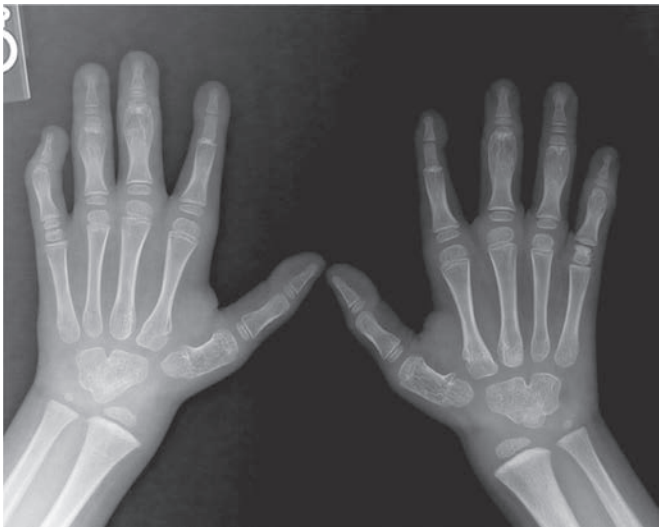

**Figure 131.17.** Bilateral symphalangism involving multiple rays with associated carpal coalitions in a 3-year-old girl.

extremity abnormalities such as polydactyly, syndactyly, and carpal coalition.

On clinical examination, the child may have a fixed degree of pronation and a mild degree of flexion at the elbow. Pain usually occurs during the teen years, when progressive and symptomatic radial head subluxation may be seen.

***Imaging.*** Osseous coalition can be seen on AP and lateral radiographs (Fig. 131.18). Radioulnar synostosis may lead to radial head dorsal dislocation and secondary dysplasia (see Fig. 131.18) due of the lack of articulation with the capitellum, which is needed for normal development.

***Treatment and Follow-up.*** Surgical treatment usually is reserved for patients with a severe pronation deformity or symptomatic radial head subluxation, particularly when it involves the dominant hand. A both bone extra-articular derotational osteotomy of the forearm may improve supination.[32] Resection of the proximal synostosis is complex and may not lead to improved forearm and hand function.

## OTHER CONGENITAL MALFORMATIONS

### Clinodactyly

Clinodactyly is a curvature of the finger in a radial or ulnar direction (in the mediolateral plane) away from the axis of joint flexion and extension. Although it may involve any digit, clinodactyly most often refers to radial curvature of the distal interphalangeal joint of the fifth digit (Fig. 131.19).[33] Clinodactyly is associated with a short middle phalanx and usually is bilateral. It may be seen in the normal population as a sporadic variant but also can be inherited in an autosomal-dominant pattern. It has been described in numerous syndromes (e.g., Down syndrome), in bone dysplasias, after trauma, and in many other conditions. The deformity may occur in the setting of a relatively normal phalanx or related to a longitudinal epiphyseal bracket deformity. Treatment is undertaken for cosmesis or for excessive scissoring of the digits.

### Camptodactyly

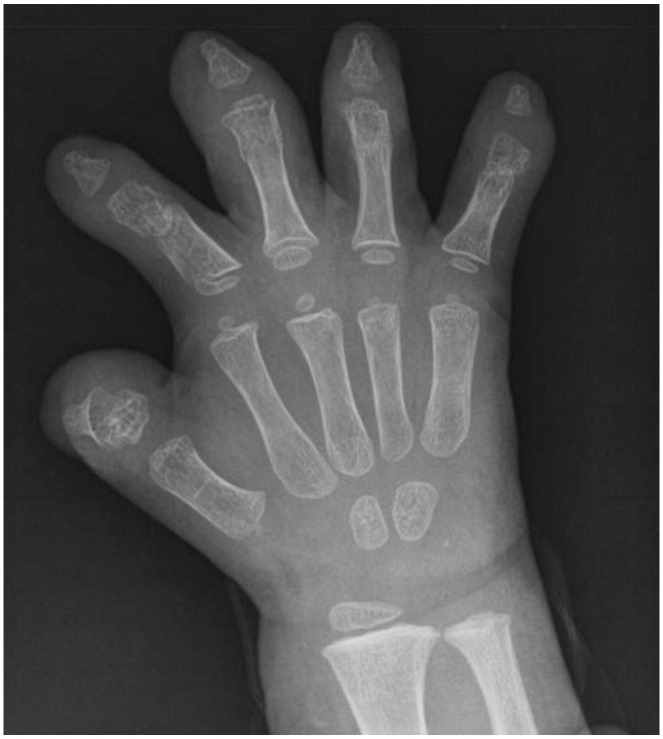
Camptodactyly refers to a congenital or acquired flexion contracture of the finger. It usually is located at the proximal interphalangeal joint of the fifth finger but also can involve the second through fourth digits (Fig. 131.20).[33] Occasionally, the distal interphalangeal joints may be affected. The cause remains unknown but may relate to abnormal insertion of the lumbrical muscles or the flexor digitorum superficialis tendon. Similar to clinodactyly, camptodactyly may be sporadic or may show an autosomal-dominant inheritance pattern. Occasionally it is associated with a chromosomal abnormality, a bony dysplasia, or another syndrome. Treatment includes bracing or, infrequently, surgical release.

### Kirner Deformity

Palmar bending of the distal phalanx of the fifth digit is termed *Kirner deformity*.[33] It usually is an isolated abnormality that is bilateral and symmetric. The long axis of the distal phalanx is bent toward the palm, and the epiphysis is normally oriented (Fig. 131.21). The physis is widened. With skeletal maturation, the physis fuses at an angle. The distal phalanx exhibits a permanent palmar curvature. Similar to the other digit deformities, Kirner deformity can be a sporadic or an autosomal-dominant inherited anomaly.

### Brachydactyly

Brachydactyly is a descriptive term that describes shortening of the digits secondary to abnormal development of the phalanges, metacarpals/metatarsals, or both of the hands or feet (e-Fig. 131.22).



**e-Figure 131.22.** Brachydactyly involving multiple digits and with symphalangism in a 3-month-old boy.

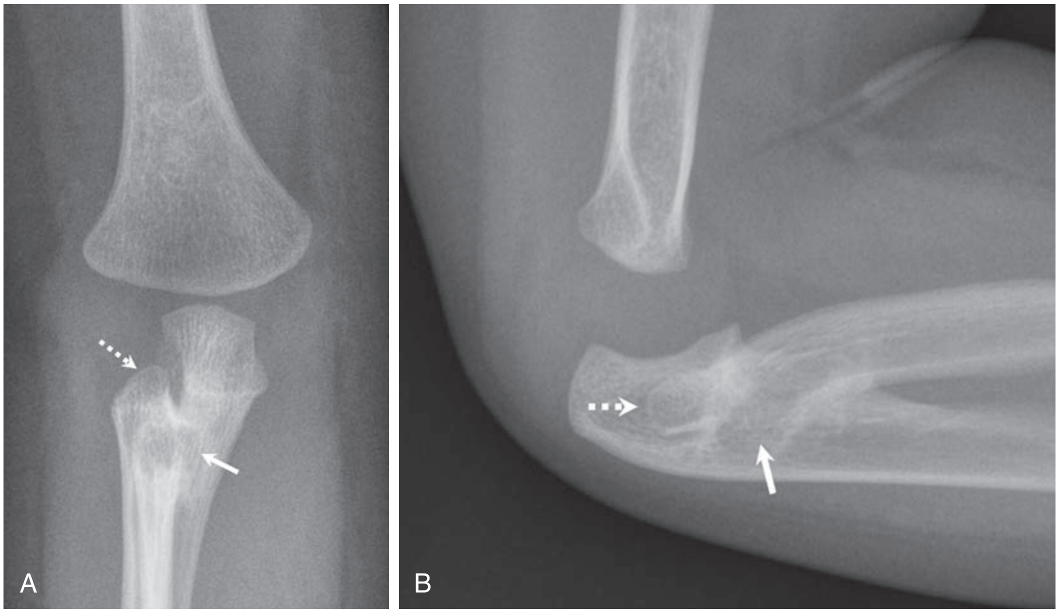


**Figure 131.18. Radioulnar synostosis in a 2-year-old girl.** Anteroposterior (A) and lateral (B) radiographs demonstrate osseous synostosis *(solid arrows)* of the proximal radius and ulna. Also note that the radial head *(dashed arrows)* is abnormally shaped and posteriorly directed with respect to the capitellum.

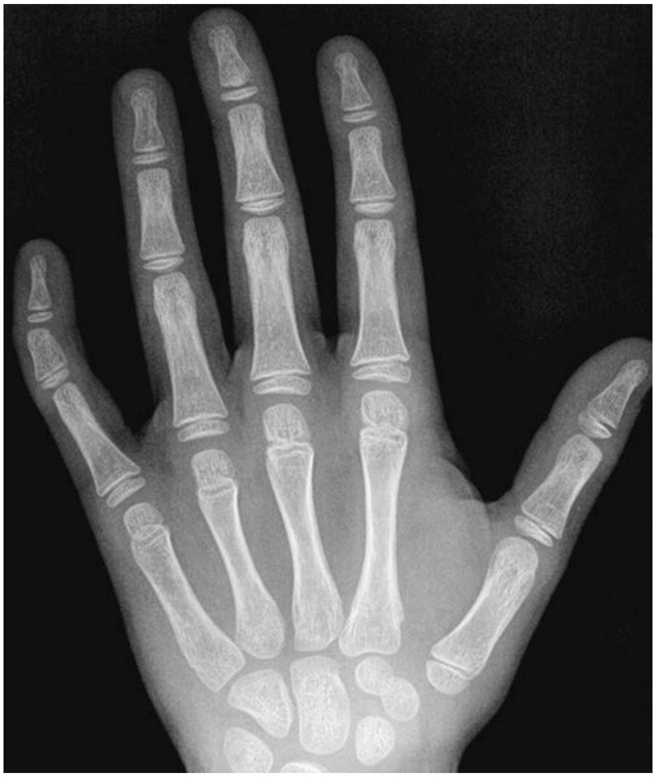

**Figure 131.19. Clinodactyly of the fifth digit in a 7-year-old girl.** Medial bending of the finger and a short middle phalanx are noted.

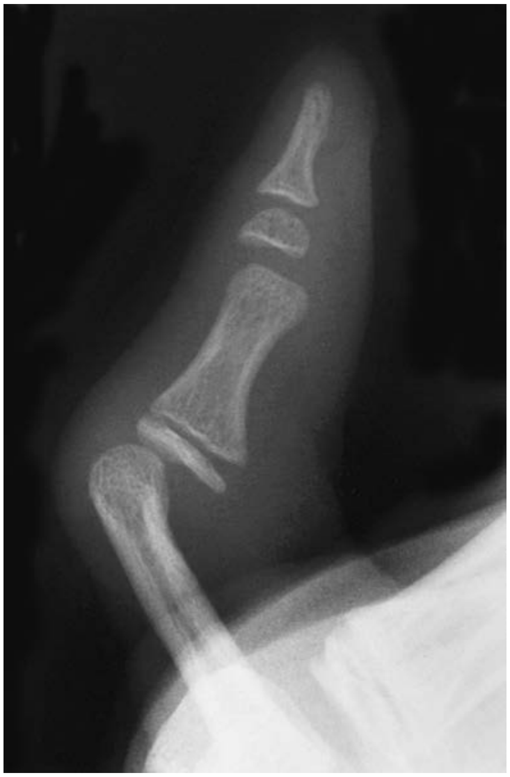

**Figure 131.20. Camptodactyly.** Flexion of the proximal interphalangeal joint is present with palmar subluxation of the middle phalanx of the little digit. The child has no skin crease.

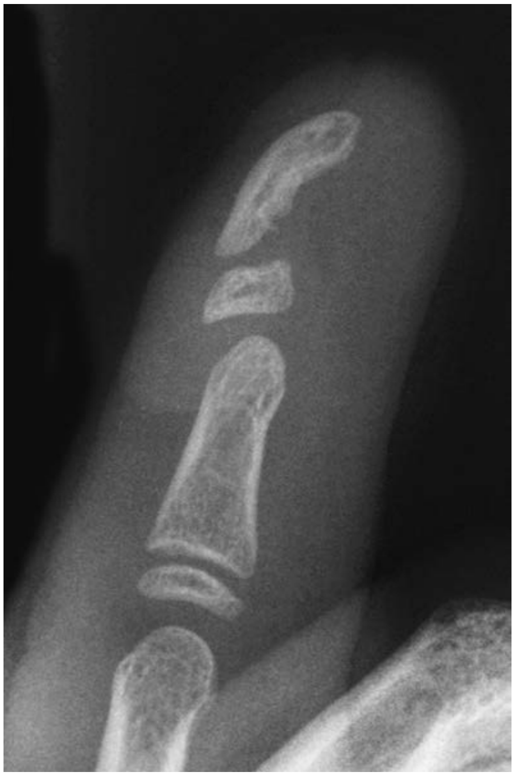

**Figure 131.21. Kirner deformity.** Palmar bending of the distal phalanx of the fifth digit is revealed. The epiphysis is in a normal position. *(From Oestreich AE, Crawford AH.* Atlas of Pediatric Orthopedic Radiology. *New York: Thieme; 1985:166.)*

Morphologically the affected bone may appear normal but just abnormally shortened compared with the other digits. The most commonly affected level is the middle phalanges. Brachydactyly may coexist with other processes such as longitudinal epiphyseal bracket and symphalangism. Brachydactyly may be sporadic or may be inherited in an autosomal-dominant fashion. Brachydactyly also may be seen with syndromes such as Apert and Poland syndromes.

## Longitudinal Epiphyseal Bracket

***Etiology.*** Longitudinal epiphyseal bracket, also referred to as *delta phalanx*, is a congenital deformity that affects the short tubular bones that normally develop a proximal epiphyseal ossification center (e.g., phalanges, first metacarpal, and first metatarsal). The deformity may be sporadic or may occur in association with conditions such as Rubinstein-Taybi syndrome and fibrodysplasia ossificans progressiva. The cause is likely incomplete development of the primary ossification center of the bone during early fetal growth. The growth disturbance relates to the longitudinally oriented cartilaginous bracket, which causes growth to follow a C-shaped curve.[34]

***Imaging.*** The involved bone is trapezoid or triangular in shape (Fig. 131.23). The diaphyseal–metaphyseal osseous unit is bracketed along the longitudinal side by a physis and an epiphysis. The physis is arclike (see Fig. 131.23B), extending from the medial proximal surface along the longitudinal margin of the bone to the distal medial surface, and is similar in configuration to a bracket. Other anomalies of the digits frequently are associated with the longitudinal epiphyseal bracket.

***Treatment and Follow-up.*** Splinting in infancy is not effective. Early surgical intervention, often a wedge osteotomy, is recommended to allow for remodeling and to facilitate longitudinal growth of the bone.[35]

## Split Hand-Foot Malformations

***Etiology.*** Split hand-foot malformation (SHFM) refers to the congenital splitting of the hands or feet into two halves. SHFM is attributed to hypoplasia or aplasia of the phalanges, metacarpals, or metatarsals of one or more fingers or toes. The deformity also is referred to as *ectrodactyly*, cleft hand or cleft foot, or lobster or crab claw deformity.

SHFM may be isolated or associated with congenital constriction band syndrome, or, most commonly, it may occur as a component of the ectrodactyly–ectodermal dysplasia–cleft lip/palate syndrome.[36] More than 75 syndromes have been associated with SHFM. Ectrodactyly–ectodermal dysplasia–cleft lip/palate syndrome usually has an autosomal-dominant inheritance pattern with incomplete penetrance and variable expression, although autosomal-recessive forms have been described. SHFM has been detected on prenatal ultrasonography, which can guide counseling and reconstructive efforts.

***Imaging.*** SHFM is highly variable in presentation. It can range from mild digital changes to the most severe monodactyly with only the fifth digit remaining. Two distinctive clinical forms have been described—typical and atypical forms. The typical form has an autosomal-dominant inheritance pattern and involves the lack of phalanges and metacarpals, resulting in a deep V-shaped cleft with the two halves resembling a lobster claw (Fig. 131.24). The much less frequent atypical form is sporadic and results in a much wider cleft, which forms a U-shaped central defect. The atypical form rarely involves the feet. Vascular disruption has been implicated as the cause. In most forms the digits frequently curve in toward the cleft, and a reduction in the number of digits may occur. Syndactyly or synostosis often is present.

***Treatment and Follow-up.*** Patients affected by SHFM usually have good functional use of their extremities and therefore surgical intervention usually is not indicated.

## Congenital Radial Head Dislocation

***Etiology.*** Congenital radial head dislocation is the most commonly identified congenital abnormality of the elbow. More than half of cases are associated with other conditions, such as anomalies of the lower extremities, scoliosis, and various syndromes (e.g., Klippel-Feil).[37] Whether it is an isolated abnormality or is associated with other conditions, congenital radial head dislocation is believed to have an autosomal-dominant inheritance pattern. The deformity can be unilateral or bilateral.

***Imaging.*** Congenital radial head dislocation is associated with a small, underdeveloped forearm, a flattened and hypoplastic capitellum, and a short ulna. The proximal ulnar diaphysis often may have posterior apex bowing (Fig. 131.25). The radial head is dysplastic with an elongated, thinned, and convex articular surface instead of the normal concave shape. The radial head is most commonly dislocated posteriorly (see Fig. 131.25). The degree of radial head dysplasia is correlated with the severity of dislocation. Radiographs should be carefully evaluated for concomitant radioulnar synostosis (see Fig. 131.18).

***Treatment and Follow-up.*** Asymptomatic dislocations are not treated. If the child has pain, the radial head can be excised. However, excision of the radial head frequently is accompanied by pain from abnormal mechanics at the wrist. Recent work suggests that open reduction of the proximal radius at an early age may be beneficial.

## Tibial Bowing Deformities

***Etiology.*** Posteromedial congenital bowing affects the tibia, fibula, and soft tissues of the lower extremity. The origin and pathogenesis remain uncertain and may be related to abnormal early embryologic development rather than to abnormal fetal

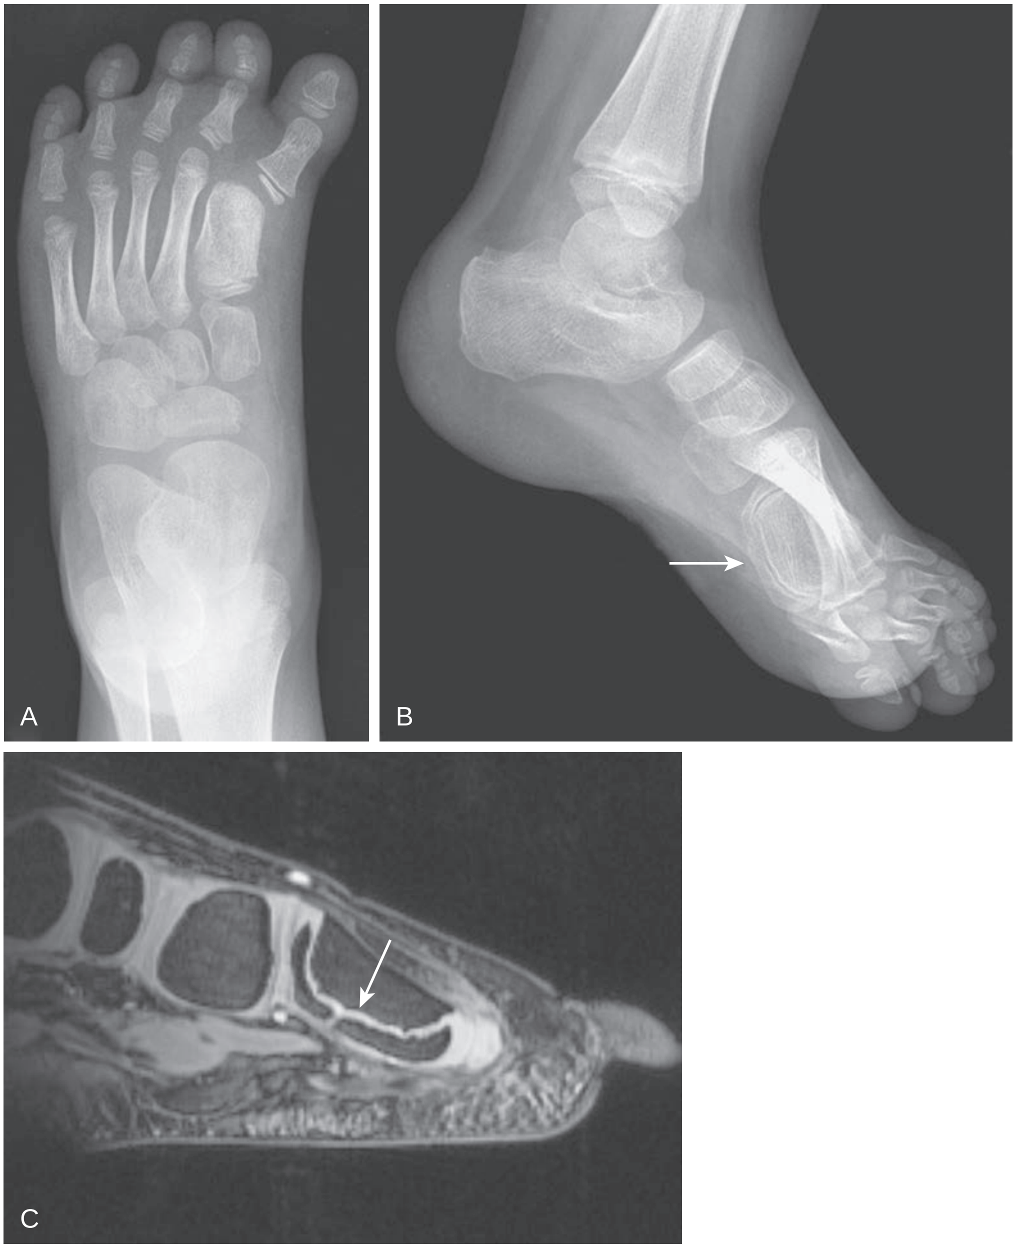

**Figure 131.23. Longitudinal epiphyseal bracket.** (A) Frontal radiograph of the foot of a 4-year-old girl. The first metatarsal is short and widened and has a shorter medial than lateral length, forming a trapezoidal shape. (B) Lateral radiograph of the same child shows the C-shaped epiphysis and physis of the first metatarsal *(arrow)*. (C) Sagittal gradient echo MR image shows a high-signal intensity C-shaped physis *(arrow)* and adjacent epiphysis.

positioning or intrauterine fracture. Fetal vascular insufficiency or compressive events associated with amnion rupture may be responsible.[38] As the child grows, tibial bowing and shortening often partially resolve.

Posteromedial congenital bowing should be differentiated from congenital tibial dysplasia (CTD). Other terms for CTD include anterolateral tibia bowing or congenital pseudoarthrosis of the tibia. It is a rare anomaly but does occur in a small number of patients with neurofibromatosis type 1 (NF1). Approximately 20% to 50% of patients with CTD do not have NF1.[39]

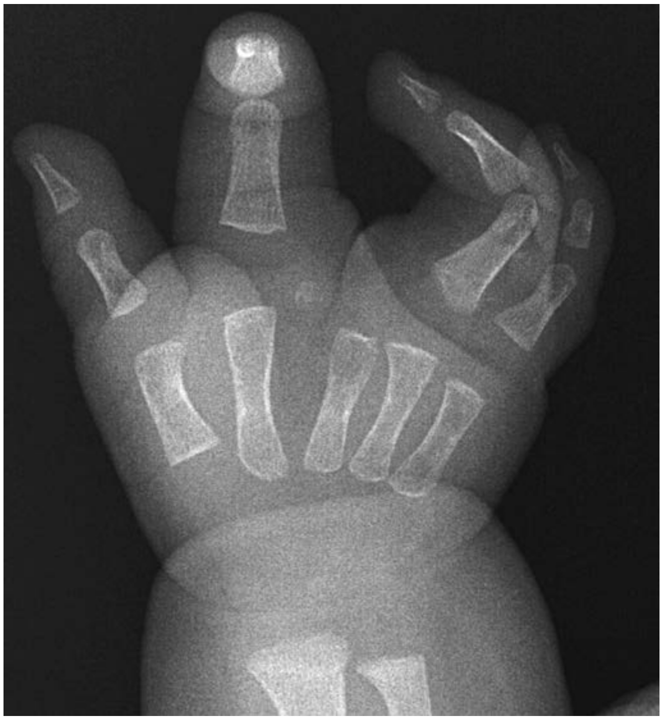

**Figure 131.24. Split hand-foot malformation in a 6-month-old boy.** The child has near complete absence of the long digit.

CTD presents as anterolateral bowing or fracture of the tibia, often before other manifestations of NF1 present. Lack of involvement of the fibula suggests that the bowing will resolve spontaneously. Pathologic studies show abnormal, highly cellular fibrovascular tissue with variable amounts of fibrocartilage and hyaline cartilage within the tibia. Bone growth and repair are abnormal. The pattern of abnormal fibrous tissue results in the dysplastic or cystic changes characteristic of the disorder.

***Imaging.*** With posteromedial congenital bowing, the tibia and the fibula show marked posteromedial bowing at the middle or distal one-third (Fig. 131.26). Rarely is the bowing lateral. At birth, the foot is held in a calcaneovalgus (dorsiflexed) position.

Radiographic changes seen with CTD are variable and include anterolateral bowing of the tibia, fracture, pseudarthrosis, hourglass-like constriction of the midshaft of the tibia, cystic changes usually at the junction of the upper and middle thirds of the tibia, sclerosis that narrows the medullary canal, and, infrequently, involvement of the fibula alone (Fig. 131.27).

***Treatment and Follow-up.*** Treatment for posteromedial congenital bowing of the tibia is conservative; corrective casts or splints may be used to hold the foot and support the leg during growth and remodeling. If a severe persistent deformity continues beyond toddler age, a leg length discrepancy, usually on the order of 3 to 7 cm, may result that requires osteotomies and lengthening procedures. Occasionally, epiphysiodesis of the contralateral side may be needed.

In persons who have anterolateral bowing associated with NF1, fracture and refracture rates are very high. Limb length inequality is frequent and results from disuse atrophy and abnormal growth at the distal tibial physis. Often a valgus deformity is noted at the ankle. Surgical management can be frustrating because nonunion or pseudarthrosis after osteotomy is frequent.

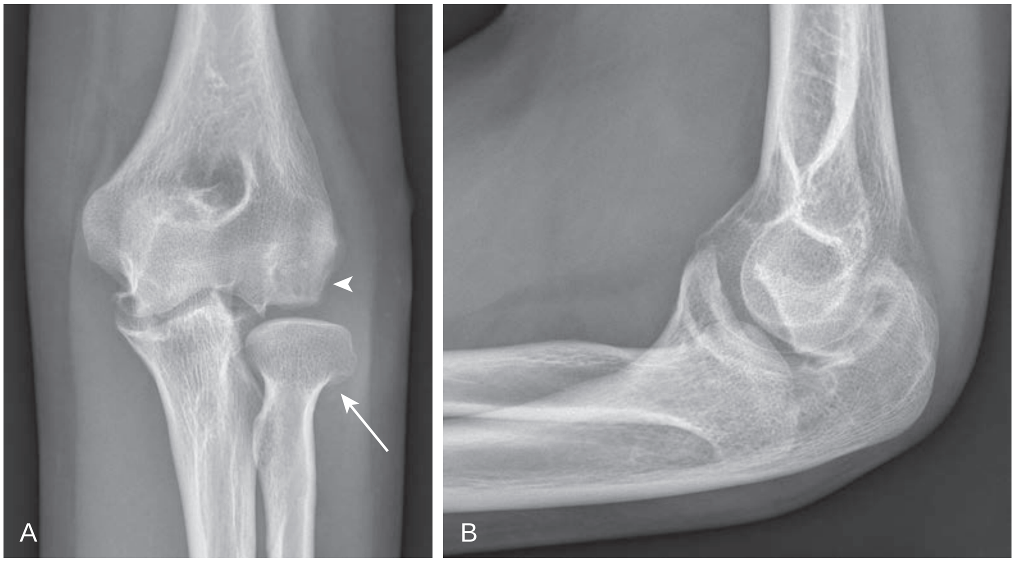

**Figure 131.25. Congenital radial head dislocation in a 12-year-old girl.** Anteroposterior (A) and lateral (B) radiographs show a dysplastic convex-shaped radial head *(arrow)* with posterior dislocation as well as posterior bowing of the proximal ulnar diaphysis. Note the presence of a capitellar osteochondral lesion *(arrowhead)* and medial compartmental osteoarthritis, which likely is related to abnormal elbow biomechanics.

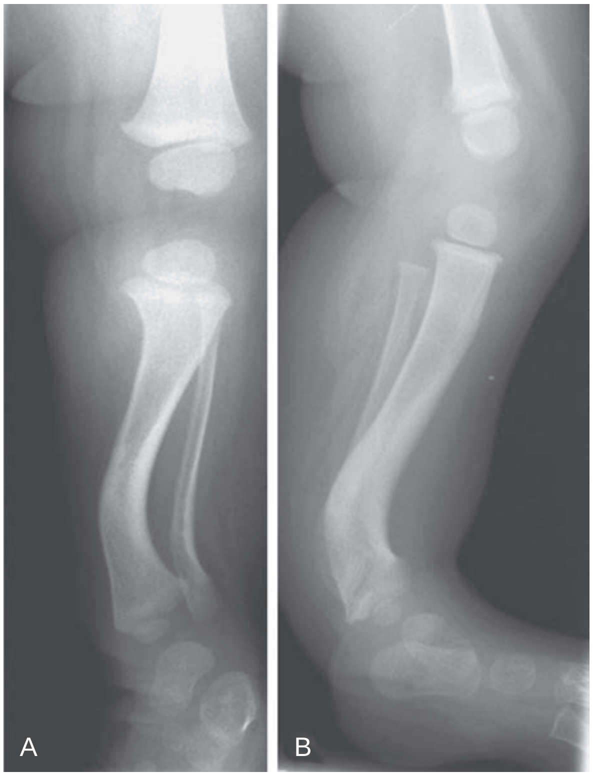

**Figure 131.26. Congenital posteromedial bowing in a 1-year-old girl.** (A) On the frontal radiograph, medial bowing is seen at the junction of the middle and distal one-third of the tibia. The fibula is similarly bowed. (B) The posterior component of the bowing is seen on the lateral radiograph.

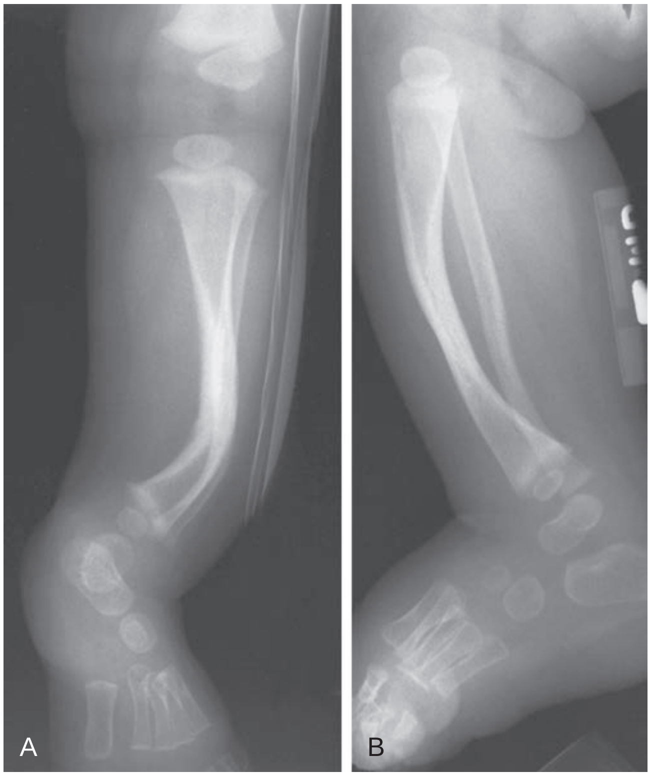

**Figure 131.27. Congenital tibial dysplasia and neurofibromatosis type 1.** Anteroposterior (A) and lateral (B) radiographs show anterolateral tibial bowing. The medullary canal is nearly obliterated, but no fracture is apparent.

## KEY POINTS

- For PFFD, the femoral head and acetabular deformities are related; the more dysmorphic the femoral head, the more severe the acetabular deformity.
- Fibular hemimelia often has coexisting deformities at the level of the knee and foot.
- The most commonly affected facet in subtalar coalitions is the middle facet.
- A complete ossific bar forms a synostosis, a cartilaginous bar forms a synchondrosis, and a fibrous union is termed a *syndesmosis*.
- Congenital radial head dislocation is associated with a convex radial head, whereas traumatic radial head dislocation shows the normal radial articular surface convexity.

# 132 Skeletal Dysplasias and Selected Chromosomal Disorders

Jerry Dwek and Ralph S. Lachman

As opposed to just a decade ago, the study of congenital syndromes is no longer an exercise in the rote memorization of seemingly disconnected syndromes. Instead, the unveiling of the intricacies of the genetic code has made apparent relationships among many inborn syndromes that had been previously unsuspected. What has emerged is that a relatively few genes are the cause of a multitude of syndromes, and by grouping syndromes and dysplasias into families based on the gene at fault, a taxonomy has emerged and has allowed a framework within which we can understand the relationships among a number of dysplasias and syndromes.

An abridged form of the International Skeletal Dysplasia Society skeletal dysplasia classification serves as the organization of this chapter (Box 132.1).[1] The full nosology text can be found at http://isds.ch/uploads/pdf_files/Nosology2010.pdf (accessed December 12, 2016). The major genetic families are presented with a short description of the salient unifying characteristics of the diseases within each group. When known, the gene and protein involved are considered and the impact of the mechanism of action discussed. The major members of each group are then expanded on to provide a clear picture for the reader.

In this chapter, the terms *syndrome* and *dysplasia* are used somewhat loosely. A syndrome is a set of characteristic findings that occur together and suggest a particular diagnosis, although the cause may not be known. A dysplasia is a set of characteristic findings in which the cause and effect are known. The distinction now has lost its value, as the cause of many "syndromes" are now known, and the term *dysplasia* is used to indicate not just purely a grouping of symptoms but the actual disease entity.

## RADIOLOGIC ASSESSMENT

In the history of the delineation of many of the specific skeletal dysplasias, radiologic assessment plays a major role. By using an orderly approach to the radiographic analysis, the general type of the dysplasia may be elucidated. Many of the skeletal dysplasias and syndromes have distinctive radiographic features that will allow an exact diagnosis when even one of those distinctive features is identified and used as a search criterion in textbooks on skeletal dysplasia. Two such texts are Taybi and Lachman's *Radiology of Syndromes, Metabolic Disorders and Skeletal Dysplasias*, which includes an excellent gamuts section, and *Bone Dysplasias, An Atlas of Genetic Disorders of Skeletal Development* by Spranger and colleagues, in which the images are particularly helpful.[2,3] In the online version of Taybi and Lachman's book, the gamut search may be built iteratively, with the diagnoses becoming more selective as findings are added to the search criteria. Internet searches can also be performed on the Online Mendelian Inheritance in Man database, which is accessed through the US Library of Medicine portal at http://www.ncbi.nlm.nih.gov/pubmed/.

### Step I: Assessment of Disproportion

*Micromelia* is overall shortening of the extremities. *Rhizomelia* is relative shortening of the femurs and humeri. *Mesomelia* is relative shortening of the radii, ulnae, tibiae, and fibulae. *Acromelia* is relative shortening of the bones of hands and feet.

Classification of the shortened appendicular segment is helpful for diagnosis. Rhizomelia may be very helpful to confirm the specific diagnosis of the rhizomelic form of chondrodysplasia punctata. Very significant mesomelia suggests a group of specific disorders loosely classified as the mesomelic dysplasias. Acromelia is found in many disorders; when it occurs by itself, several specific dysplasias are suggested, including acrodysostosis, acromicric dysplasia, or pseudohypoparathyroidism.

The pattern of brachydactyly may facilitate diagnosis. For instance, brachydactyly type E manifests with variable shortening of the metacarpals and distal phalanges, and brachydactyly type A4 manifests with shortening restricted to the second and fifth middle phalanges. Even the absence of acromelia may be helpful. The lack of significant hand and foot shortening is a significant feature of spondyloepiphyseal dysplasia congenita (SEDC), a type 2 collagenopathy.

### Step II: Assessment of Epiphyseal Ossification

If epiphyseal ossification is delayed or if the ossified epiphyses are very small, irregular for age, or both, then an epiphyseal dysplasia of some sort is present. Carpal and tarsal bones are often affected. In diseases that can be considered pure epiphyseal dysplasias such as multiple epiphyseal dysplasia (MED) and pseudoachondroplasia, carpal and the tarsal bones are markedly crenellated and small (Fig. 132.1). Another excellent location for epiphyseal analysis is the ring apophyses of the vertebral bodies, which exhibit delayed and irregular epiphyseal ossification in epiphyseal dysplasia. Central anterior vertebral body protrusions (central tongues or beaking) noted in Morquio syndrome and pseudoachondroplasia are also disorders related to abnormalities of the ring apophyses.

### Step III: Assessment of Metaphyses and Physes

Fraying and irregularity of the physes and abnormal flaring of the metaphyses indicate disturbed endochondral ossification. Marked irregularity of the physes is characteristic of the pure metaphyseal dysplasias such as metaphyseal dysplasia, Jansen or Schmid type. When the metaphyses are merely flared and the physes are fairly normal, endochondral ossification may be slowed, but the actual process of endochondral ossification progresses normally. This occurs in achondroplasia. The metaphyses are flared, whereas the physis and the zone of provisional calcification (ZPC) are sharply defined (Fig. 132.2).

Rickets also disturbs the physis. In rickets, physeal abnormalities lead to the classic appearance of metaphyseal cupping and fraying. Except in healing rickets, the ZPC is inapparent. In metaphyseal chondrodysplasias, the ZPC is present, although it is markedly irregular (Fig. 132.3). Analysis of the sclerotic line of the ZPC is frequently an excellent differentiating feature. Other factors include prominent osteopenia in rickets with blurring of the trabeculae; clinical data are also very helpful.

### Step IV: Assessment of the Diaphyses

Diaphyseal abnormalities primarily include bent bones and thickened sclerotic bones. The classic bent bone dysplasia is

## Abstract:

Contained in this chapter is an updated guide to skeletal dysplasias and select chromosomal disorders. Included are descriptions of some of the more prominent and common syndromes as well as some of the more obscure syndromes. While some of these latter syndromes are indeed rare, the recent advances in molecular genetics makes these rarities important for a deeper understanding of how these syndromes occur and how they manifest themselves. By understanding the interlacing of molecular genetics and radiologic phenotypes, these rare syndromes are no longer isolated in the great mélange of unconnected disease states. Instead they become real and more comprehensible disease states and indeed are made more interesting. In order to run we must first learn to walk and to that end the chapter begins with a stepwise methodology that may be used when a skeletal dysplasia is analyzed. This is probably the most important part of this chapter upon which the rest of the chapter is built. The remainder of the chapter uses an abridged version of the official Nosology and Classification of genetic skeletal disorders as a way to organize the findings and for ease of reading.

**MESOMELIC DYSPLASIA GROUP**

- Dyschondrosteosis

**BENT BONE DYSPLASIA GROUP**

- Campomelic dysplasia

**CHONDRODYSPLASIA PUNCTATA GROUP**

- Rhizomelic type

**INCREASED BONE DENSITY GROUP (WITHOUT MODIFICATION OF BONE SHAPE)**

- Osteopetrosis
- Pyknodysostosis
- Osteopoikilosis
- Osteopathia striata
- Melorheostosis

**INCREASED BONE DENSITY GROUP WITH METAPHYSEAL AND/OR DIAPHYSEAL INVOLVEMENT**

- Craniodiaphyseal dysplasia
- Craniometaphyseal dysplasia
- Pyle disease

**OSTEOGENESIS IMPERFECTA AND DECREASED BONE DENSITY GROUP**

- Osteogenesis imperfecta

**ABNORMAL MINERALIZATION GROUP**

- Hypophosphatasia

**LYSOSOMAL STORAGE DISEASES**

- Hunter syndrome or Hurler syndrome
- Morquio syndrome
- Mucolipidosis type II (I-cell disease)

**OSTEOLYSIS GROUP**

- Hajdu-Cheney dysplasia

**OVERGROWTH SYNDROMES WITH SKELETAL INVOLVEMENT**

- Marfan syndrome
- Congenital contractural arachnodactyly
- Proteus syndrome

**CLEIDOCRANIAL DYSPLASIA AND ISOLATED CRANIAL OSSIFICATION DEFECTS GROUP**

- Cleidocranial dysplasia

**DYSOSTOSES WITH PREDOMINANT VERTEBRAL INVOLVEMENT**

- Currarino triad

**BRACHYDACTYLIES**

- Rubinstein-Taybi syndrome
- Poland anomaly

**LIMB HYPOPLASIA REDUCTION DEFECTS GROUP**

- Brachydactyly A-E
- Brachmann-De Lange syndrome
- Holt-Oram syndrome

**MISCELLANEOUS ASSOCIATIONS, SYNDROMES AND CHROMOSOMAL DISORDERS**

- *VATER/VACTERL*
- Klinefelter syndrome
- Trisomy 13
- Trisomy 18
- Trisomy 21
- Turner Syndrome (chromosome X monosomy)

*VACTERL,* Vertebral, anorectal, cardiac, tracheoesophageal, renal, limb.

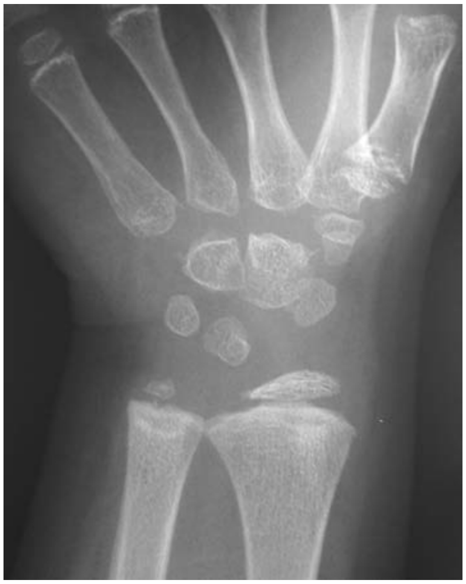

**Figure 132.1. Multiple epiphyseal dysplasia in an 8-year-old boy.** Note the small and crenellated carpal bones.

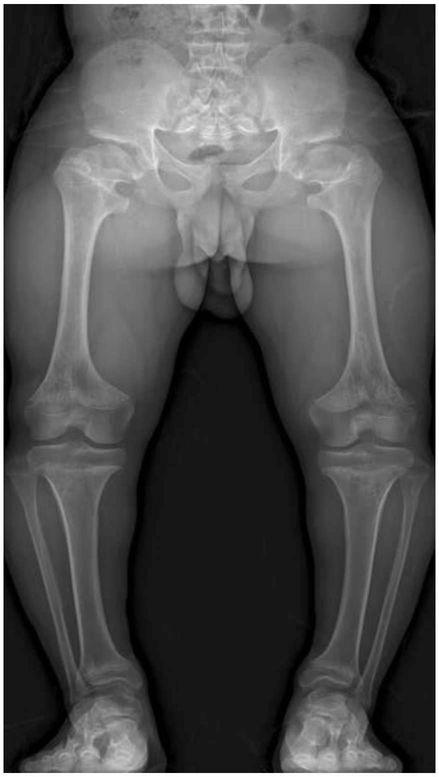

**Figure 132.2. Achondroplasia in a 14-year-old boy.** The long bones are short and thick. Note the normal, sharp-appearing physes.

campomelic dysplasia. Others include hypophosphatasia and kyphomelic dysplasia. Thickened and sclerotic diaphyseal cortices may indicate one of the craniotubular dysplasias.

## Step V: Analysis of the Vertebral Bodies

Decreased height of the vertebral bodies is termed *platyspondyly*. The lumbar vertebral bodies are the best level to analyze compared with the cervical level, especially in infancy. The cervical vertebral bodies tend to appear relatively hypoplastic compared with other levels in the normal infant. This is because ossification occurs later in cervical vertebral bodies compared with vertebral bodies elsewhere. In addition to platyspondyly, other vertebral body changes are important. In the lumbar spine in normal children, the interpediculate distance usually widens on a frontal film moving inferiorly. Inferior narrowing of the interpediculate distance is a feature of fibroblast growth factor receptor 3 (FGFR3) abnormalities such achondroplasia and thanatophoria.

Anisospondyly is when the vertebral body shape varies wildly (e-Fig. 132.4). Multiple ossification centers may also be present. Although rare, this is a specific finding in dyssegmental dysplasia.

## Step VI: Assessment of Bone Mineralization

Bone mineral density should be assessed by not only examining the actual “whiteness” of bones but also by determining the relative thickness of the cortices relative to the medullary cavity and the coarseness of the trabeculae. Osteopenia, especially when severe, indicates defective bone mineralization, as seen in rickets, hypophosphatasia, and osteogenesis imperfecta (OI). Abnormally dense bones may indicate one of the craniotubular disorders such as pyknodysostosis and osteopetrosis. In the neonate, bones are normally sclerotic and the medullary cavity narrowed. Distinguishing abnormally dense bones from normal neonatal sclerosis can be difficult.

## Step VII: Assessment of Joints

Multiple joint dislocations are a salient and persistent feature of some dysplasias. A standard skeletal survey frequently includes only frontal views of the skeleton, which may make it difficult to identify joint dislocations, especially in the infant. The elbow is frequently involved in the setting of dislocations secondary to a dysplasia. Dedicated lateral views are recommended when dislocation is clinically suspected.

## Step VIII: Summation

After all radiologic findings have been established, a gamut search of some or all of these abnormalities, in conjunction with the clinical findings, may lead to the specific diagnosis. If the “group” of dysplasias has been established, then the specific diagnosis can often be made by referring to a differential diagnosis table such as that developed by Taybi and Lachman.[2]

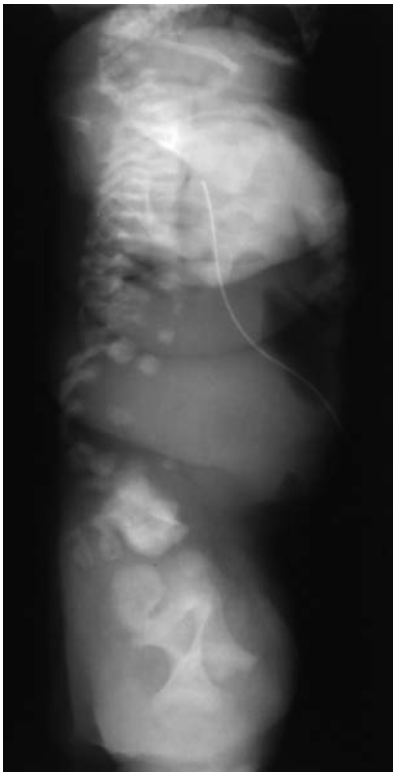
# SELECTED SKELETAL DYSPLASIAS AND SYNDROMES

## Fibroblast Growth Factor Receptor Type 3 Group

***Overview.*** This group includes thanatophoric dwarfism and achondroplasia. The former is probably the most common lethal skeletal dysplasia and the latter the most common skeletal dysplasia. The group includes the milder variant called *hypochondroplasia*, and homozygous achondroplasia, which is similar to thanatophoria.[4]

A common genetic locus *(4p16.3)* is involved. Differing allelic mutations are the cause of the variable severity of expression. The protein encoded is FGFR3, which governs the velocity of endochondral growth. Although long believed that achondroplasia and thanatophoria were caused by loss of function mutations, the mutation in this group actually results in an upmodulation of FGFR3 activity, which is inversely related to the velocity of endochondral growth.[5]

There are common radiologic features in this group. FGFR3 slows endochondral bone growth, so long bones are short. However, it does not affect overall bone thickness because of normal



**e-Figure 132.4. Dyssegmental dysplasia in a newborn.** The vertebral bodies vary markedly in size and shape typical of anisospondyly.

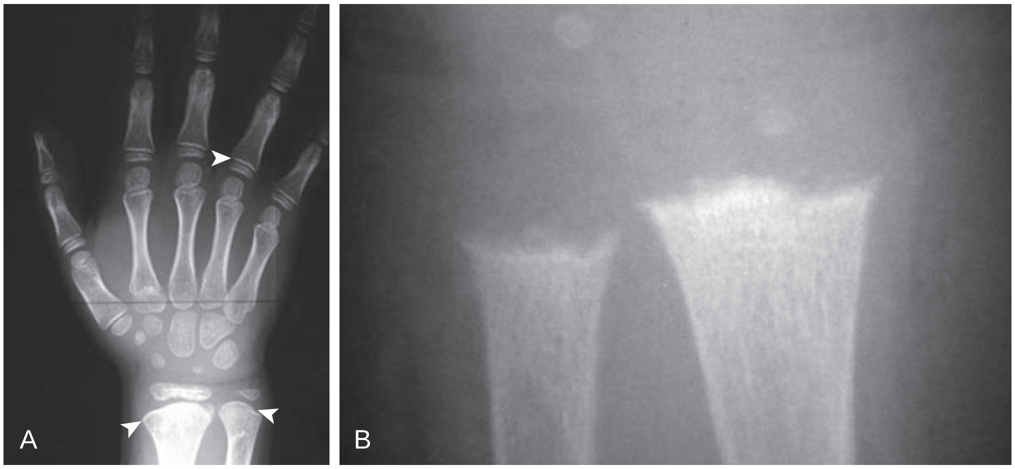


**Figure 132.3. Schmid metaphyseal chondrodysplasia in an 8-year-old boy.** (A) Note the presence of zone of provisional calcification *(arrowheads)*. Normal laboratory values help confirm the diagnosis. (B) Compare this to a 15-month-old girl with rickets. The physes are frayed with mild metaphyseal cupping. The bright white line of the zone of provisional calcification is not evident.

membranous ossification. Therefore long bones are relatively thick. The fibula is usually longer than the tibia. Femoral necks are short and broadened and have a peculiar scooped-out appearance. It is seen as an ovoid lucency of femoral necks, as if an ice cream scoop was radiographed en face. The finding can be seen in all forms of thanatophoria. It is well seen in achondroplasia but not in most forms of hypochondroplasia.

In the normal individual, on a frontal radiograph, the horizontal distance between the pedicles of the vertebral bodies should widen moving inferiorly. FGFR3 group abnormalities exhibit narrowing in the interpediculate distance in the lumber spine. The decrease in the velocity of endochondral ossification also causes platyspondyly. Brachydactyly of all the bones of the hand is present. Because soft tissues are relatively unaffected, fingers are splayed into the "trident configuration."

## Common Features in FGFR3 Group

- Platyspondyly
- Narrow sacrosciatic notch
- Interpediculate narrowing
- Short, thick long bones
- Ovoid lucency at femoral necks (scooped out appearance)
- Frontal bossing
- Trident hands
- Fibula longer than tibia

## Thanatophoric Dwarfism

Given the lethality of this dysplasia, it is aptly named after Thanatos, the Greek god of death (*Thanatophoria*, meaning "death loving").

Type 1 includes "cloverleaf skull," caused by in utero craniosynostosis, and curved long bones. The femurs have a "French telephone receiver" appearance. The type 2 variant has straight long bones and no craniosynostosis.

Platyspondyly is severe. The vertebral bodies are described as U-shaped or H-shaped on an anteroposterior projection.

***Radiographic Findings*** (Fig. 132.5)

1. *Skull:* proportionately large skull in relation to the body, narrow skull base, cloverleaf skull (type 1 only)
2. *Thorax:* long, narrow trunk; very short ribs; handlebar clavicles
3. *Spine:* severely flattened, small vertebral bodies with round anterior ends
4. *Pelvis:* small, flared iliac bones; very narrow sacrosciatic notches; flat, dysplastic acetabula
5. *Extremities:* generalized micromelia; ovoid lucency of femoral necks, round proximal femoral metaphyses with medial spike, curved long bones (type 1 only)

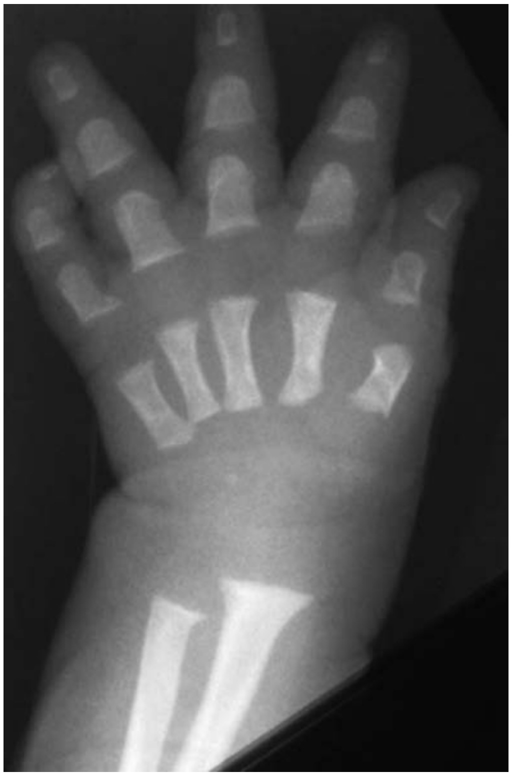
## Achondroplasia

Patients with achondroplasia have normal mentation and a normal or near normal lifespan. As in other members of the FGFR3 family, long bones are short and thick. Interpediculate narrowing is present. In infancy, femoral necks have a scooped out appearance. Since the sacrosciatic notches are narrowed, the pelvic inlet has an appearance of a wide-mouthed champagne glass.

Except for the portions of the occipital bone that form the margin of the foramen magnum, all the bones of the skull are formed by membranous ossification.[6] This results in an enlarged forehead and is termed *frontal bossing*. In contrast, the foramen magnum is narrowed and can cause cervicomedullary compression.

***Radiologic Findings*** (Fig. 132.6 and e-Fig. 132.7)

1. *Skull:* enlarged, with significant midface hypoplasia; hydrocephalus rarely present; small skull base with tight foramen magnum
2. *Thorax:* small; shortened and anteriorly splayed ribs
3. *Spine:* short pedicles with decreased interpediculate distance most marked in the lumbar spine moving downward; posterior vertebral body scalloping, gibbus deformity
4. *Pelvis:* round iliac wings with lack of flaring (elephant ear–shaped), flattened acetabular roofs, narrow sacrosciatic notches with champagne glass shaped pelvic inlet
5. *Extremities:* rhizomelic micromelia
6. *Hands:* brachydactyly with trident hands
7. *Knees:* central deep notch in growth plates (Chevron deformity)
8. *Hips:* proximal femoral ovoid lucency (infancy); hemispheric capital femoral epiphyses, short femoral necks
9. *Legs:* prominent tibial tubercle apophyseal region, fibula overgrowth
10. *Arms:* Cortical hyperostosis at deltoid insertion on anterolateral humerus



**e-Figure 132.7. Achondroplasia in a 1 year old.** Brachydactyly and trident appearance of the hand is apparent.

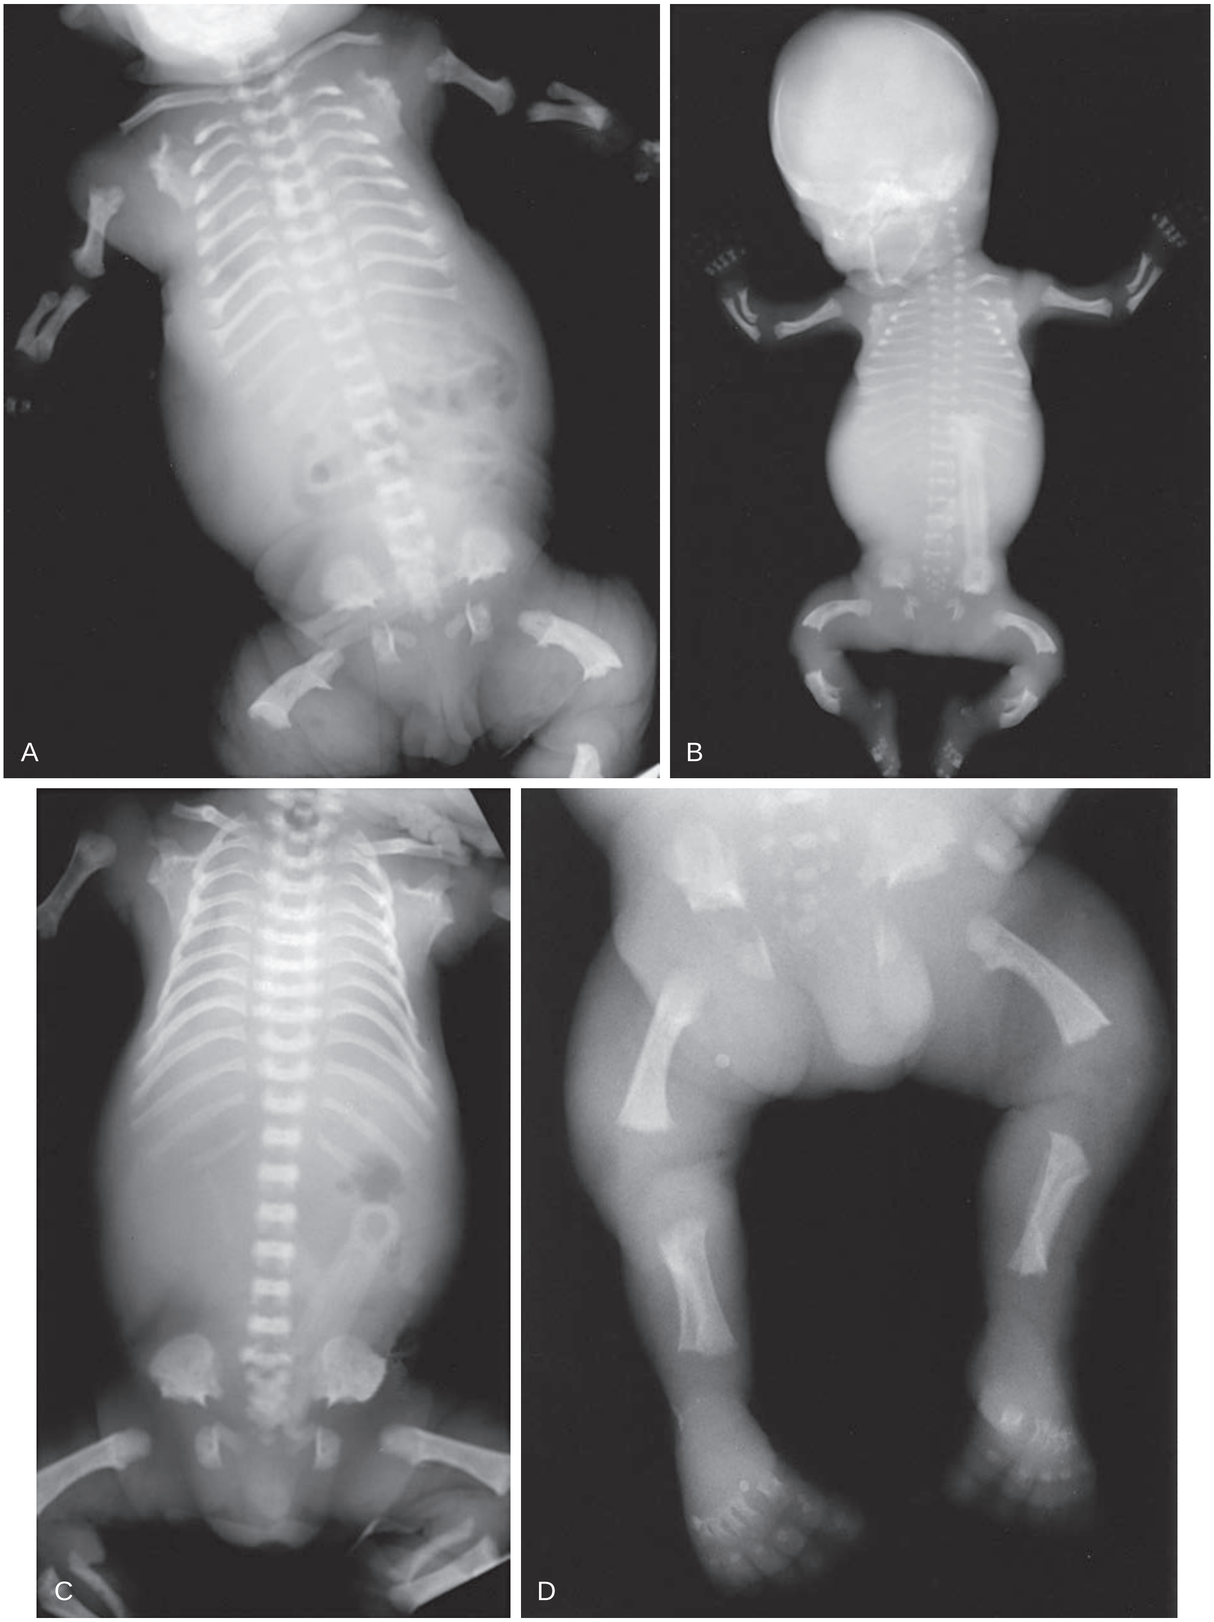


**Figure 132.5. Thanatophoric dysplasia.** (A and B) Radiographic findings in thanatophoric dysplasia type I. In an affected fetus of 30 weeks' gestation (A), a long, narrow trunk; very short ribs; severe platyspondyly are seen. Note the H and U shapes of the vertebral bodies are caused by angle of incidence of the x-ray beam; small, flared iliac wings; narrowed sacrosciatic notches; dysplastic (trident) acetabular roofs; and French telephone receiver–shaped femurs. At 22 weeks' gestation in another affected fetus (B), a proportionally large skull, micromelia, and other findings similar to those in (A) are seen. (C and D) Radiologic findings in thanatophoric dysplasia type II. An affected preterm fetus (C) exhibits findings similar to those in type I except for taller vertebral bodies and straighter femurs. Another affected fetus (D) also shows the same findings as in type I but with straighter femurs.

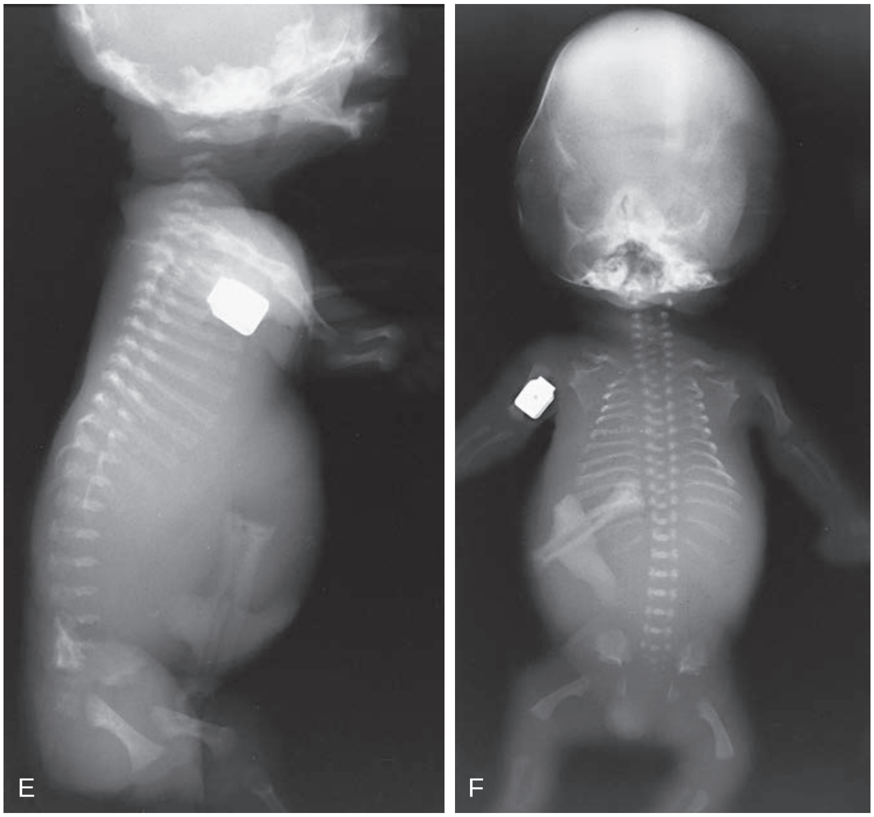

**Figure 132.5, cont'd.** (E) Radiograph of affected infant with severe platyspondyly, anteriorly rounded vertebrae, straight femurs, and severely constricted skull base. (F) Cloverleaf skull and almost straight femurs; otherwise, radiographic findings are similar to those in (C). Note the ovoid lucency at the femoral necks in all cases.

## Hypochondroplasia

In hypochondroplasia, radiographic and clinical findings are less severe compared with achondroplasia, and the diagnosis can be challenging. Stature is slightly shortened but is highly variable and may be normal given the range of normal stature in society. Radiographically, aside from shortening of the long bones, interpediculate narrowing is the most sensitive finding.[7]

## TYPE 2 COLLAGEN GROUP

***Overview.*** Type 2 collagen is present in cartilaginous epiphyses and in the vitreous humor.[8] Therefore abnormalities of collagen 2 manifest with platyspondyly due to lack of normal growth at the vertebral ring apophysis, a general delay in epiphyseal ossification, and myopia. Cleft palate completes the phenotypic picture.

## Common Features in Type 2 Collagenopathy Group

- Platyspondyly
- Delay in epiphyseal ossification most apparent in femoral heads
- Cleft palate
- Myopia
- Short stature
- Occipitoatlantal or atlantodental instability

## Spondyloepiphyseal Dysplasia Congenita

The combination of platyspondyly and short long bones make SEDC a good example of short-limbed, short-trunk dwarfism. It is also a good model for an epiphyseal dysplasia. Ossification in the vertebral bodies begins in the fetus at the lower thoracic spine and progresses superiorly and inferiorly. The cervical spine ossifies last. The normal cervical spine vertebrae at birth are slightly dorsally wedged and are small. In infants with SEDC, the cervical vertebral bodies show little or no ossification. Thoracic and lumbar bodies are, however, small, dorsally wedged, and anteriorly rounded (pear- or oval-shaped), similar in appearance to the cervical spine in the normal infant. In childhood, characteristic central beaks, typical of epiphyseal delay, may be seen. In the adult, vertebral bodies are flattened with irregular end plates.

At birth, no ossification of the talus, calcaneus, or the epiphyses at the knee is present. Normally, the talus and the calcaneus ossify at 20 to 24 weeks' gestation and the epiphyses at about 36 weeks' gestation.

One salient feature is that the hands and feet in patients with SEDC are normal, apart from carpal, midfoot, and hindfoot ossification delay.

***Radiologic Findings*** (Fig. 132.8)

1. *Thorax:* small; short ribs
2. *Spine:* dorsally wedged or oval vertebral bodies (at birth); anteriorly rounded platyspondyly (later)
3. *Pelvis:* absent pubic ossification (at birth and during infancy), vertical ischia with short ilia
4. *Extremities:* normal tubulization with mild micromelia, significant generalized ossification delay (early), and hypoplastic-appearing or dysplastic epiphyses (later), unossified talus or calcaneus in the newborn, normal hands and feet with ossification delay (epiphyses or carpal, tarsal)

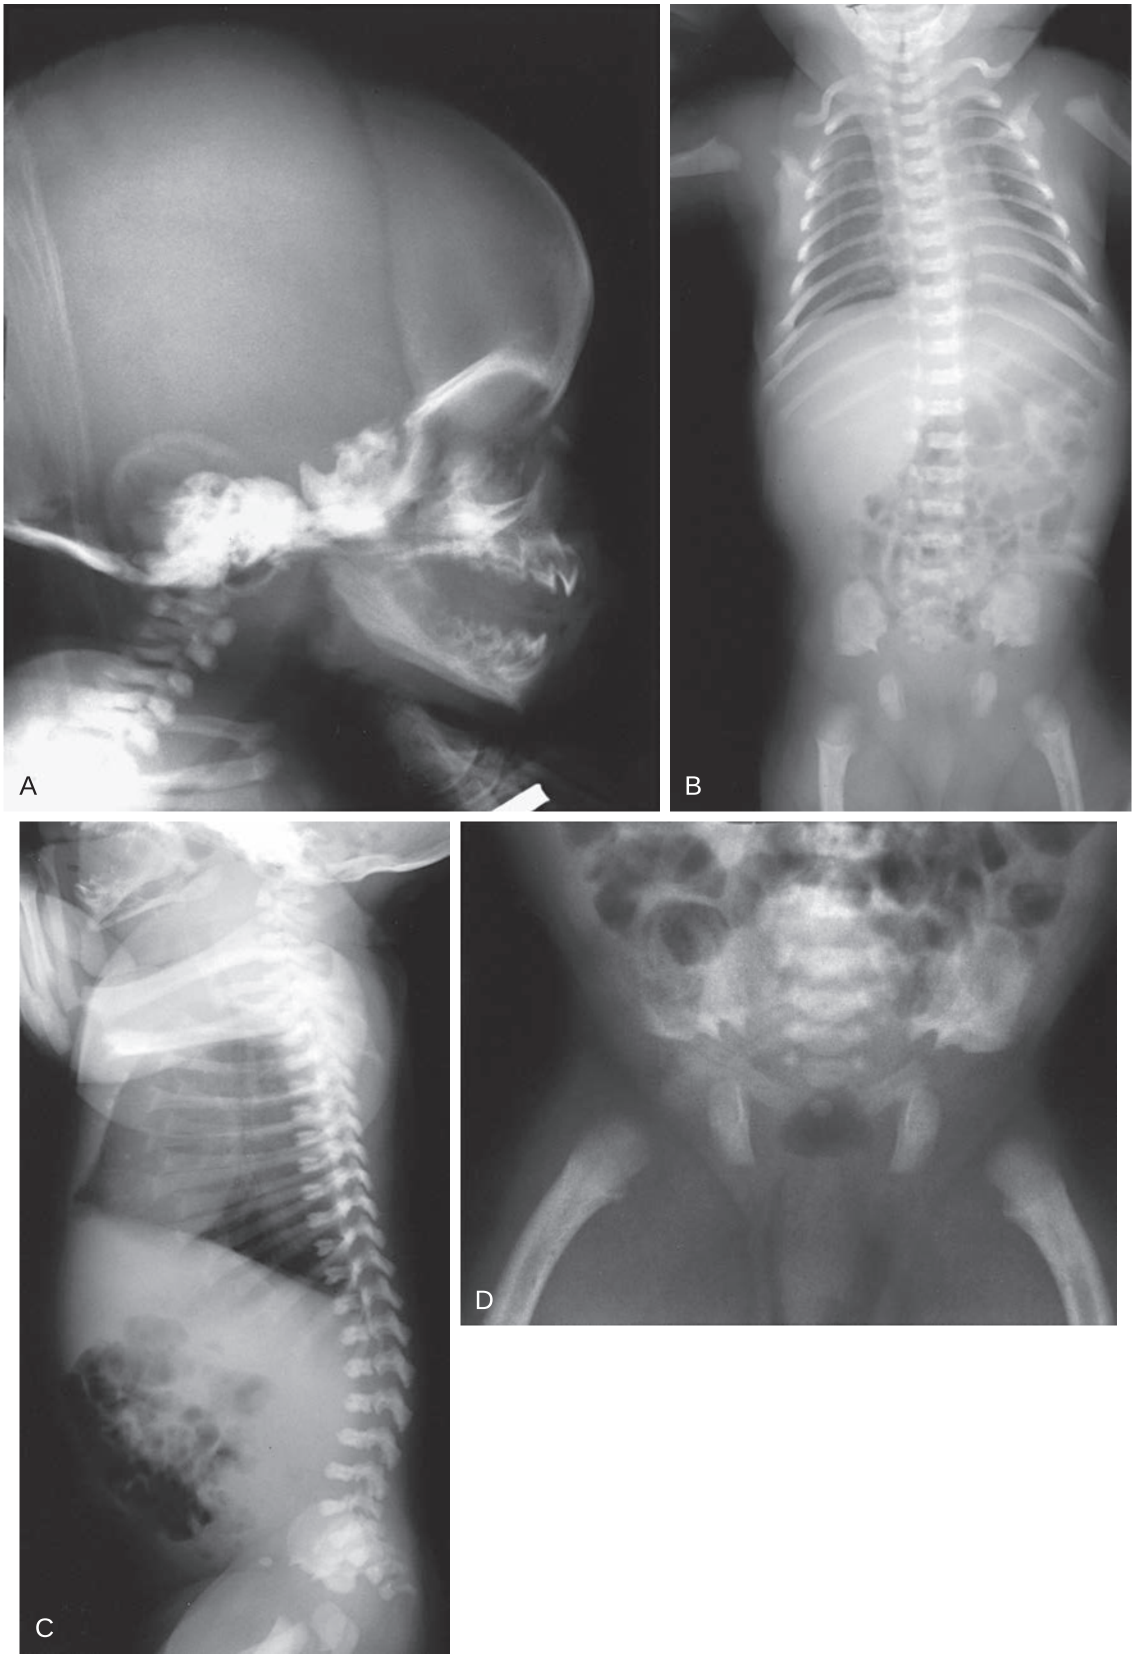

**Figure 132.6. Achondroplasia.** (A–D) Radiographs of an affected newborn. (A) Severe midface hypoplasia. (B) Thorax: small thorax and short ribs. (C) Thorax: short ribs with anterior scalloping and bullet-shaped vertebrae. (D) Pelvis: rounded ilia (elephant ear–shaped) iliac bones, narrow sacrosciatic notches, flat acetabular roof, and proximal femoral ovoid lucency.

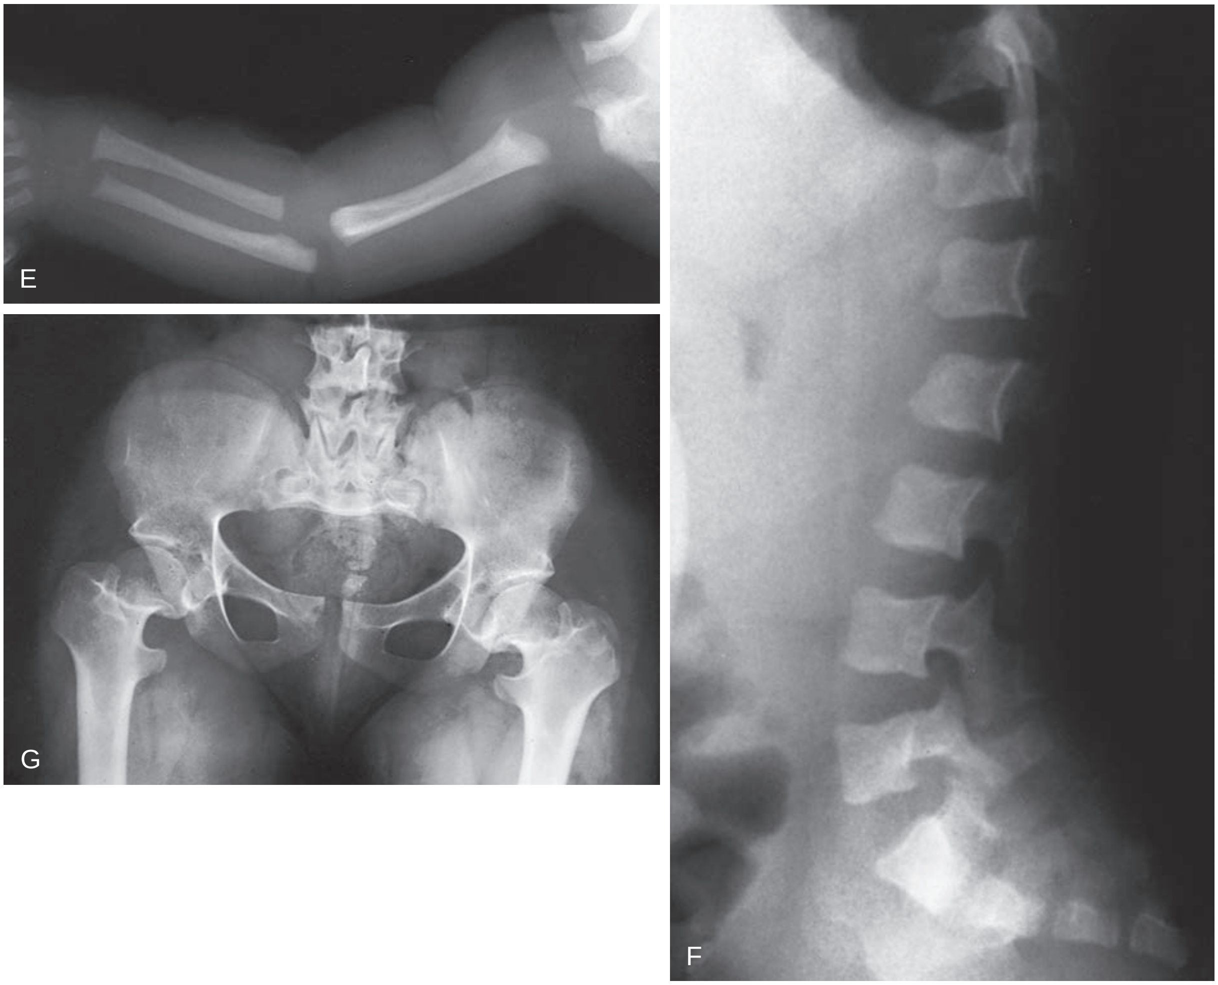

**Figure 132.6, cont'd.** (E) Extremities: rhizomelia and mesomelia. (F) Radiograph in an affected 1½ year old with classic vertebrae with short pedicles, posterior scalloping, and somewhat short vertebral bodies. (G) Radiograph in an affected woman with flat acetabular roofs, elephant ear–shaped iliac wings, and short femoral necks (compare with D). *(G, From Silverman FN. Achondroplasia.* Prog Pediatr Radiol. *1973;4:94–124.)*

## Kniest Dysplasia

The same delay in epiphyseal ossification is seen along with platyspondyly. Cloudlike dystrophic calcification is present in abnormally enlarged epiphyses as the child gets older. On magnetic resonance imaging (MRI), the areas of calcification have prolonged T2 values that are likely related to the degeneration of abnormal collagen matrix.[9]

***Radiologic Findings*** (e-Fig. 132.9)

1. *Thorax:* small to normal
2. *Spine:* coronal clefts (at birth and during infancy), platyspondyly with endplate irregularity (later)
3. *Extremities:* dumbbell femurs; generalized ossification delay, epiphyses becoming hypoplastic or dysplastic and then later even mega-epiphyses, cloudlike irregular calcification in physeal plate regions (in late childhood and early adulthood); hands with bulbous joints (metaphyseal flaring or epiphyseal fragmentation) mimicking rheumatoid arthritis

*Note:* In the newborn, Kniest syndrome is radiographically identical to SEDC except for coronal clefts and dumbbell femurs.

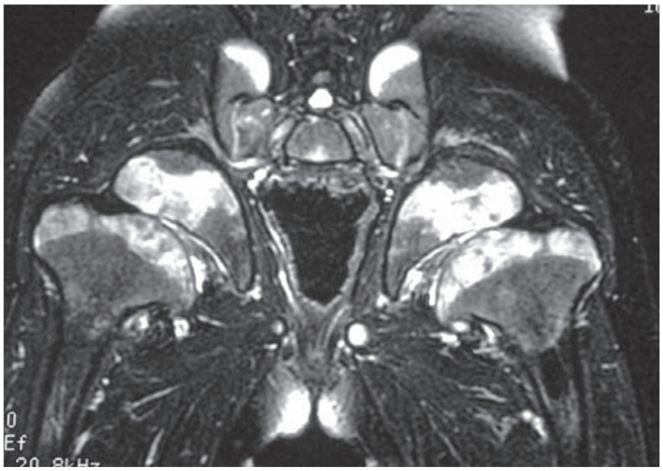
## TYPE 11 COLLAGENOPATHY GROUP

***Overview.*** Members of this group include Stickler syndrome type 2, Marshall syndrome, oto-spondylo-mega-epiphyseal dysplasia (OSMED), autosomal-dominant type (Weisenbach-Zweymuller phenotype and Stickler type 3).[10]

The multiple synonyms and names applied to the different members of the group cause some confusion. Stickler syndrome type 2 is a type 11 collagenopathy and has a similar appearance to Stickler syndrome type 1 (see type 2 collagenopathy previously discussed) with milder ocular changes and more severe auditory changes. It is autosomal recessive. Marshall syndrome is very similar to Stickler syndrome type 2 and may be considered, for all practical purposes, the same entity.

OSMED autosomal-dominant type is a type 11 collagenopathy as well. It is also called *nonocular Stickler syndrome*, *Stickler syndrome type 3*, *or Weisenbach-Zweymuller syndrome*. Osseous changes in OSMED are usually worse with greater shortening of the long bones and platyspondyly.

Adding to the confusion is a very similar form of Stickler syndrome, which is a type 9 collagenopathy. The similarity is not coincidental. Type 11 and type 2 collagens along with type 9 collagen form collagen fibrils so that the phenotypic expression of a type 2, type 11, or type 9 collagenopathy may be similar. This is an important point in the phenotypic expression of genetic abnormalities. Because the tissues of the body are constructed of multiple elements, differing genetic and biochemical abnormalities may have similar outcomes when considering the end results of the tissues produced.



**e-Figure 132.9. Kniest dysplasia in a 5-year-old girl.** Coronal fast-spin echo T2-weighted fat-saturated magnetic resonance (MR) image of the pelvis shows that the unossified epiphyseal cartilage manifests bizarre heterogeneity with lakes of bright signal intensity.

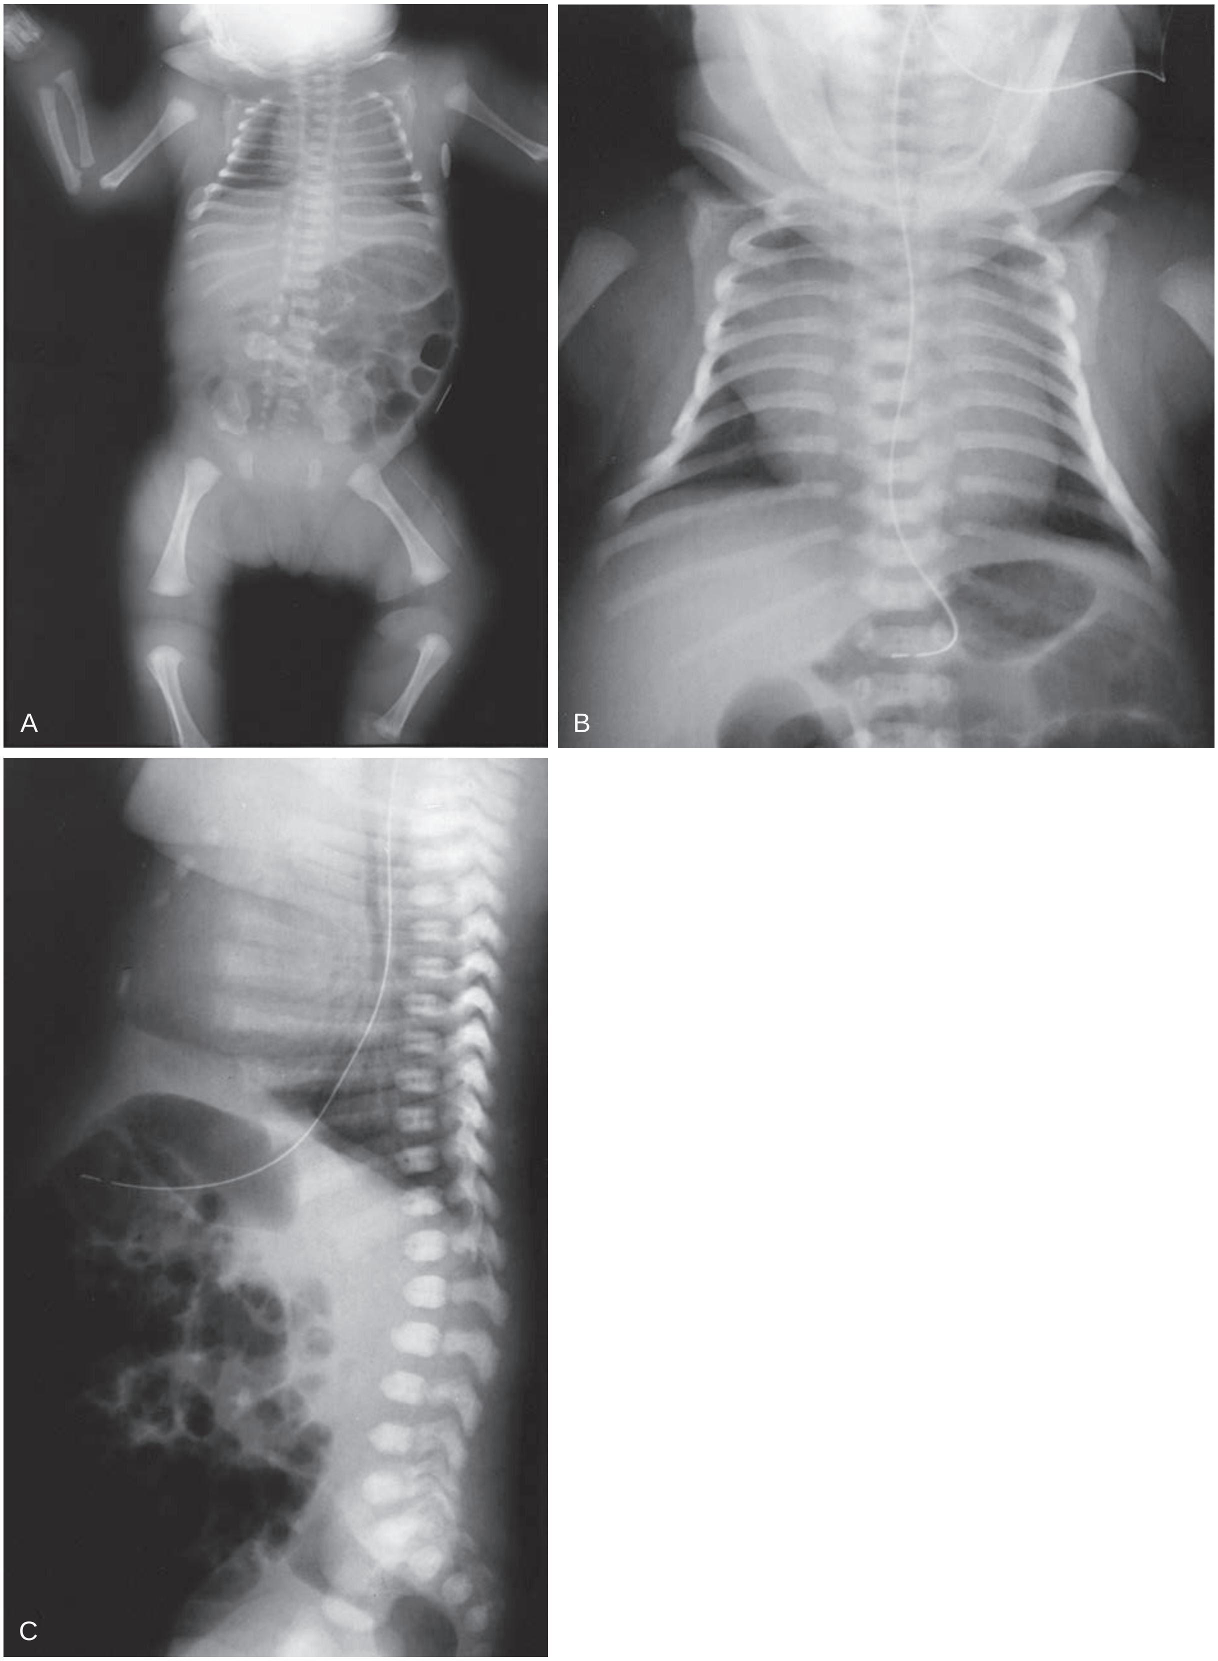


**Figure 132.8. Spondyloepiphyseal dysplasia congenita.** (A) Radiograph in an affected newborn with a small thorax, rounded iliac wings, vertical ischia, absence of pubic ossification, short femurs, and metaphyseal rounding of long bones. (B) Radiograph in an affected newborn with bell-shaped chest, short ribs, and elongated clavicles. (C) Radiograph in an affected newborn with moderately short ribs with mild anterior splaying and anteriorly rounded vertebral bodies with minimal flattening and no coronal clefts.

In practice, when faced with a case with a resemblance to a mild or intermediate severity type 2 or type 11 collagenopathy, both paths should be investigated.

### Common Features in Type 11 Collagenopathy Group

- Similar to type 2 collagenopathy
- Cleft palate
- Sensorineural hearing loss
- Myopia (except for Stickler type 3)
- Epiphyseal dysplasia (may be large or mildly flattened)
- Early arthritis
- Platyspondyly

## ABNORMAL SULFATION GROUP

The abnormal sulfation group is a molecularly defined group of disorders with a defect in the sulfate transporter gene on chromosome 5 coding for the diastrophic dysplasia sulfate transporter (DTDST) protein. This group comprises not only diastrophic dysplasia but also a form of MED as well as achondrogenesis type IB and atelosteogenesis type II.[11] These conditions are all autosomal recessive, and the severity of the phenotype is inversely related to the level of sulfation.[12,13]

### Common Features in Abnormal Sulfation Group

- Platyspondyly
- Scoliosis
- Proximally placed and short first metacarpal ("hitchhiker thumb")
- Clubfoot
- Short, thick long bones

### Diastrophic Dysplasia

Diastrophic dysplasia, like all the other disorders of this group, is an autosomal-recessive condition. It is commonly identifiable at birth and usually nonlethal.

***Radiologic Findings*** (Fig. 132.10)

1. *Head:* ear pinna calcification, cleft or high arched palate
2. *Thorax:* moderately small
3. *Spine:* progressive scoliosis, kyphosis, upper cervical subluxation (odontoid hypoplasia), cervical kyphosis, posterior process clefting (cervical and sacral)
4. *Extremities:* often micromelia; short, thick tubular bones; generalized brachydactyly; short ovoid first metacarpal delta phalanx causing proximal placement of thumb (hitchhiker thumb), twisted metatarsals, accessory and irregular carpal bones; epiphyseal dysplasia with multiple joint contractures
5. *Other sites:* precocious costochondral and laryngeal area cartilage calcification; multiple sternal and patella centers

### Multiple Epiphyseal Dysplasia: Multilayered Patellae/Brachydactyly/Clubfeet

In some cases of MED, *DTDST* gene abnormalities exist. Radiographs reveal MED changes, but patients also exhibit mildly short or normal stature, clubfeet, and additional deformities due to the *DTDST* gene abnormality.

***Radiologic Findings.*** Extremities show the following: epiphyseal dysplasia, especially at the hips; double-layered or multilayered patella (visible on lateral knee radiograph); mild brachydactyly; clubfeet or twisted metatarsals; and mildly shortened long bones, some with mild undertubulation.

## FILAMIN GROUP

The filamin group combines a wide group of dysplasias that have in common an abnormality in the number and configuration of carpal, tarsal, and vertebral bones with joint dislocations. The identification of the group is another triumph in the study of molecular genetics, as it reclassifies correctly a group of disorders described as "syndromes" within a common framework of genetically determined diseases no different from other skeletal dysplasias.[14,15] The group includes oto-palato-digital (OPD) syndrome types 1 and 2, Larsen syndrome, frontometaphyseal dysplasia, Melnick-Needles osteodysplasty, and spondylo-carpal-tarsal synostosis.

### Common Features in the Filamin Group

- Sensorineural hearing loss
- Carpal and digital anomalies
- Joint dislocation
- Skull thickening

### Oto-Palatal-Digital Syndrome

OPD syndrome causes hearing loss, cleft palate, and deformity of the digits, especially the first digit. Hearing loss is caused by malformation of the auditory ossicles. Multiple carpal bone abnormalities, including accessory carpal bones and carpal bone fusion, are present. The capitate may be malformed, with its long axis in the transverse plane. The trapezoid is commonly fused to the base of the second metacarpal, although the finding may not manifest until skeletal ossification nears maturity in late adolescence. The distal phalanx of the thumb is short and wide. The same deformity is present in the foot, where the hallux is short. Prominence of the frontal and occipital bones is present, with a prominent supraorbital ridge. In the more severe type 2 variety, rib shortening is marked. The radial head is usually dislocated.

***Radiographic Findings in OPD*** (e-Fig. 132.11)

1. *Head:* prominent supraorbital ridge
2. *Spine:* small pedicles with wide interpediculate distance
3. *Extremities:* accessory carpal bones, double ossification center of lunate, fusion of carpal bones especially trapezoid and scaphoid, fusion of the second metacarpal to trapezoid in adolescence, similar findings in feet; short first metatarsal and phalanges of great toe, and short and wide distal phalanx of thumb; radial head dislocation

### Larsen Syndrome

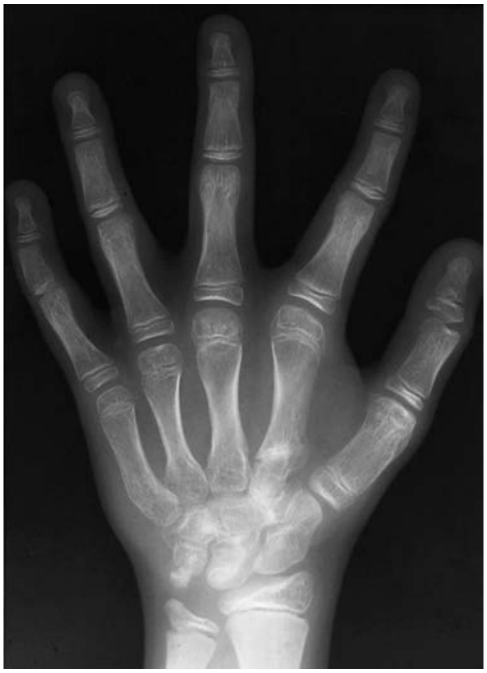
In Larsen syndrome, multiple joint dislocations are present. In keeping with the common theme of filamin abnormalities, supernumerary carpal bones are common along with other digital changes. A doubled calcaneal ossification center is a helpful clue to accurate diagnosis. Scoliosis is common.

***Radiographic Findings*** (Fig. 132.12 and e-Fig. 132.13)

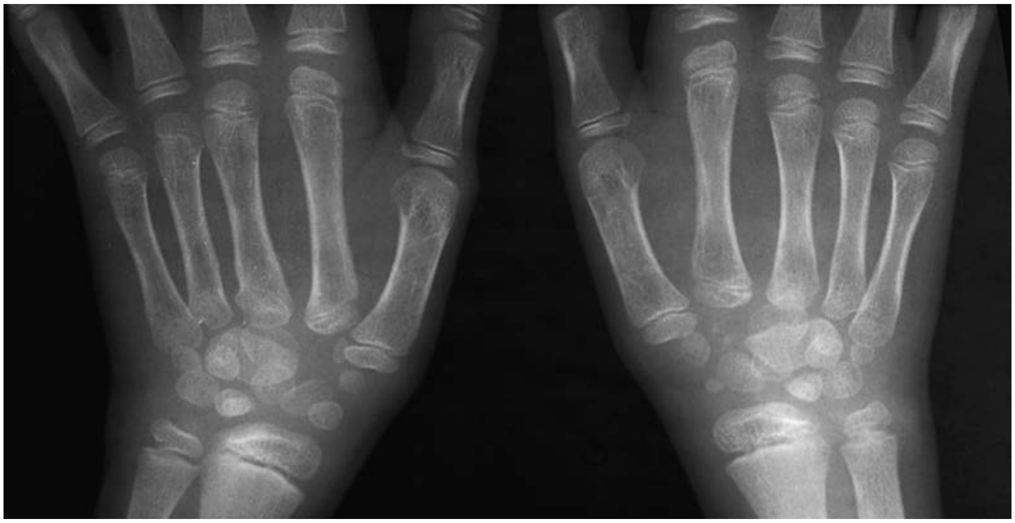
1. *Spine:* cervical spine kyphosis
2. *Extremities:* multiple joint dislocations, double or triple calcaneal ossification center, accessory carpal bones, broad irregular metacarpals

## TRPV4 GROUP

TRPV4 (transient receptor potential cation channel, subfamily 5, member 4) is a calcium permeable nonselective cation channel that appears to play an important role in chondrogenesis. This channelopathy is also the cause of several other nonskeletal syndromes such as Charcot Marie-Tooth disease, scapula-peroneal



**e-Figure 132.11. Oto-palato-digital syndrome.** Frontal radiograph shows fusion of the second metacarpal with the adjacent deformed carpal bones. Widening and abnormal tubulation of the metacarpals are seen. The distal phalanx of the thumb is short with a coned-shaped epiphysis. Clinodactyly is present.



**e-Figure 132.13. Larsen syndrome in an 8-year-old girl.** Posteroanterior radiograph of the wrists shows multiple extra carpal bones with deformity of the second metacarpal heads. An accessory ossification center is seen at the base of the second metacarpal.

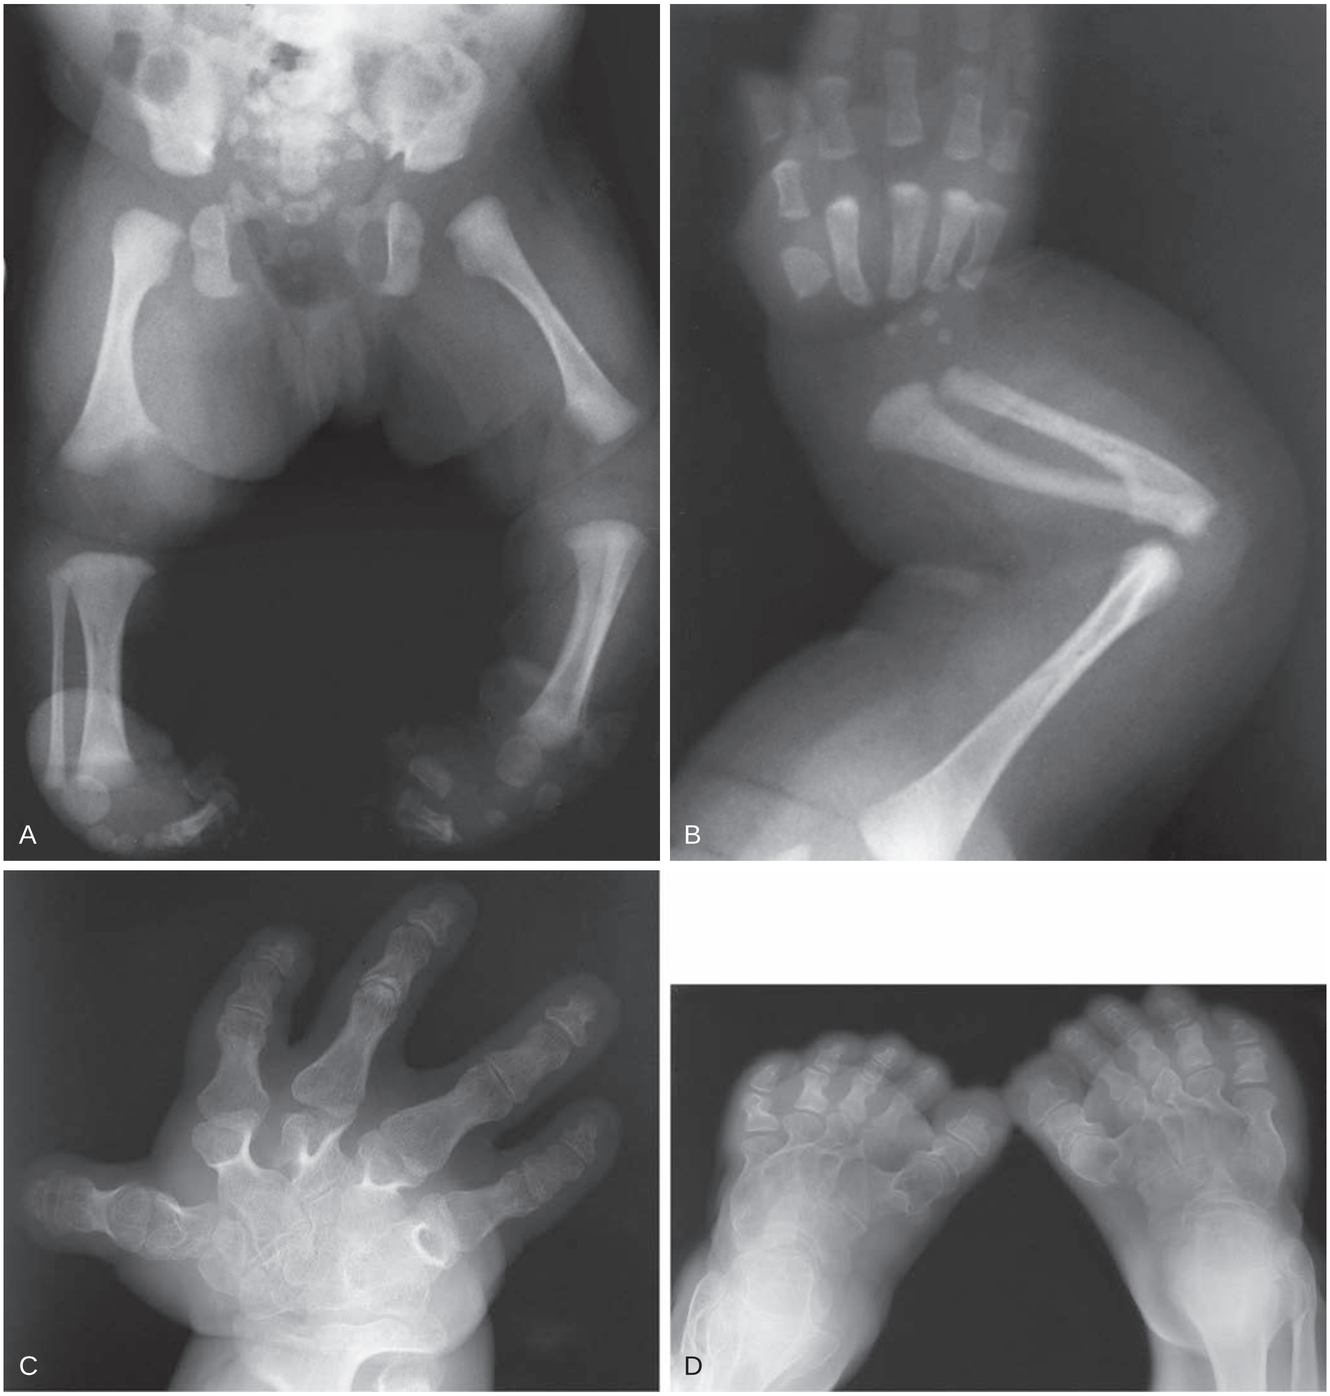


**Figure 132.10. Diastrophic dysplasia.** (A and B) Radiographs from an affected newborn. (A) Lower extremities: rhizomelia and mesomelia and severe clubfeet deformities. (B) Upper extremity: elbow dislocation and short, ovoid first metacarpal. (C and D) Radiographs from an affected 21 year old. (C) Upper extremity: hitchhiker thumb, ovoid first metacarpal, brachydactyly, and irregular and extra carpal bones. (D) Lower extremities: unusual clubfoot and twisted metatarsals.

spinal muscular atrophy, and congenital distal spinal muscular atrophy.[16,17]

The key to this group is the appearance of the vertebral bodies on a frontal view. Because of a relatively wide but flat vertebral body, the pedicles appear "overfaced." This means that the pedicle outline projects completely within the contour of the vertebral body instead of at the margin of the body overlying the superior end plate. The appearance has been also described as an "open staircase." Additionally, the major members of the group—metatropic dysplasia, brachyolmia (autosomal-dominant type), and spondylometaphyseal dysplasia (SMD) Koslowski type—also manifest delay in carpal bone ossification. Although brachyolmia primarily affects the vertebral bodies, subtle metaphyseal changes are seen as they are in metatropic dysplasia and SMD Koslowski type. It may be very difficult to differentiate between metatropic dysplasia and SMD Koslowski type.

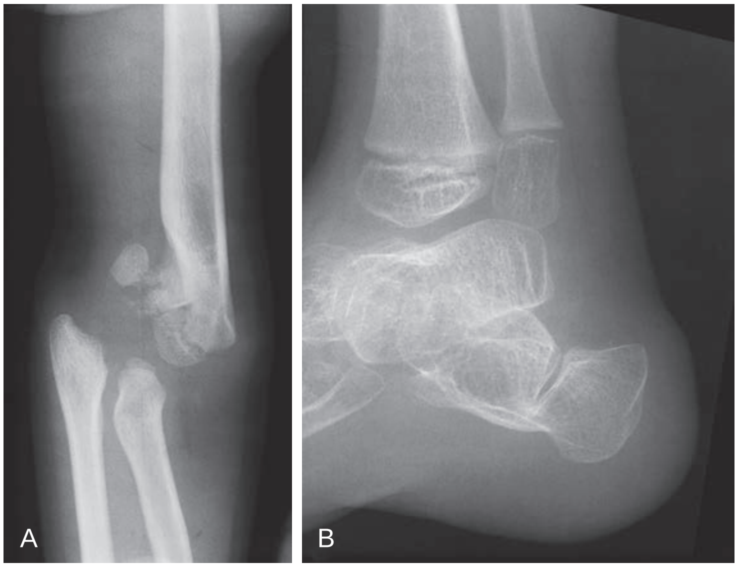

**Figure 132.12. Larsen syndrome in a 5-year-old girl.** (A) Anteroposterior elbow radiograph shows chronic dislocation with epiphyseal deformities. (B) Lateral radiograph of an ankle in a 5-year-old boy shows a bifid calcaneus and deformity of the talus and distal tibial epiphysis.

## Common Features in the TRPV4 Group

- Platyspondyly with overfaced pedicles
- Carpal ossification delay
- Metaphyseal or physeal irregularity

## Metatropic Dysplasia

Metatropic dysplasia, or metatropic dwarfism, is evident in the newborn with a relatively long trunk and markedly shortened limbs. This "changing" dysplasia over time produces a short-trunk or short-limb form of dwarfism. Although heterogeneous, most cases are nonlethal and are autosomal dominant.

***Radiologic Findings*** (Fig. 132.14)

1. *Thorax:* small; short ribs
2. *Spine:* dense wafer vertebral bodies (newborns), reconstituted platyspondyly (children and adults), scoliosis (adults)
3. *Pelvis and hips:* short, squared iliac wings; flat, irregular acetabular roof; narrow sacrosciatic notches; widening of proximal femoral metaphyses with a pronounced medial aspect about lesser trochanter (halberd [hunting ax]–shaped proximal femurs)
4. *Extremities:* flared metaphyses (trumpet shaped), with epiphyseal dysplasia and shortening (dumbbell shape).

## Spondylometaphyseal Dysplasia Koslowski Type

Characteristic radiographic findings (e-Fig. 132.15) include severe platyspondyly with overfaced pedicles. The extremities show sclerosis, flaring, and irregularity at the metaphyses. Carpal bone ossification is delayed and may not be apparent until age 5 to 6 years.

## SHORT RIB DYSPLASIAS

The short rib dysplasias with or without polydactyly (short rib–polydactyly [SRP]) group of disorders is a diverse group, linked only radiologically by extreme rib shortening.

Some members of this group are now known to be ciliopathies. Including several types of SRP and types of asphyxiating thoracic dysplasia (ATD).[18] ATD are caused by mutations in genes encoding for normal dynein heavy chains or other aspects of the ciliogenesis. It is interesting to note that situs abnormalities are a feature of these dysplasias attesting to the important role cilial transport plays in body situs.

## Short Rib–Polydactyly Dysplasia

SRP dysplasia is a subgroup of disorders that are typed largely on radiographic grounds. Types I and III are quite similar, as are types II and IV. The role of the pediatric radiologist is to make the diagnosis of this subgroup as separate from ATD and chondroectodermal dysplasia. To that end, it is important to note the SRP dysplasias have the shortest ribs of any of the skeletal dysplasias.

***Radiologic Findings*** (Fig. 132.16)

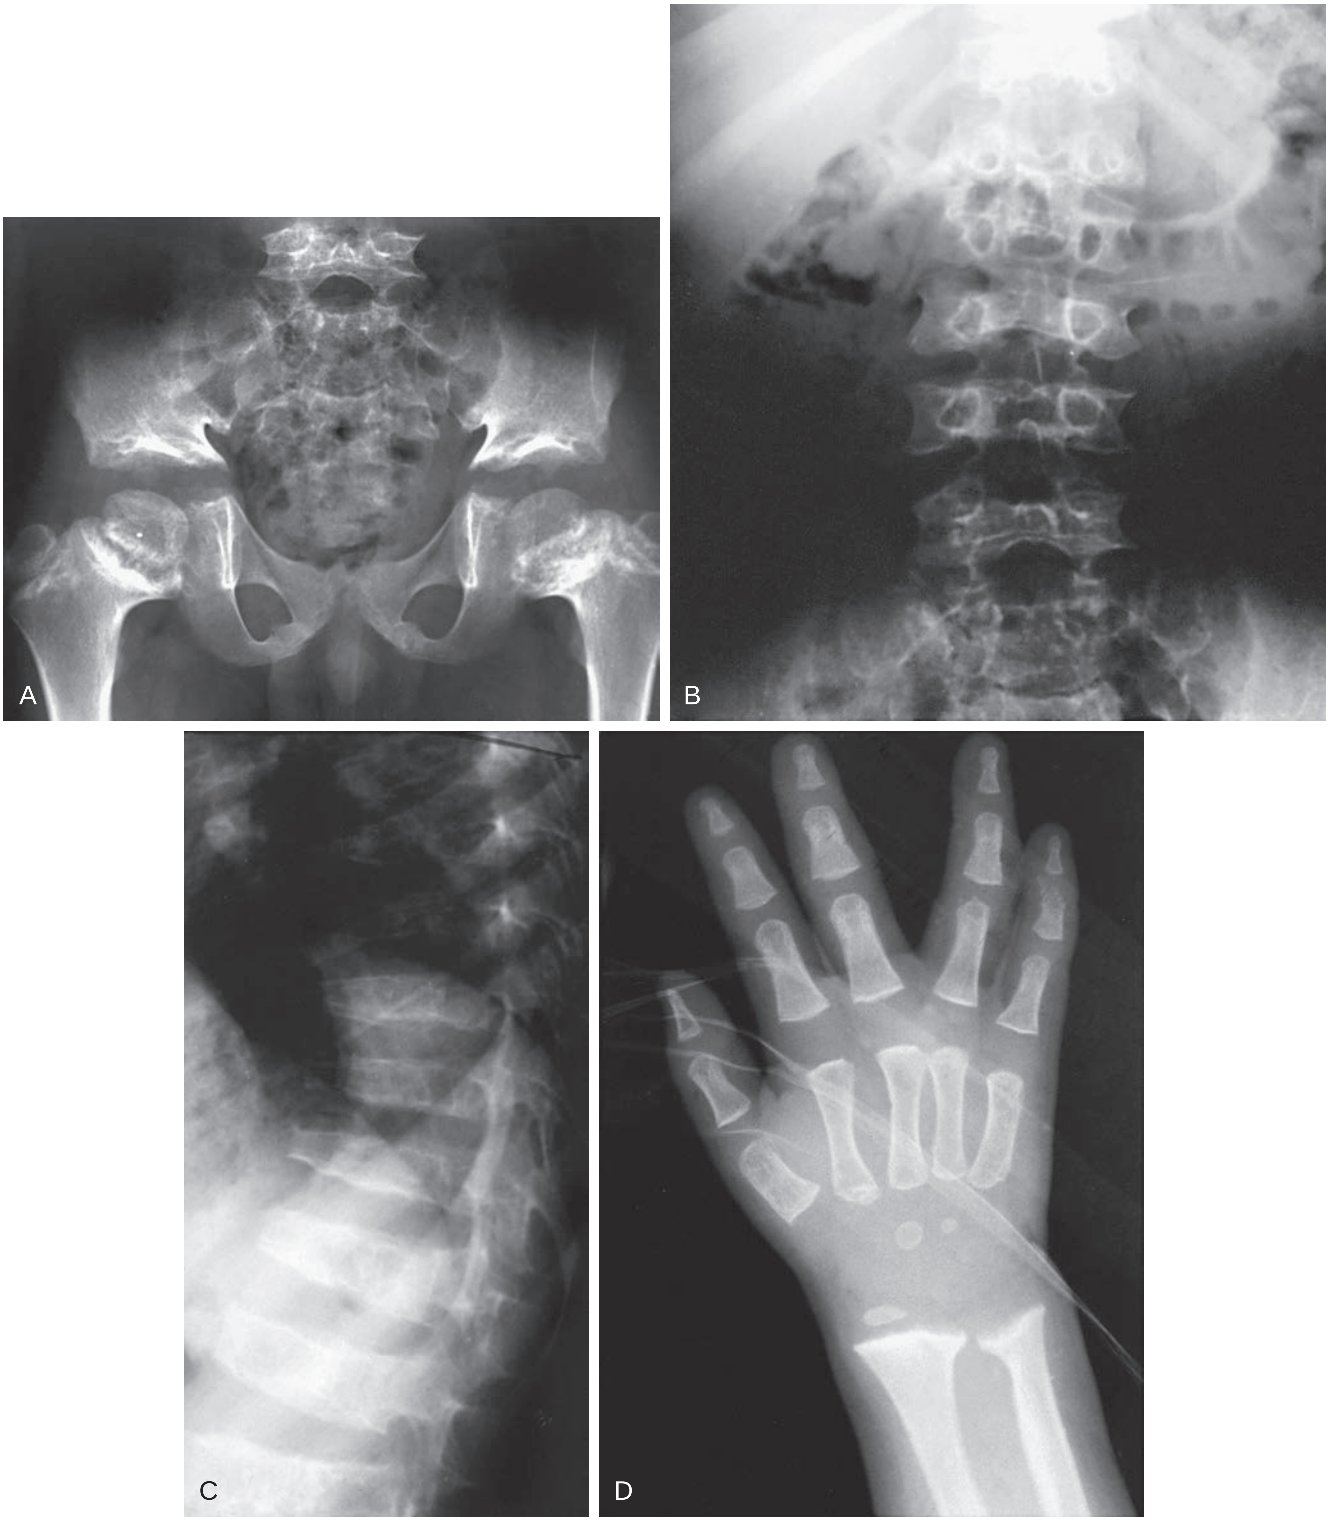
1. *Thorax:* small; very short horizontal ribs
2. *Spine:* relatively normally shaped
3. *Pelvis:* small, dysplastic ilia
4. *Extremities:* micromelia; medial and lateral spurs at metaphyses; ovoid or tiny, normal-shaped tibias; severe brachydactyly with hypoplastic middle and distal phalanges; polydactyly commonly present

## Asphyxiating Thoracic Dysplasia (Jeune Syndrome)

ATD is a genetically heterogeneous disorder with a mixed prognosis. Many affected patients die in the perinatal period from respiratory complications related to a small chest. Survivors may die from renal complications (progressive nephropathy) later in life. Sometimes, postaxial polydactyly is present. Definite radiographic (but not clinical) similarities to chondroectodermal dysplasia are evident. Some cases are so alike radiologically that they are best termed *ATD/Ellis–van Creveld syndrome complex*.

***Radiologic Findings*** (Fig. 132.17)

1. *Thorax:* long and barrel-shaped, handlebar clavicles, short horizontal ribs with bulbous anterior ends



**e-Figure 132.15. Kozlowski-type spondylometaphyseal dysplasia.** (A–C) Radiographs from an affected 8 year old. (A) Pelvis: narrow sacrosciatic notches, ossification defect (acetabular roofs), and widened epiphyseal plates. (B and C) Spine: overfaced vertebral bodies ("open staircase," or closely set pedicles) and flattened, irregular vertebral bodies (platyspondyly). (D) An affected 2 year old with metaphyseal widening and irregularity at the wrist and short tubular bones of the hands, with almost no carpal bone ossification. Note the similarities in proximal femurs to metatropic dysplasia (see Fig. 132.14).

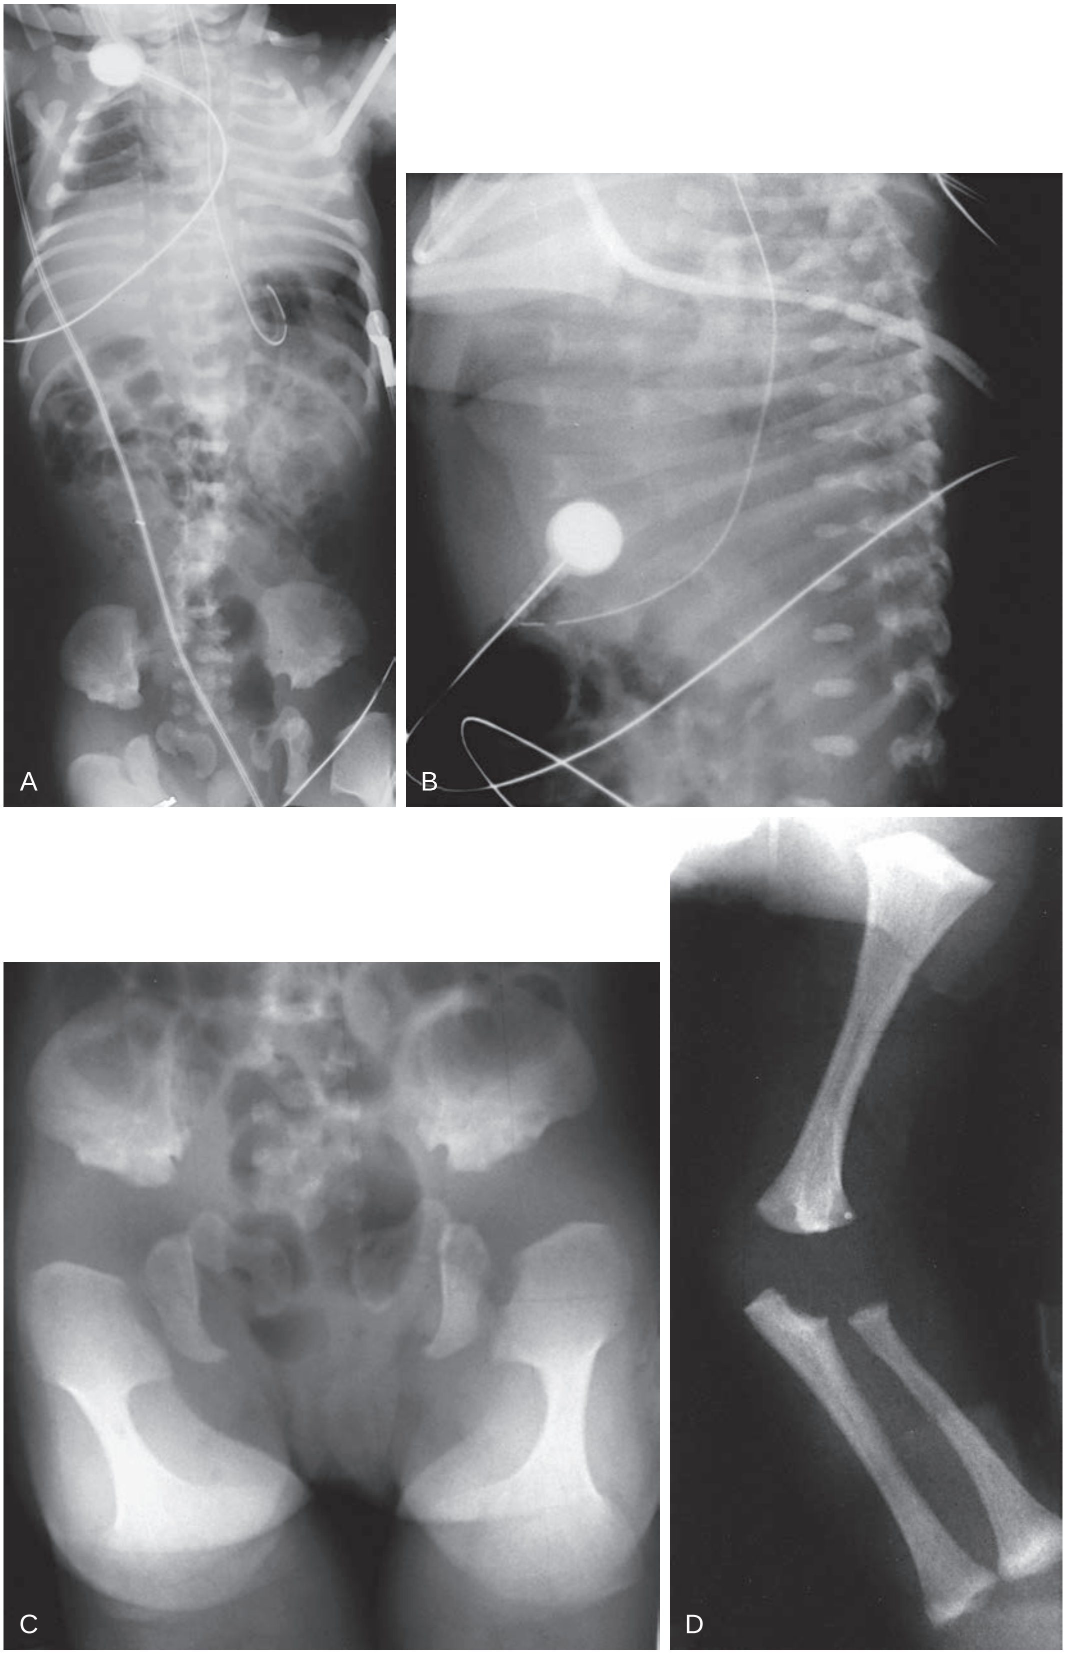


**Figure 132.14. Metatropic dysplasia in a newborn.** (A) Thorax: long trunk and small chest. (B) Spine: dense wafer vertebral bodies and short ribs with anterior splaying. (C) Pelvis: short iliac wings; narrow sciatic notches; irregular acetabular roofs; and rounded, enlarged proximal femoral metaphyses (halberd shaped) with markedly flared distal metaphyses (trumpet-shaped). (D) Upper extremities: flared proximal humeral and distal radial and ulnar metaphyses; shortened long bones.

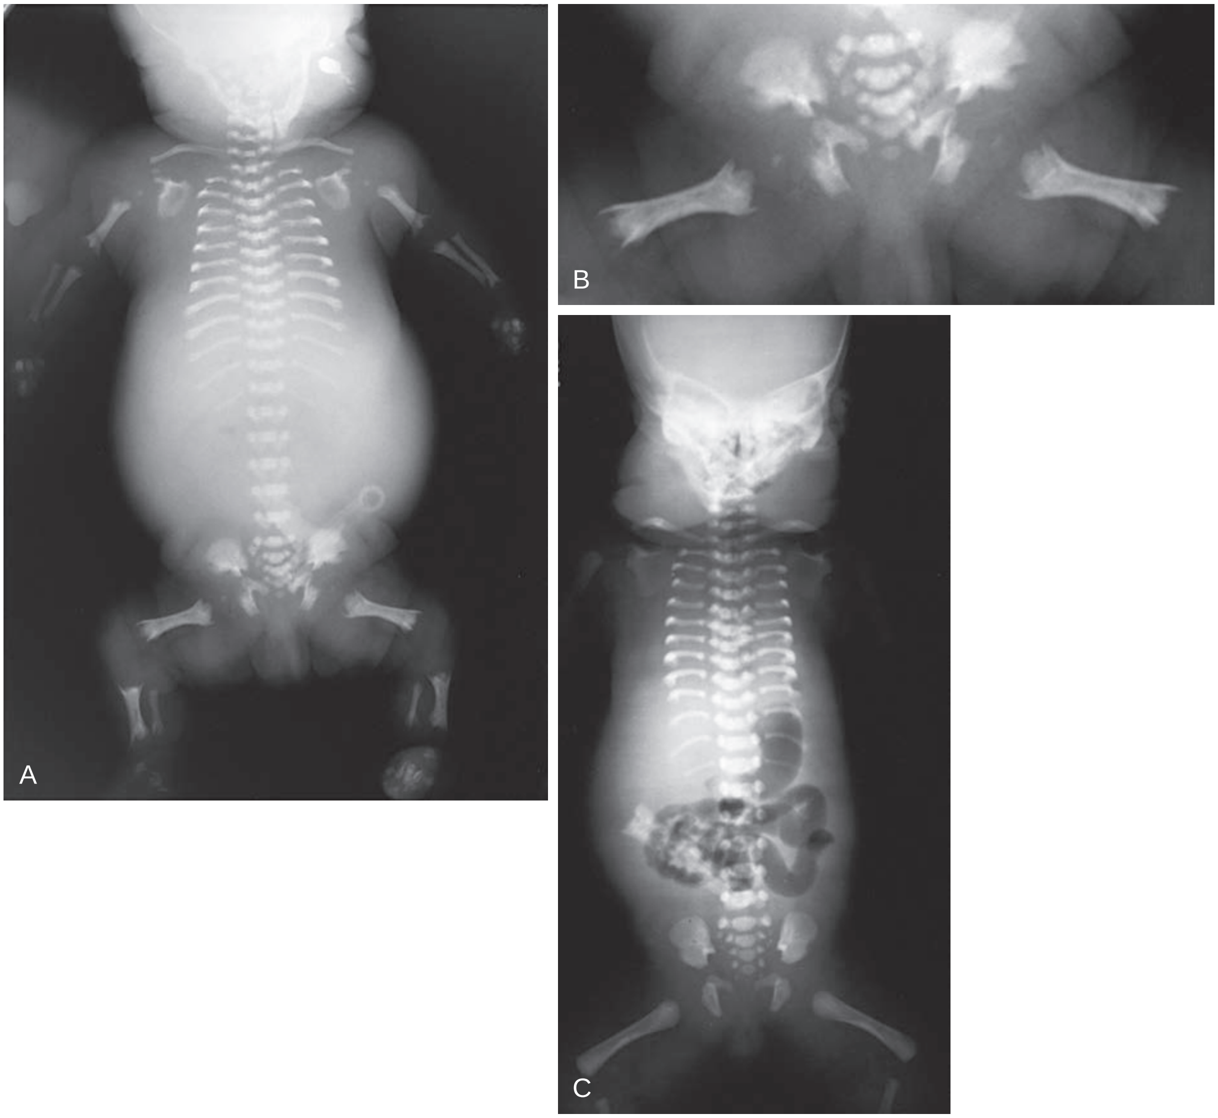

**Figure 132.16. Short rib–polydactyly dysplasia.** (A) Radiograph from a stillborn infant with type I/III form, demonstrating very short ribs and, handlebar clavicles. (B) Magnified, coned view of pelvis shows hypoplastic pelvis with notched acetabula, and metaphyseal-spiked femurs. (C) Radiograph from a stillborn infant with short rib–polydactyly dysplasia type II. Findings are similar to those in type I/III but with round-ended femurs and hypoplastic acetabula.

2. *Spine:* normal
3. *Pelvis:* small; short, flared iliac wings; trident acetabular roof; narrowed sacrosciatic notches
4. *Extremities:* generalized shortening, precocious proximal femoral epiphyseal ossification, cone-shaped epiphyses in hands, metaphyseal flaring with irregularity (more pronounced in childhood)

## Chondroectodermal Dysplasia (Ellis–Van Creveld Syndrome)

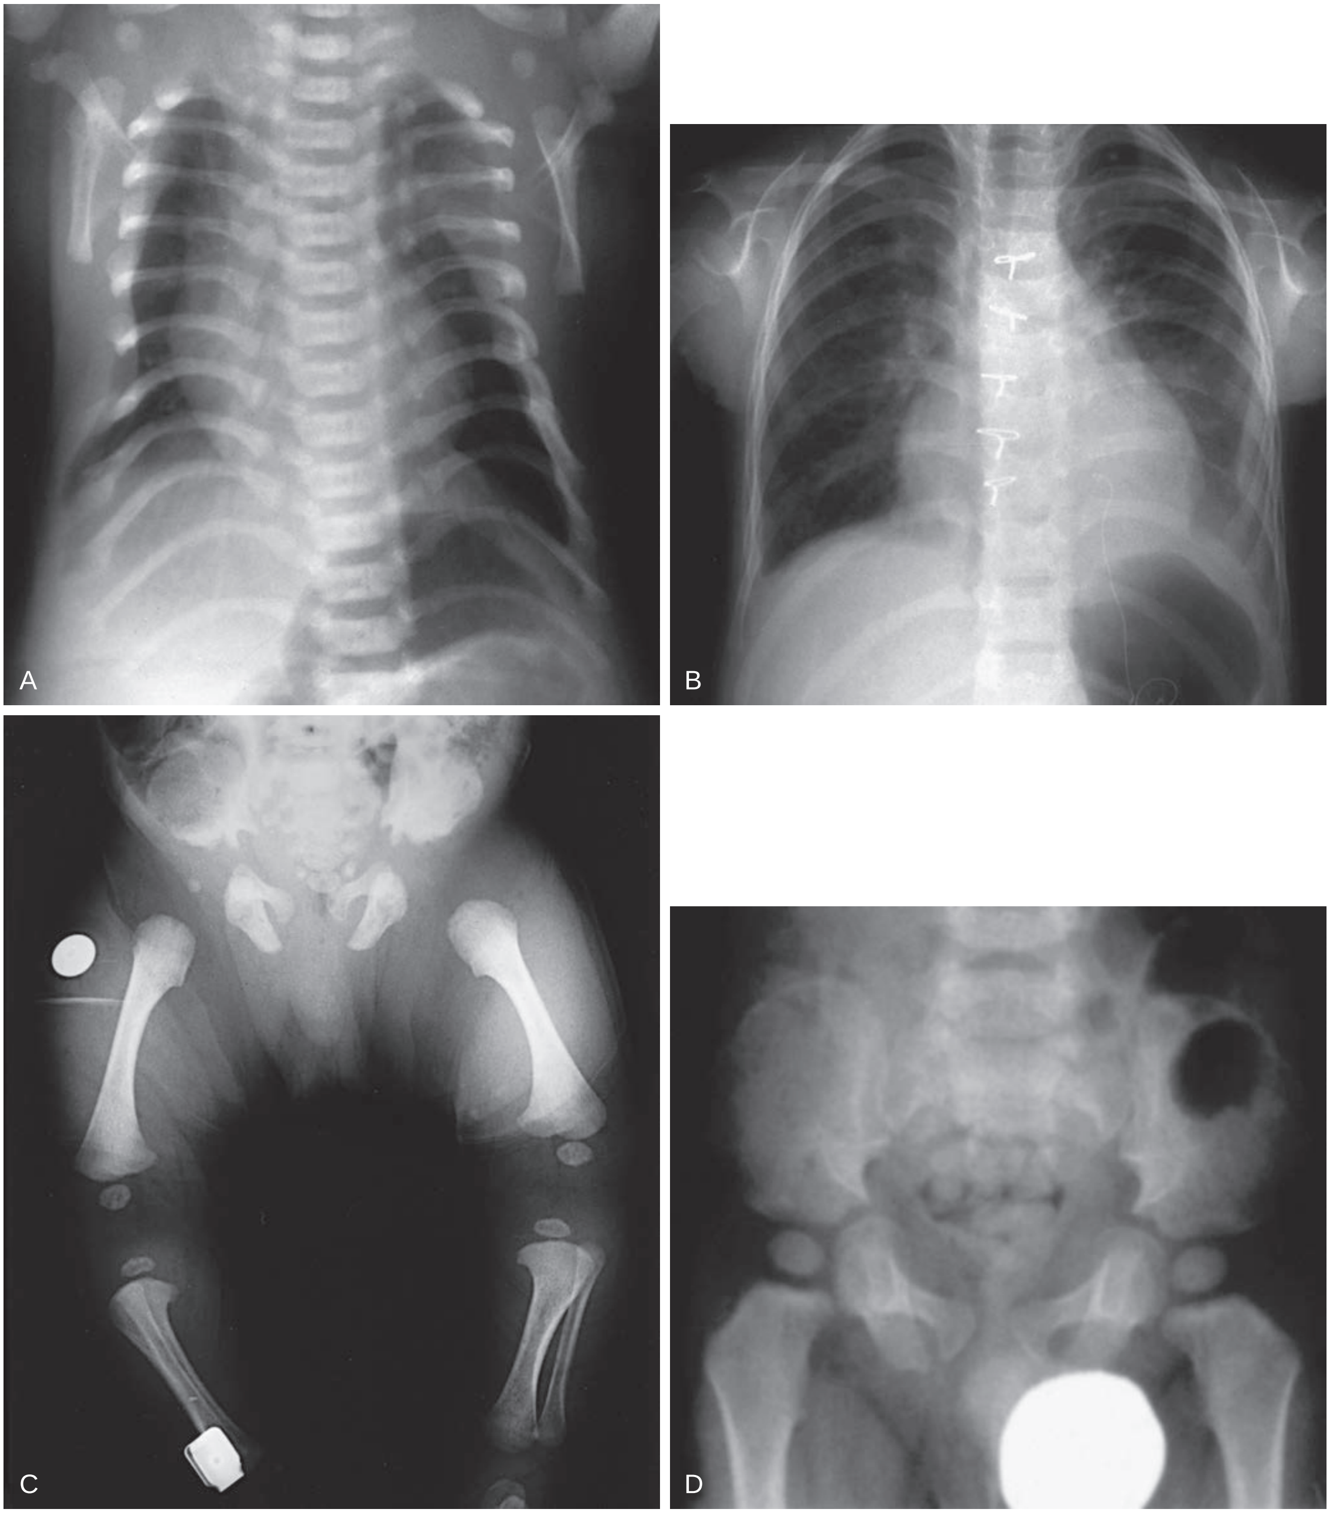
Chondroectodermal dysplasia is a nonlethal skeletal dysplasia. The nonskeletal involvement in this disorder is important in defining this condition and distinguishing this lesion from ATD. Signs include hair, nail, and teeth abnormalities, as well as congenital heart disease. Polydactyly is almost invariably present. The radiologic findings are very similar to those of ATD.

***Radiologic Findings*** (e-Fig. 132.18)

1. *Thorax:* small; moderately short ribs
2. *Pelvis:* small; short, flared iliac wings; trident acetabula; narrowed sacrosciatic notches
3. *Spine:* almost normal
4. *Extremities:* generalized shortening with more mesomelia and acromelia; premature ossification of capital femoral epiphyses; delayed ossification of proximal tibial epiphyses; humeral and femoral bowing; exostosis of proximal/medial portion of tibia
5. *Hands:* characteristic postaxial polydactyly, capitate/hamate (and other carpal) fusions, extra carpal bone, cone-shaped epiphyses
6. *Feet:* polydactyly

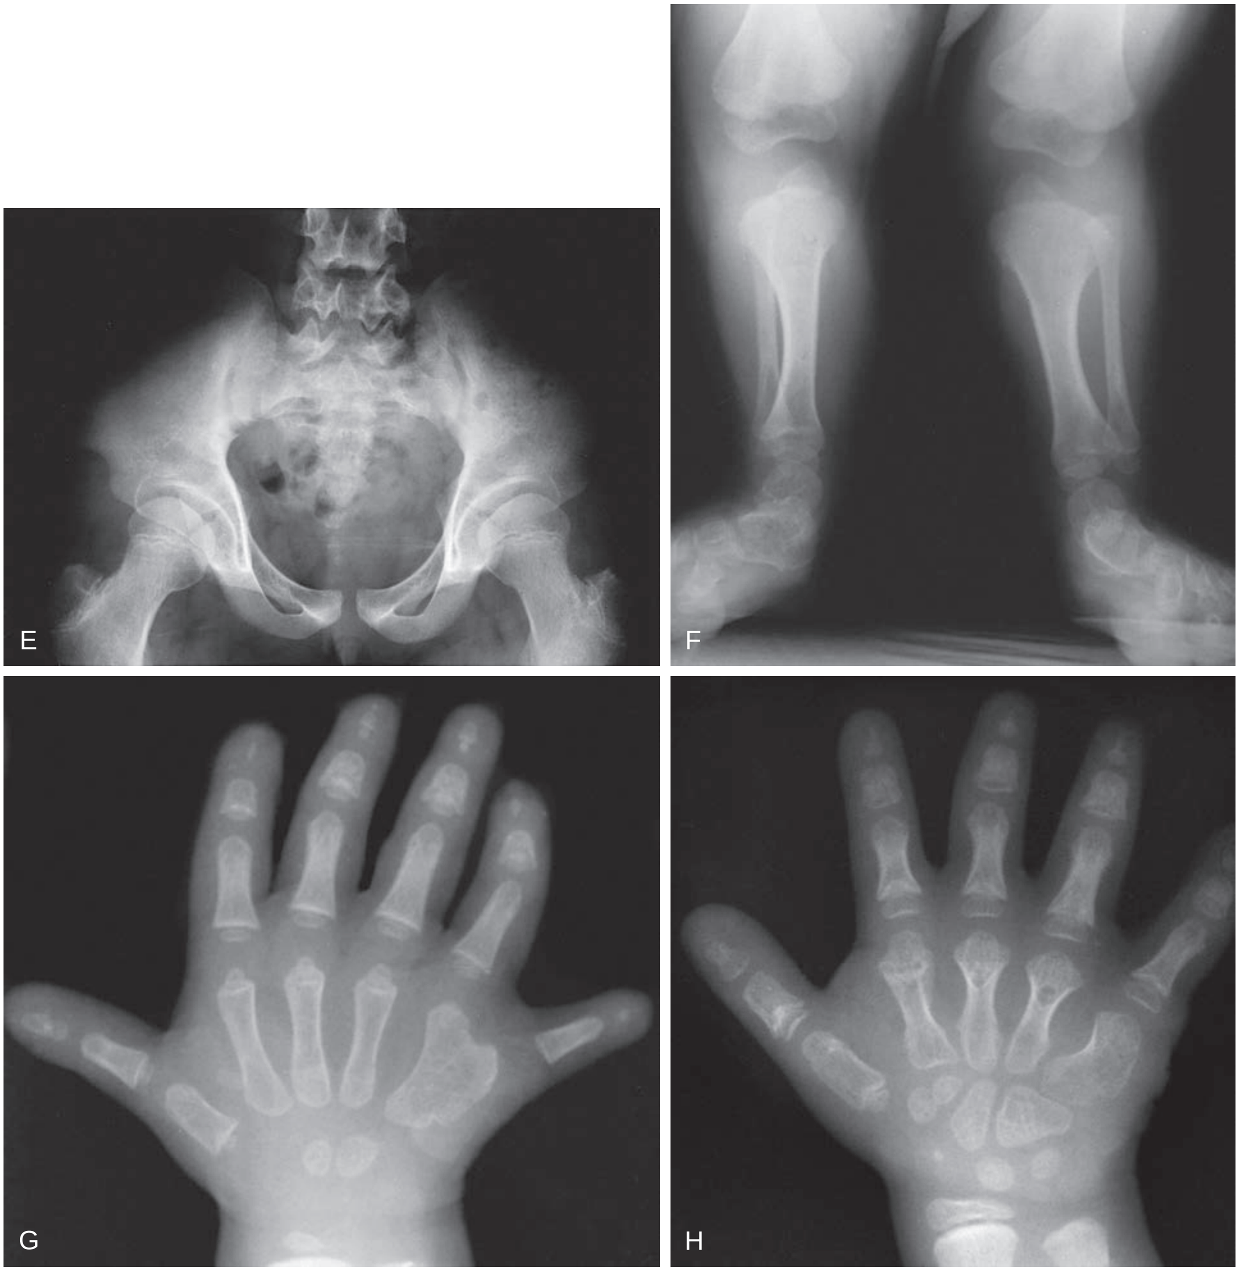
## MULTIPLE EPIPHYSEAL DYSPLASIA AND PSEUDOACHONDROPLASIA GROUP

Pseudoachondroplasia and some cases of typical MED are cartilage oligomeric protein (COMP) gene defects on chromosome 19 (70%) and share some commonality of radiographic findings.



**e-Figure 132.18. Chondroectodermal dysplasia (Ellis–van Creveld syndrome).** (A) Radiograph from an affected 3-month-old infant with a narrow thorax, short ribs, anterior rib flaring, and a normal spine. (B) Radiograph from an affected 5 year old with similar chest configuration; cardiomegaly is present, with sternal sutures from a primum defect repair. (C) Radiograph from an affected 3 month old with short, flared iliac wings; trident acetabula; and mesomelia and rhizomelia. (D and E) Radiographs from an affected child at 2½ (D) and 12 years of age (E), showing near normalization of pelvis. Chondroectodermal dysplasia (Ellis–van Creveld syndrome). (F) Radiograph from an affected 2½ year old with remarkable mesomelia. (G) Radiograph from an affected 2 year old with characteristic hands: polydactyly, middle and distal phalangeal hypoplasia, cone-shaped epiphyses of middle phalanges. (H) Radiograph from the same child as in (G) at 6 years of age. After polydactyly repair, a residual wide fifth metacarpal is seen.

*Continued*



e-Figure 132.18, cont'd.

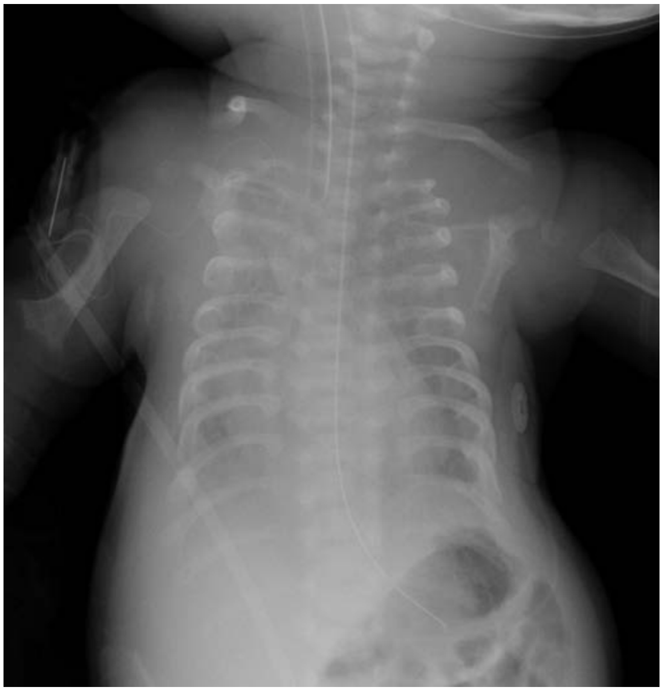


**Figure 132.17. Asphyxiating thoracic dysplasia in a newborn.** Note the short ribs (although not as short as ribs in short rib–polydactyly (see Fig. 132.16) and metaphyseal flaring and irregularity in proximal humeri.

However, many other cases of MED (with the same apparent radiologic abnormalities) represent type IX collagen defects, matrilin 3 defects, or defects on the locus responsible for diastrophic dysplasia (DTDST). The majority of the MED cases belong to either COMP or matrilin abnormalities. The described entities within this group are autosomal-dominant disorders.

### Multiple Epiphyseal Dysplasia

Historically, MED was divided into the milder Ribbing form and the more severe Fairbanks form. Although the classification does not agree with molecular genetics data, the distinction is helpful from a clinical point of view. Ribbing MED may entail only hip involvement and can be confused with bilateral Legg-Calvé-Perthes disease and Meyer dysplasia. Differentiation from these entities is possible because almost all patients with MED have clinically significant short stature. Many patients with MED later go through an asymptomatic phase of avascular necrosis of the capital femoral epiphyses. This makes differentiation of MED from Legg-Calvé-Perthes disease very difficult if old radiographs are not available. The Fairbanks form has involvement of all the long bone epiphyses to some degree. MED manifests after about 2 years of age but is most commonly diagnosed in an adolescent or young adult. Involvement is always bilateral and symmetric. The shortening is quite mild.

It is possible to suggest the molecular defect from the radiologic changes. Those affected by the *COMP* gene locus have tiny capital femoral epiphyses, irregular and poorly formed acetabula, and brachydactyly. On the other hand, vertical striations in the metaphyses point toward an error in matrilin.[19]

***Radiologic Findings*** (Fig. 132.19 and e-Fig. 132.20)

1. *Spine:* in young adults, disk herniations into vertebral end plates (Schmorl nodes)
2. *Extremities:* small, irregular, flattened ossification centers (epiphyses); small, irregular carpal (and tarsal) centers

### Pseudoachondroplasia

This short-limb, short-trunk form of skeletal dysplasia was referred to at first as *achondroplasia with a normal face*.

***Radiologic Findings*** (Fig. 132.21)

1. *Skull:* normal
2. *Thorax:* mild anterior rib widening
3. *Spine:* superiorly and inferiorly rounded vertebral bodies, anterior central tongue (unossified ring epiphyses), normalization of vertebrae (later)
4. *Pelvis:* rounded iliac wings; hypoplastic, poorly formed acetabular roofs
5. *Extremities:* mini-epiphyses in the hips, moderate to severe generalized epiphyseal "dysplasia" (small, irregular, poorly ossified), mushroom-like metaphyseal widening and irregularity in the knees, proximally rounded metacarpals with mini-epiphyses in hands, irregular carpal and tarsal bones

## METAPHYSEAL CHONDRODYSPLASIA GROUP

Metaphyseal chondrodysplasias (MCDs) are also a heterogeneous group of disorders that have common radiologic features. Members of this group include Jansen-type MCD, Schmid-type MCD, McKusick-type MCD, and Shwachman-Diamond dysplasia. Spines are usually normal except in Schmid-type MCD, in which mild platyspondyly may be seen. Immune deficiencies are notable in Shwachman syndrome and McKusick-type MCD (cartilage-hair hypoplasia).

### Jansen-Type Metaphyseal Chondrodysplasia

This is the severest form of MCD. The presentation is in the neonatal period or during late infancy, with marked short stature and a waddling gait. This is a distinct autosomal-dominant disorder with an abnormality in a parathyroid receptor gene *(PTHR)*, leading to hypercalcemia and its complications. However, the radiographic findings in the skeleton are not those of typical hyperparathyroidism or hypoparathyroidism.[20]

***Radiologic Findings*** (Fig. 132.22)

1. *Skull:* brachycephaly, platybasia, underdeveloped mandible
2. *Thorax:* normal size; expanded irregular anterior rib ends
3. *Extremities:* extensive irregularity of markedly expanded metaphyses involving all metaphyseal regions; hands exhibit wide separation of epiphyses from metaphyses

*Note:* As in other parathyroid abnormalities, pathologic fractures (in 45% of affected patients) and subperiosteal bone resorption (in 50%) are common.

### Schmid-Type Metaphyseal Chondrodysplasia

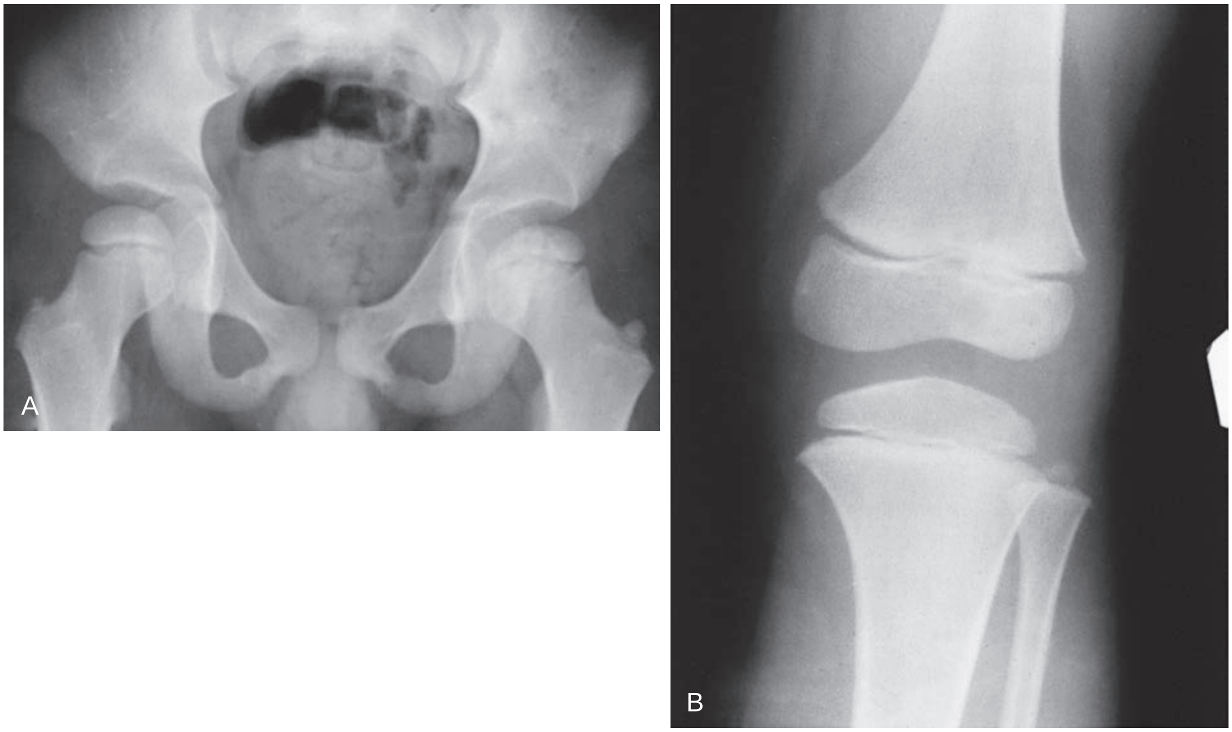
This form of MCD is an autosomal-dominant condition caused by a specific defect in collagen type X, the gene for which is located on chromosome 6. This disorder is the mildest of the MCDs. Presentation is usually at about 2 years of age or later with a waddling gait or bowed legs, or both. Mild short stature is present.

***Radiologic Findings*** (Fig. 132.23)

1. *Thorax:* widened anterior rib ends
2. *Spine:* mild platyspondyly
3. *Extremities:* metaphyseal flaring, cupping and fraying, especially at the knees; rounded capital femoral megaepiphysis with widened growth plate; usually no hand involvement

### McKusick-Type Metaphyseal Chondrodysplasia

*Cartilage-hair hypoplasia*, as this entity is also known, is an autosomal recessive disorder. The genetic defect is at the 9p region (*RMRP*



**e-Figure 132.20. Ribbing-type multiple epiphyseal dysplasia in a 7 year old.** Radiographs reveal small-appearing capital femoral epiphyses (A) and relatively normal-sized knee epiphyses (B).

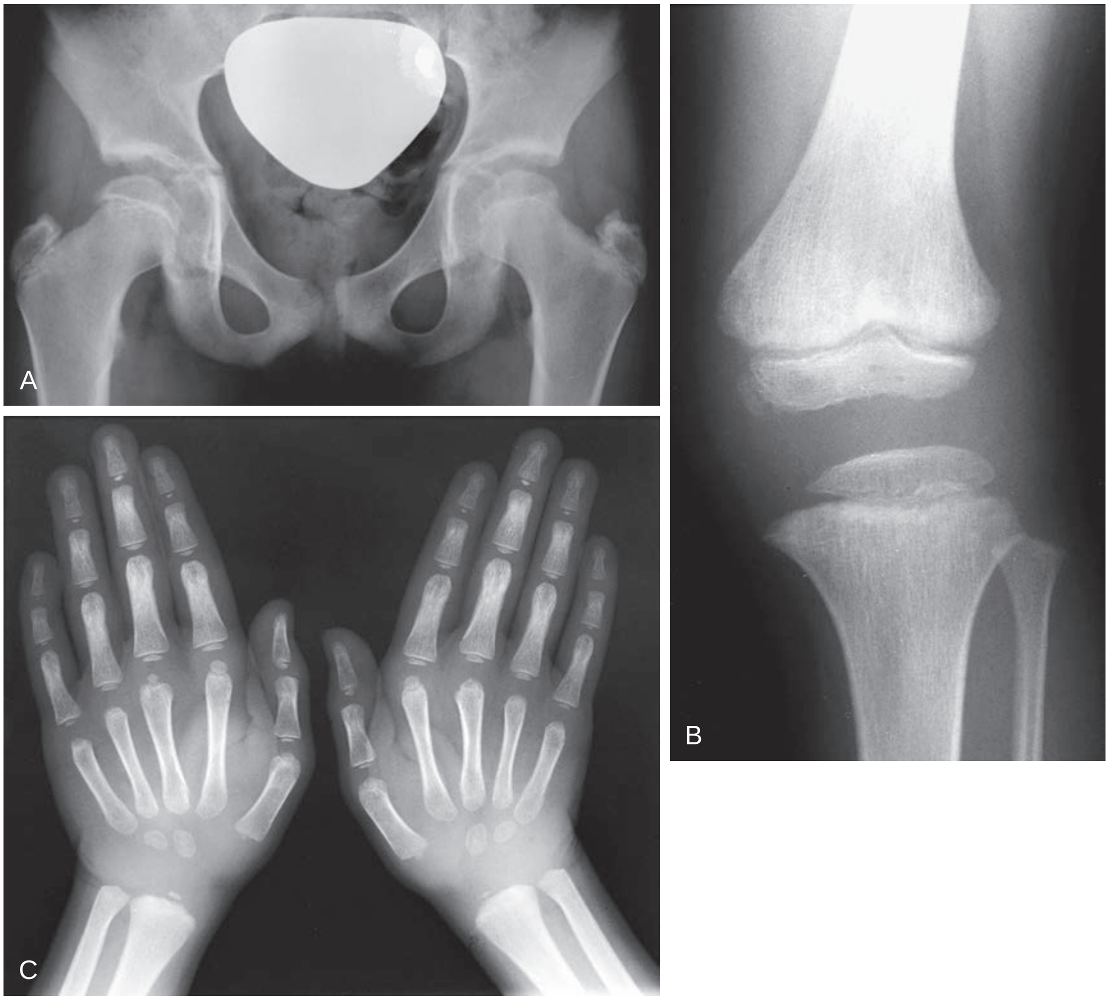


**Figure 132.19. Fairbanks-type multiple epiphyseal dysplasia.** (A) Radiograph from an affected 10 year old with small ossified proximal femoral epiphyses (ossification defect). (B and C) Radiographs from an affected 6 year old. (B) Similar epiphyseal ossification defects in the knee. (C) Small epiphyses of the short tubular bones of the hands and carpal ossification delay (epiphyseal equivalents), but no brachydactyly.

gene), with a high frequency among the Amish and Finnish populations.[21–23] The presentation is of variable short-limbed dwarfism in early childhood. Significant clinical features indicate the diagnosis and are important for medical management: sparse, thin, light-colored hair; Hirschsprung disease; immunologic problems; and increased incidence of malignancy.

***Radiologic Findings*** (e-Fig. 132.24)

1. *Thorax:* anterior rib widening/flaring
2. *Spine:* slightly small square vertebral bodies
3. *Extremities:* flaring, cupping, and fragmentation of metaphyses (especially knees), hips usually spared; brachydactyly with cone shaped epiphysis

### Shwachman-Diamond Dysplasia

This rare autosomal-recessive disorder is also known as *MCD*. Major clinical findings include pancreatic insufficiency and cyclic neutropenia. It manifests in infancy with recurrent infections and failure to thrive. The skeletal radiographic features are quite mild.

***Radiologic Findings*** (e-Fig. 132.25)

1. *Thorax:* anterior rib irregularity or splaying
2. *Extremities:* metaphyseal irregularity and sclerosis, especially at knees and hips
3. *Gastrointestinal:* malabsorption pattern on small bowel examination; lipomatosis of pancreas

## SPONDYLOMETAPHYSEAL DYSPLASIA GROUP

### Spondyloenchondromatosis

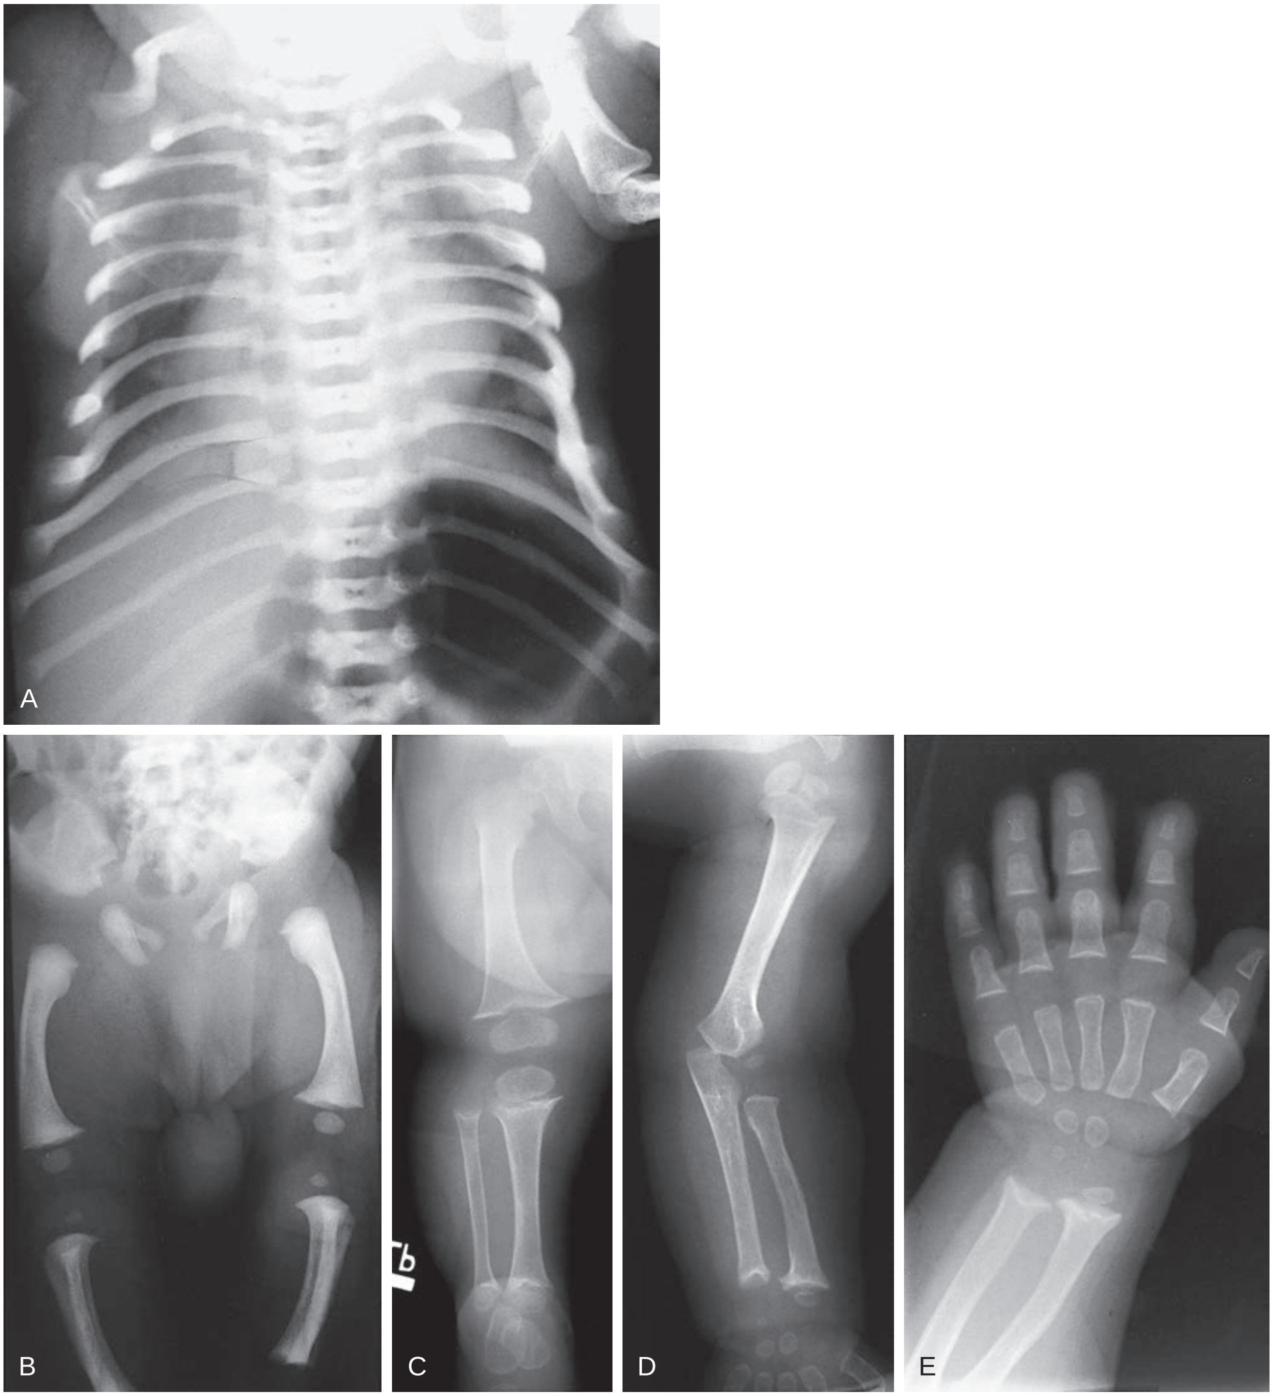
This autosomal-recessive disorder is also known as *spondyloenchondrodysplasia*, characterized by low-normal or mild short stature, with kyphosis, lordosis, or both. Prominent joints may be apparent.

***Radiologic Findings*** (e-Fig. 132.26)

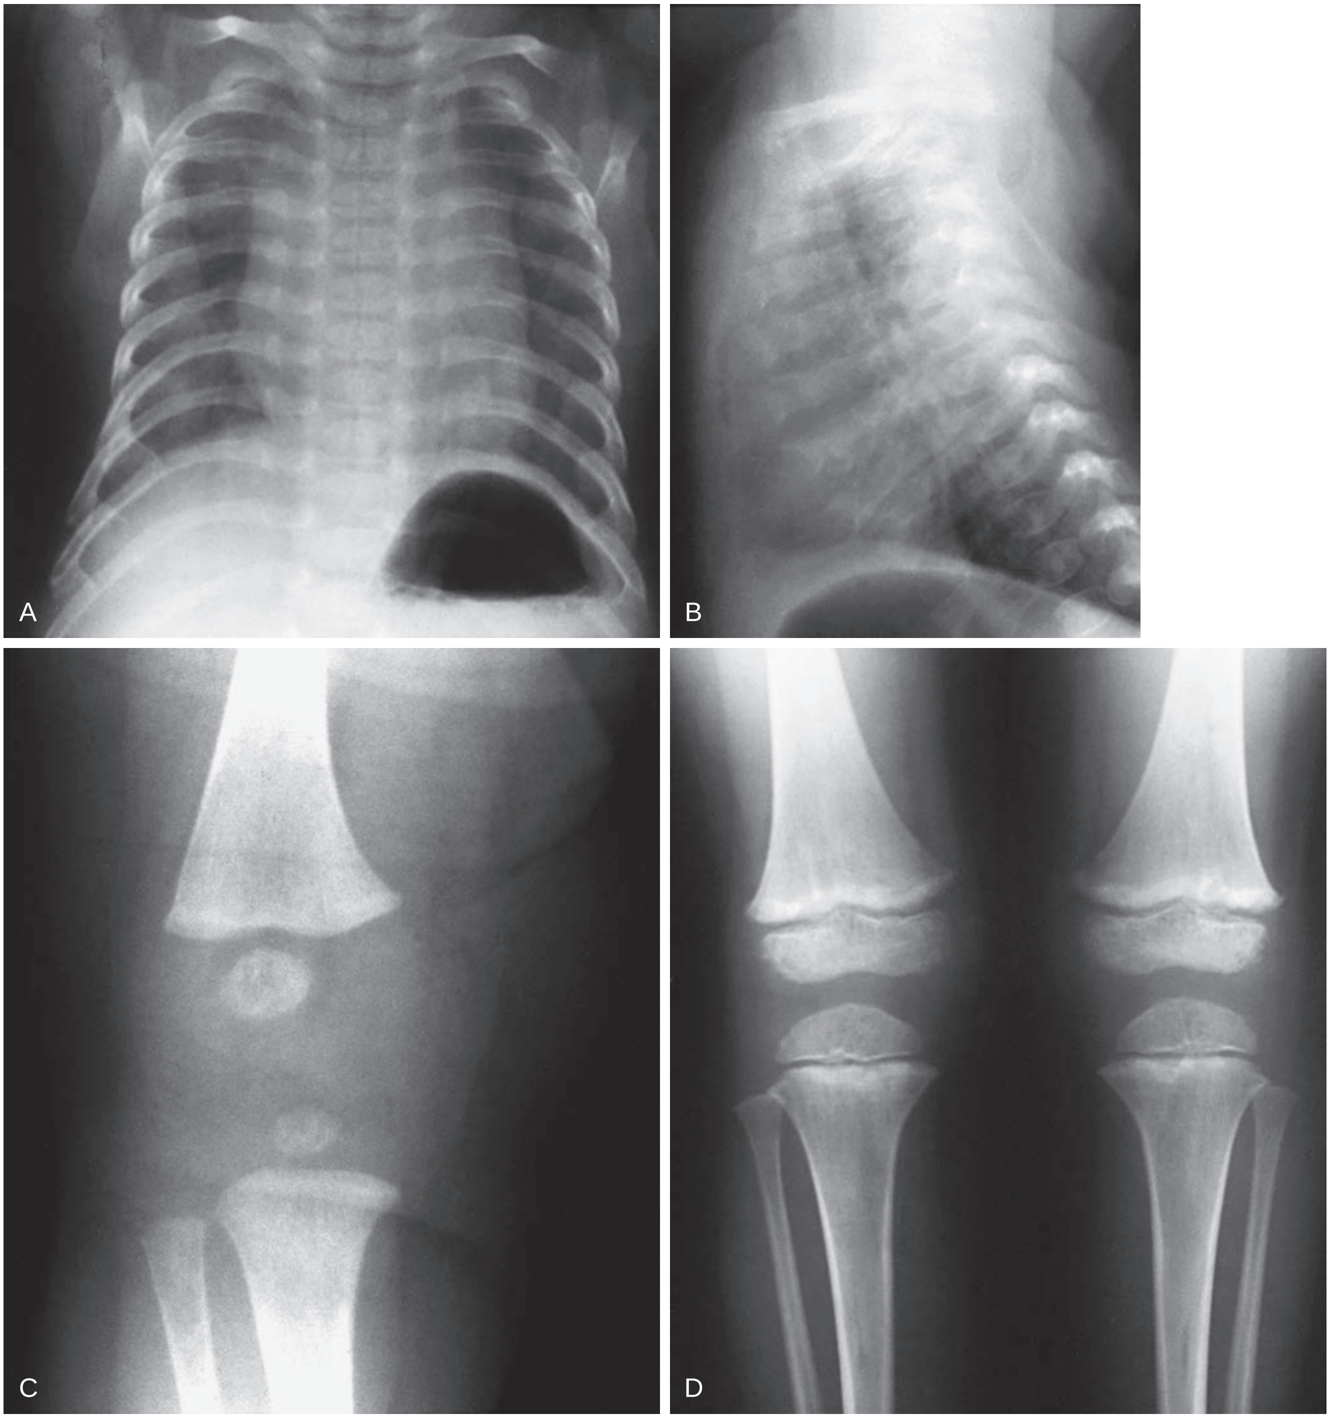
1. *Spine:* severe platyspondyly with endplate irregularity
2. *Extremities:* enchondromatosis in long bones, but rarely involving hands and feet

## ACROMELIC/ACROMESOMELIC DYSPLASIA GROUP

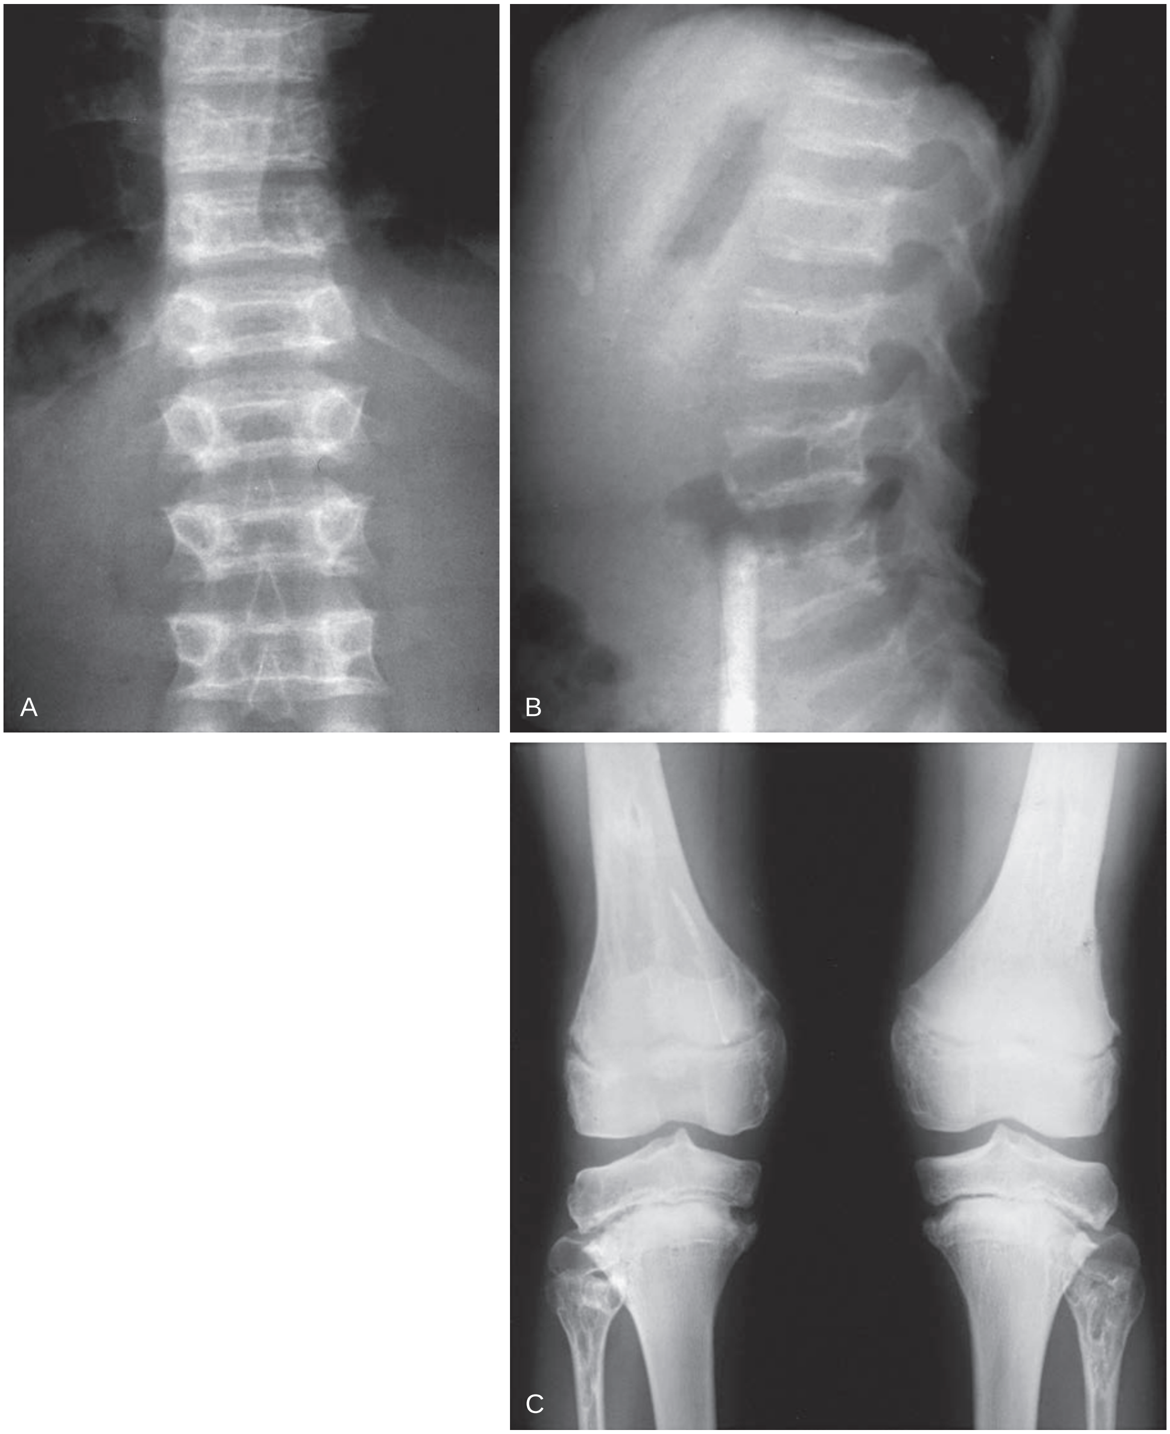
The acromelic/acromesomelic dysplasia group consists of a large, heterogeneous collection of disorders. For a number of these dysplasias, the molecular defect has been delineated. Only trichorhinophalangeal syndrome (TRPS) types I and II are described here.



**e-Figure 132.24. McKusick-type metaphyseal chondrodysplasia (cartilage-hair hypoplasia).** (A and B) Radiographs from an affected newborn. (A) Thorax: anterior rib end widening and cupping. (B) Lower extremities: mild femoral bowing with minimal distal femoral flare. (C and D) Radiographic findings in late infancy. (C) Lower extremity: metaphyseal flaring and irregularity at the knees and ankles (but the hips are spared). (D) Upper extremity: similar metaphyseal changes at the wrists (the shoulders are spared). (E) At 6 months of age, metaphyseal widening and cupping of the short tubular bones of the hand, with similar metaphyseal changes in the wrist, are seen.



**e-Figure 132.25. Shwachman-Diamond dysplasia.** (A and B) At 2 months, a narrow thorax with anterior rib splaying is seen. (C) At 2 months, the knees are normal. (D) At 4 years, sclerotic, irregular, widened metaphyses in the knees are seen.



**e-Figure 132.26. Spondyloenchondromatosis in a 14 year old.** (A and B) Platyspondyly with end plate irregularity. (C) Multiple enchondromata in the long bones.

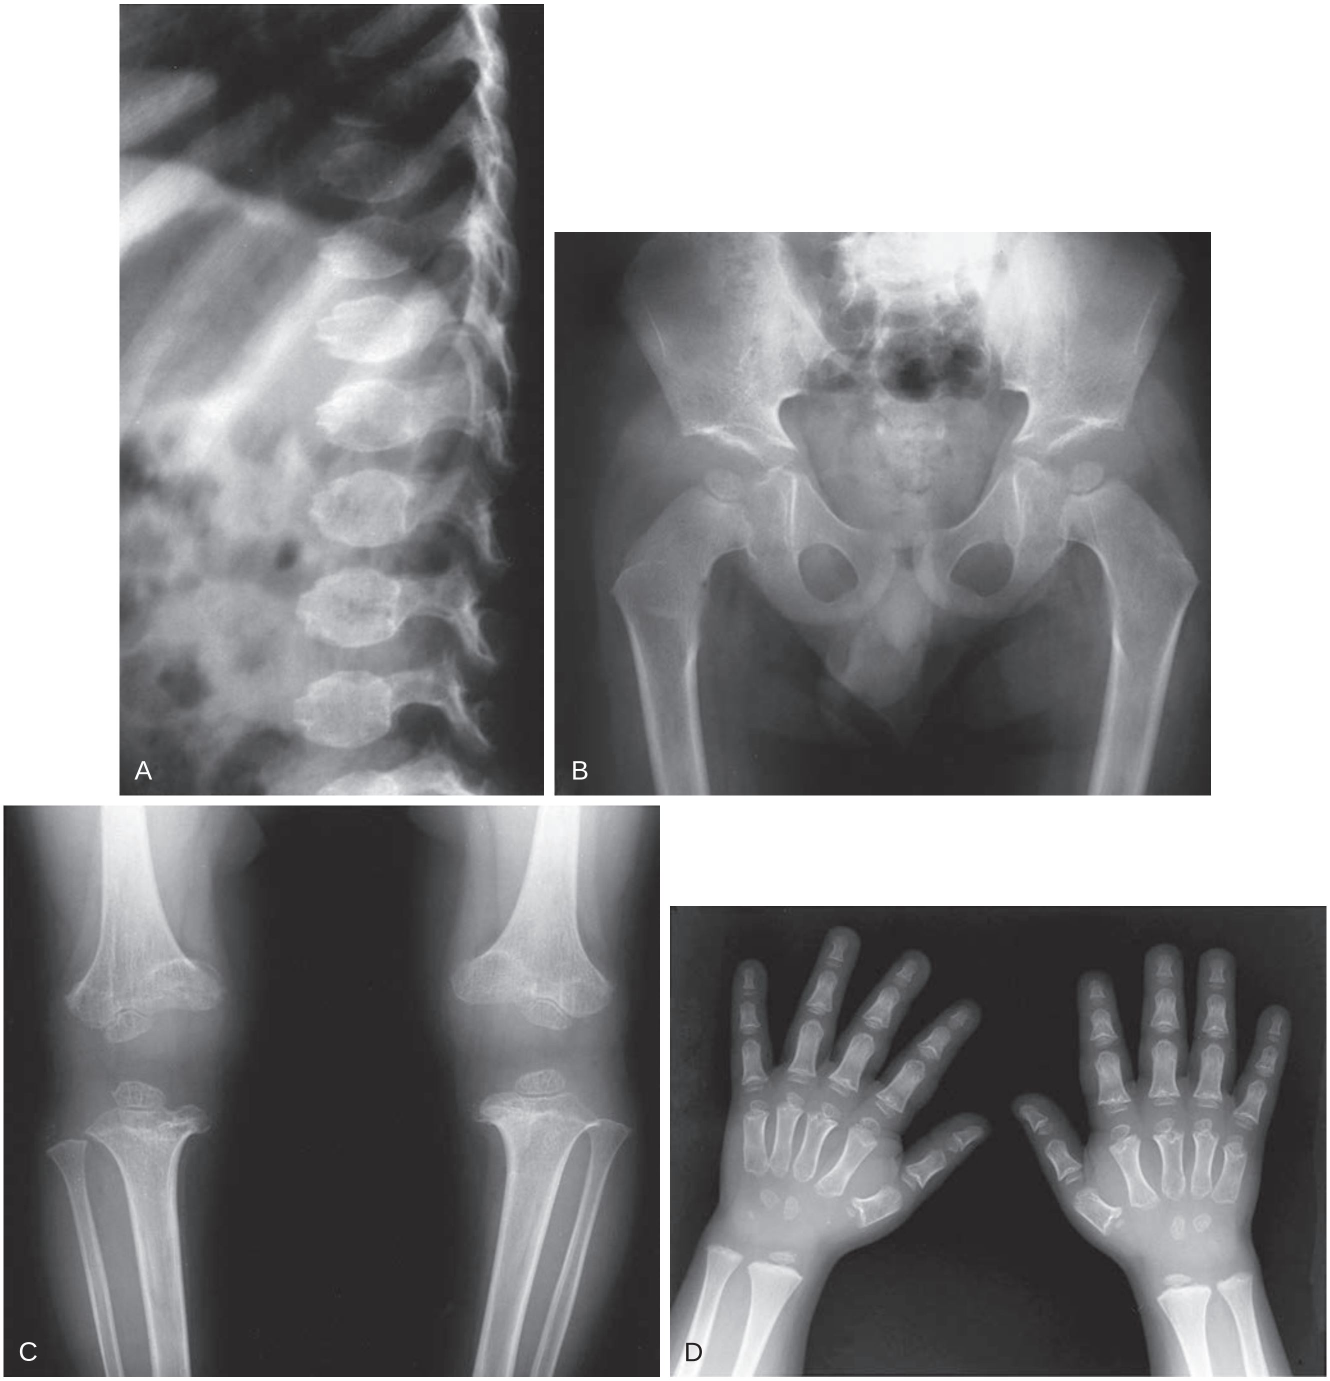


**Figure 132.21. Pseudoachondroplasia.** Radiologic findings at ages 3 years (A and C) and 4 years (B and D). (A) Central anterior tonguing and superior and inferior rounding of vertebral bodies. (B) Acetabular roof hypoplasia and mini-epiphyses. (C) Small knee epiphyses and metaphyseal widening with ossification defects. (D) Proximal metacarpal rounding, small epiphyseal centers, metaphyseal widening and irregularity, and carpal ossification delay.

## Trichorhinophalangeal Syndrome Types I and II

Both of these disorders have been located on the long arm of chromosome 8. The gene implicated in TRPS type I (also known as *Giedion syndrome*) is *TRPS1*. TRPS type II (also known as *Langer-Giedion syndrome*) is slightly more complicated. TRPS type II is the result of a contiguous gene abnormality resulting from the loss of not only *TRPS1* but also *EXT1*, a major cause of multiple hereditary exostoses located distal to *TRPS1*. TRPS type I is autosomal dominant, whereas most cases of TRPS type II are sporadic. The clinical manifestations of both disorders include mild short stature; sparse, slow-growing hair; pear-shaped nose;

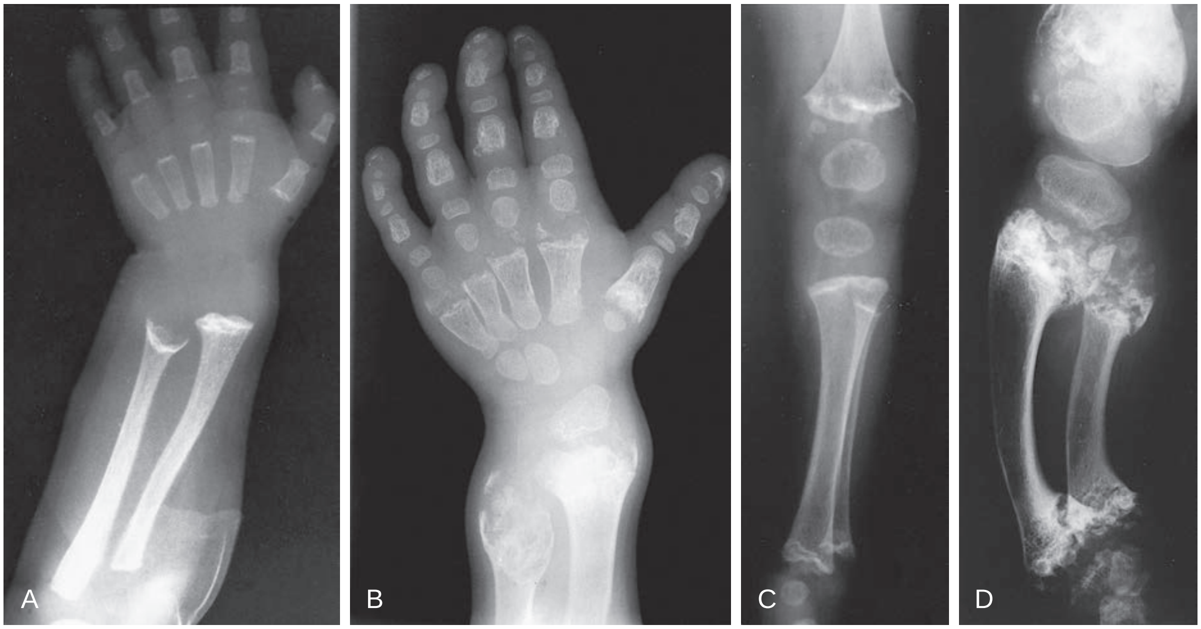

**Figure 132.22. Jansen-type metaphyseal chondrodysplasia.** (A) At 1 year, severe metaphyseal cupping and splaying are present at the wrists and also in the hand bones. (B) At 7 years, increasing metaphyseal change is seen at the wrists with enlarged epiphysis; enlarged epiphyses with wide epiphyseal plates are also present in the hands. (C) At 1 year, severe metaphyseal irregularities at the knees and ankles (femur, tibia, and fibula) and enlarged, rounded epiphyses are present. (D) At 7 years, severely fragmented, sclerotic metaphyses, wide epiphyseal plates, and enlarged epiphyses are present.

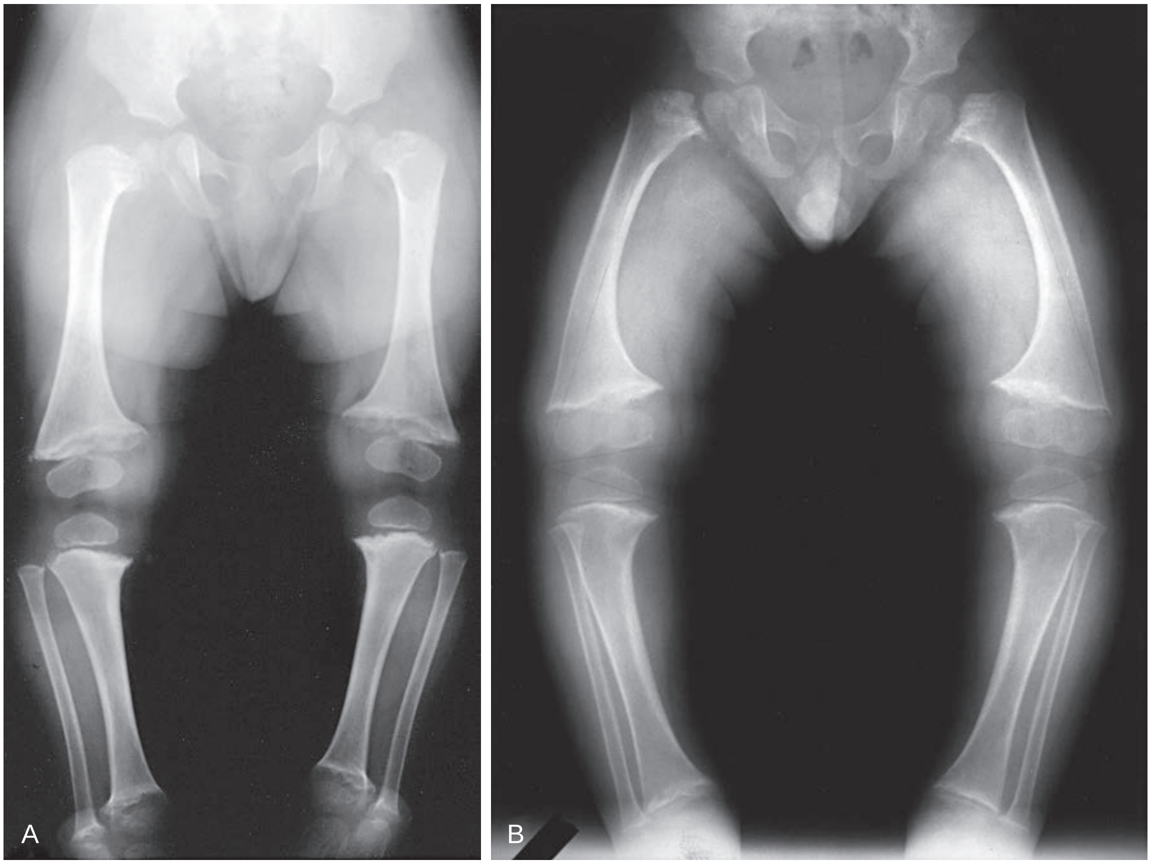

**Figure 132.23. Schmid-type metaphyseal chondrodysplasia.** (A) Radiograph from an affected 19-month-old with severe coxa vara and moderate metaphyseal changes (cupping irregularity, widening) at the knees and ankles. (B) Radiograph from an affected 3 year old with coxa vara, genu varum, and moderate metaphyseal changes at hips and knees (widening, irregularity).

and short, crooked fingers. The contiguous gene abnormality explains the added features in TRPS type II, which include multiple exostoses and mental retardation.[24]

***Radiologic Findings*** (Fig. 132.27)

- *Extremities:* Perthes-like changes at the hips, brachydactyly with multiple cone-shaped epiphyses in the phalanges of both hands. With TRPS type II, multiple exostoses are also present.

## MESOMELIC DYSPLASIA GROUP

The mesomelic dysplasia (mesomelic dwarfism) group consists of a large number of disorders involving shortening of the middle segment bones. Milder shortening of other segments may also be noted. The most common entity in this group is dyschondrosteosis.

### Dyschondrosteosis

This skeletal dysplasia, also known as *Leri-Weill syndrome*, is an autosomal-dominant condition. It consists of a pseudoautosomal homeobox gene (*SHOX* gene) found on the short arm of the X chromosome. Dyschondrosteosis manifests with mild to moderate short stature, usually with both forearm and calf shortening. Madelung deformity is the major marker for this disease. Interestingly, Madelung deformity is also common in Turner syndrome

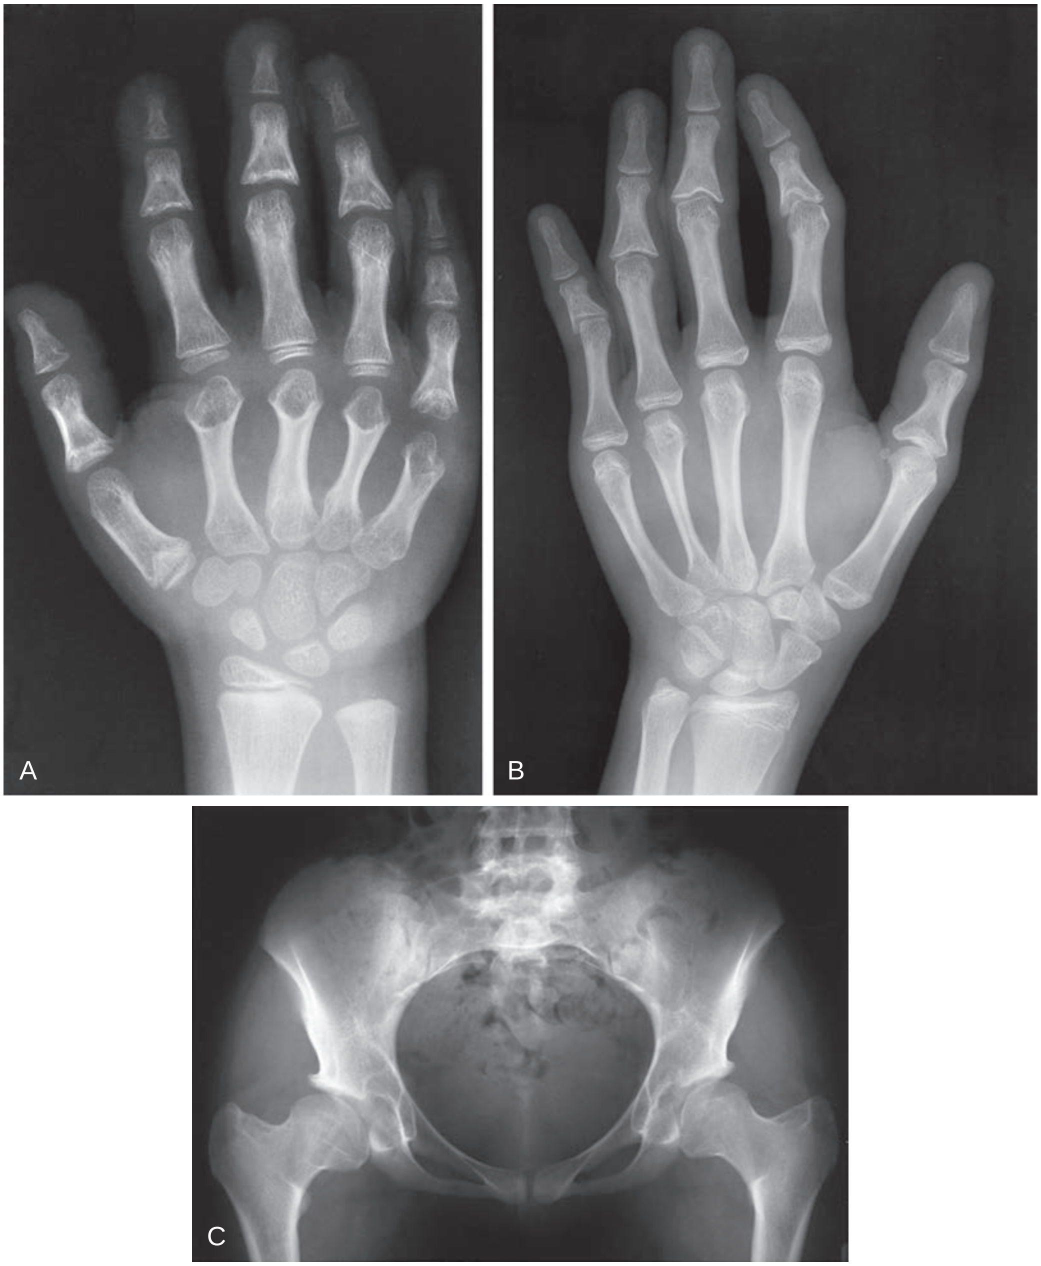

**Figure 132.27. Trichorhinophalangeal syndrome type I.** (A) In an affected 8 year old, cone-shaped epiphyses involving the first metacarpal, the proximal fifth phalanx, and all middle phalanges and metacarpals in the second through fifth digits (early fusion) are present. (B) The radiograph from an affected 18 year old shows similar changes. (C) In an affected young adult, coxa vara and small capital femoral epiphyses are present.

because of the lack of two copies of *SHOX* as only one X chromosome is present (see discussion of Turner syndrome later).

MRI is important here from a therapeutic point of view. A thickened ligament has been described by Vickers and Nielsen, which appears to tether the medial radial physis.[25] It can be found on the volar side of the joint and may be an abnormally thickened volar radiolunotriquetral ligament. Operative lysis of this structure if performed early can ameliorate the Madelung-type deformity. Radiographically, the ligament should be suspected when a triangular lucency is seen at the medial aspect of the distal radial metaphysis. On MRI, the ligament is clearly visible as a thick hypointense band of tissue originating at the medial radial physis.[26]

***Radiologic Findings*** (Fig. 132.28)

- *Extremities:* symmetric bowing and shortening of both radii, shortened ulnas, radiographic Madelung deformity changes, variable tibial and fibular shortening; short stature with abnormal upper to lower segment ratio

## CHONDRODYSPLASIA PUNCTATA GROUP

The chondrodysplasia punctata (stippled epiphyses) group is very diverse, united by the radiographic commonality of epiphyseal stippling. Several but not all of these entities are related to each other. The rhizomelic form of chondrodysplasia punctata is a peroxisomal enzyme abnormality; the Conradi-Hünermann type is associated with a gene on the long arm of the X chromosome (*EBP* gene defect); and the brachytelephalangic type is on the short arm of the X chromosome (a defect in the *ARSE* gene).

### Rhizomelic Chondrodysplasia Punctata

This is a distinct form of chondrodysplasia punctata and has an autosomal-recessive inheritance pattern. It is a symmetric rhizomelic skeletal dysplasia manifesting in the neonatal period. Affected infants usually die in the first year of life. Associated clinical findings include cataracts, skin lesions, alopecia, and joint contractures. Later manifestations are severe psychomotor retardation and spasticity. These infants appear to be in constant pain. Abnormalities in three genes *(PEX7*, *DHPAT*, *AGPS)* have been noted.

***Radiologic Findings*** (Fig. 132.29)

1. *Spine:* coronal clefting, anteriorly rounded vertebral bodies
2. *Extremities:* stippled epiphyseal ossification, symmetric bilateral shortening of femurs (and humeri) with less severe shortening of all the remaining long bones

## BENT-BONE DYSPLASIA GROUP

The bent-bone dysplasia group of disorders is a rather small but diverse group, with campomelic dysplasia (campomelic dwarfism) having been well described molecularly. These dysplasias have been grouped together because of their radiographic expression.

### Campomelic Dysplasia

This unusual entity is an autosomal-dominant disorder diagnosable at birth, manifesting as bent thighs, clubfeet, respiratory distress, and unusual small facies. Sex reversal is often present. All the extremities are moderately short. Neonatal or perinatal death occurs in most cases. The molecular defect is a homeobox gene abnormality called *SOX9*, found on chromosome 17. Radiographically the combination of bent femora with severe hypoplasia of the blade of the scapula makes for an easy diagnosis.

***Radiologic Findings*** (Fig. 132.30)

1. *Skull:* enlarged, narrow with a small face
2. *Thorax:* mildly short ribs, numbering 11; severe hypoplasia of the bodies of the scapulae
3. *Spine:* nonossification of thoracic pedicles, cervical kyphosis, hypoplasia of cervical vertebral bodies
4. *Pelvis:* narrow, tall iliac wings
5. *Extremities:* proportionately long, bowed femurs with shortened bowed tibias; shortened upper extremity long bones

## DISORDERS OF INCREASED BONE DENSITY WITHOUT MODIFICATION OF BONE SHAPE

The disorders of increased bone density without modification of bone shape include several entities of interest. These disorders are grouped by their radiographic expression but have in common either diffuse or focal areas of bone sclerosis.

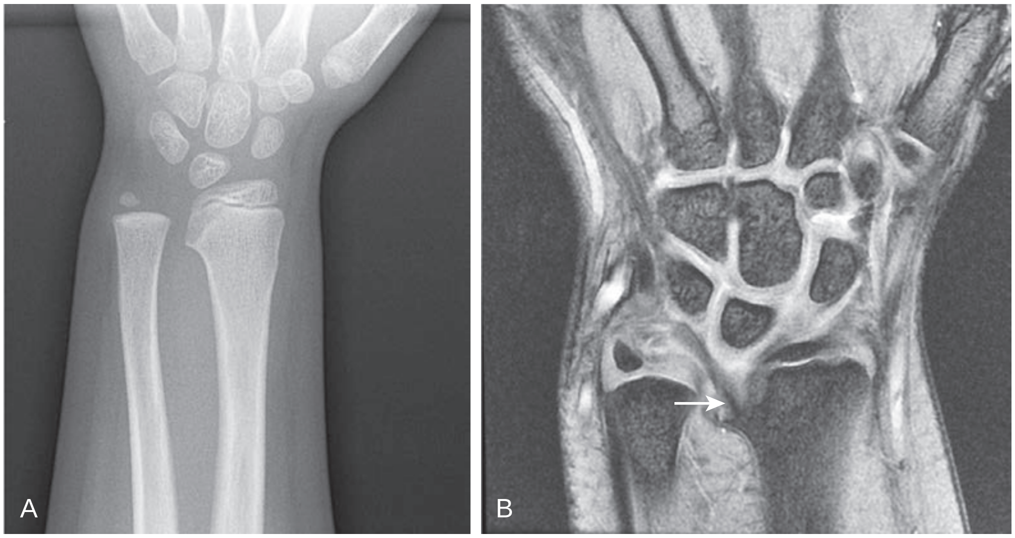

**Figure 132.28. Dyschondrosteosis in a 7-year-old girl.** (A) Frontal radiograph and (B) coronal gradient echo MRI show a Madelung deformity. Note the triangular lucency in the distal radius on the radiograph. The MRI shows Vickers ligament *(arrow)* inserting in this area tethering the physis.

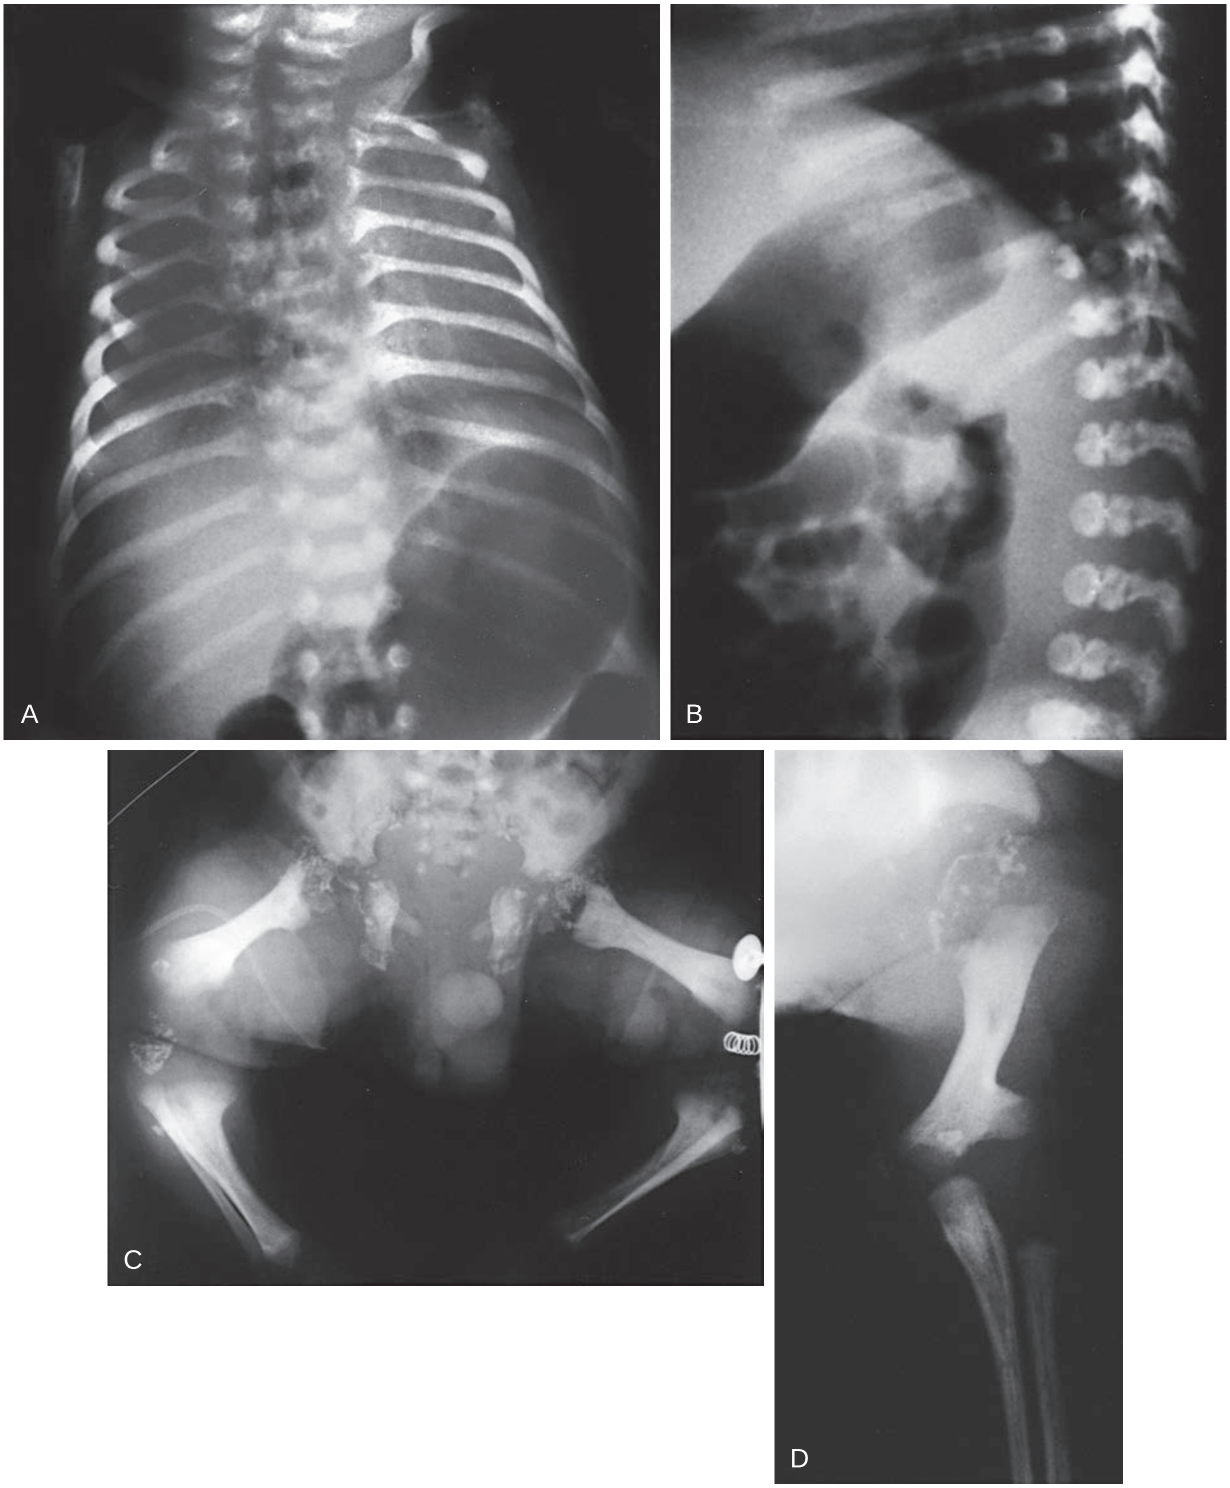

**Figure 132.29. Rhizomelic chondrodysplasia punctate in a newborn.** (A and B) Radiographs reveal a small thorax, punctate vertebral body ossification, and coronal clefting. (C and D) Diffuse stippling in epiphyseal regions and rhizomelia (femurs and humeri).

## Osteopetrosis

Our understanding of osteopetrosis has evolved considerably and no less than 13 general mutation loci have been described. For clinical purposes, the disease can be distinguished by age at onset. The types with onset in infancy are the most severe.

The very severe precocious or malignant type is autosomal recessive. Patients with this type present in infancy with hepatosplenomegaly, pancytopenia, multiple infections (osteomyelitis), and leukemia. Early death is common. The delayed type (late-onset form) is autosomal dominant. Lifespan is normal, and the condition is frequently diagnosed when a radiograph is obtained after minor

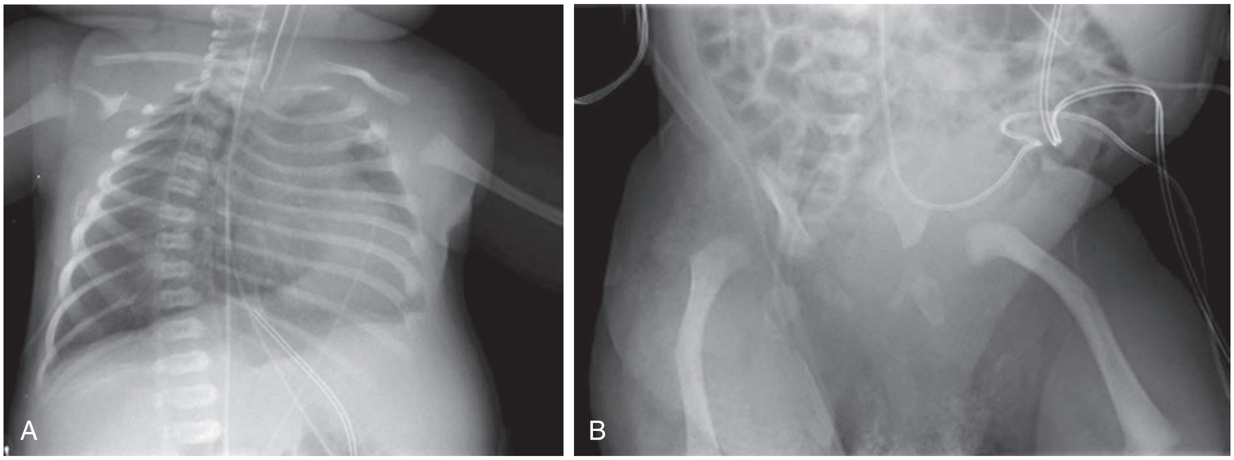

**Figure 132.30. Campomelic dysplasia in a newborn.** (A) Chest radiograph reveals slender ribs and marked scapular hypoplasia. (B) Frontal radiograph of the pelvis and thighs shows classic bent bone appearance of the femurs. Both hips are dislocated and the pelvis is very narrow.

trauma causes a fracture. Individuals with this type sustain multiple fractures and are at increased risk of osteomyelitis, particularly in the mandible.

The condition known as *osteopetrosis with renal tubular acidosis (carbonic anhydrase II deficiency)* is a rare entity localized to chromosomal locus 8q and gene *CA2* (carbonic anhydrase II). Diffuse dense cerebral calcifications suggest the correct diagnosis.

An intermediate form is also recognized with onset within the first decade, and although significant clinical abnormalities are present, including hematologic disease, findings are milder than in the infantile form.

Although multiple genes are involved, the defect ultimately leads to osteoclast dysfunction because of unresponsiveness to parathyroid hormone. Without the remodeling activity of normal osteoclasts, bone becomes sclerotic and brittle. Long bone fractures are common.

Of importance is the seemingly contradictory presentation of osteopetrosis with rickets. This occurs in the severe malignant form. With this combination, dense osteopetrosis changes are seen in conjunction with rickets physeal changes. It can be understood when considering that 99% of the calcium store is bound in highly calcified dense bone. Without osteoclast function, that calcium is unavailable for correct physeal growth and mineralization, and a relative calcium deficiency is present.

Bone marrow transplantation is curative as it repopulates the marrow with normally functioning osteoclasts.

***Radiologic Findings*** (e-Fig. 132.31 and Fig. 132.32)

1. Generalized increased bone density
2. *Skull:* thick and dense, especially at the base
3. *Thorax:* splayed anterior ribs
4. *Spine:* “sandwich” vertebral bodies, “picture frame” vertebral bodies
5. *Extremities:* splayed metaphyses, bone-within-bone configuration, dense metaphyseal bands
6. *Central nervous system*: carbonic anhydrase II deficiency has diffuse dense cerebral calcifications

## Pyknodysostosis

Pyknodysostosis is an autosomal-recessive disorder that often manifests in infancy. Clinical findings include short-limbed dwarfism, micrognathia, fractures, and short fingertips. The impressionist painter Toulouse-Lautrec likely had this condition.[27]

***Radiologic Findings*** (Fig. 132.33)

1. Generalized osteosclerosis
2. *Skull:* marked delay in closure of fontanels and sutures, wormian bones, obtuse or absent mandibular angle, dense skull
3. *Thorax:* resorbed acromial ends of clavicles
4. *Extremities:* resorbed phalangeal tufts mimicking acro-osteolysis

## Osteopoikilosis

This is an autosomal-dominant condition caused by mutations in LEMD3.[28] The gene function and its relationship to this disease are not clear. It is often asymptomatic and identified on routine radiographs. These lesions often show increased uptake on bone scans. When skin lesions of dermatofibrosis are also present, the combination is called *Buschke-Ollendorff syndrome*.

***Radiologic Findings*** (Fig. 132.34)

- Small foci of bone sclerosis (round, oval, lenticular) located primarily in cancellous bone

## Osteopathia Striata

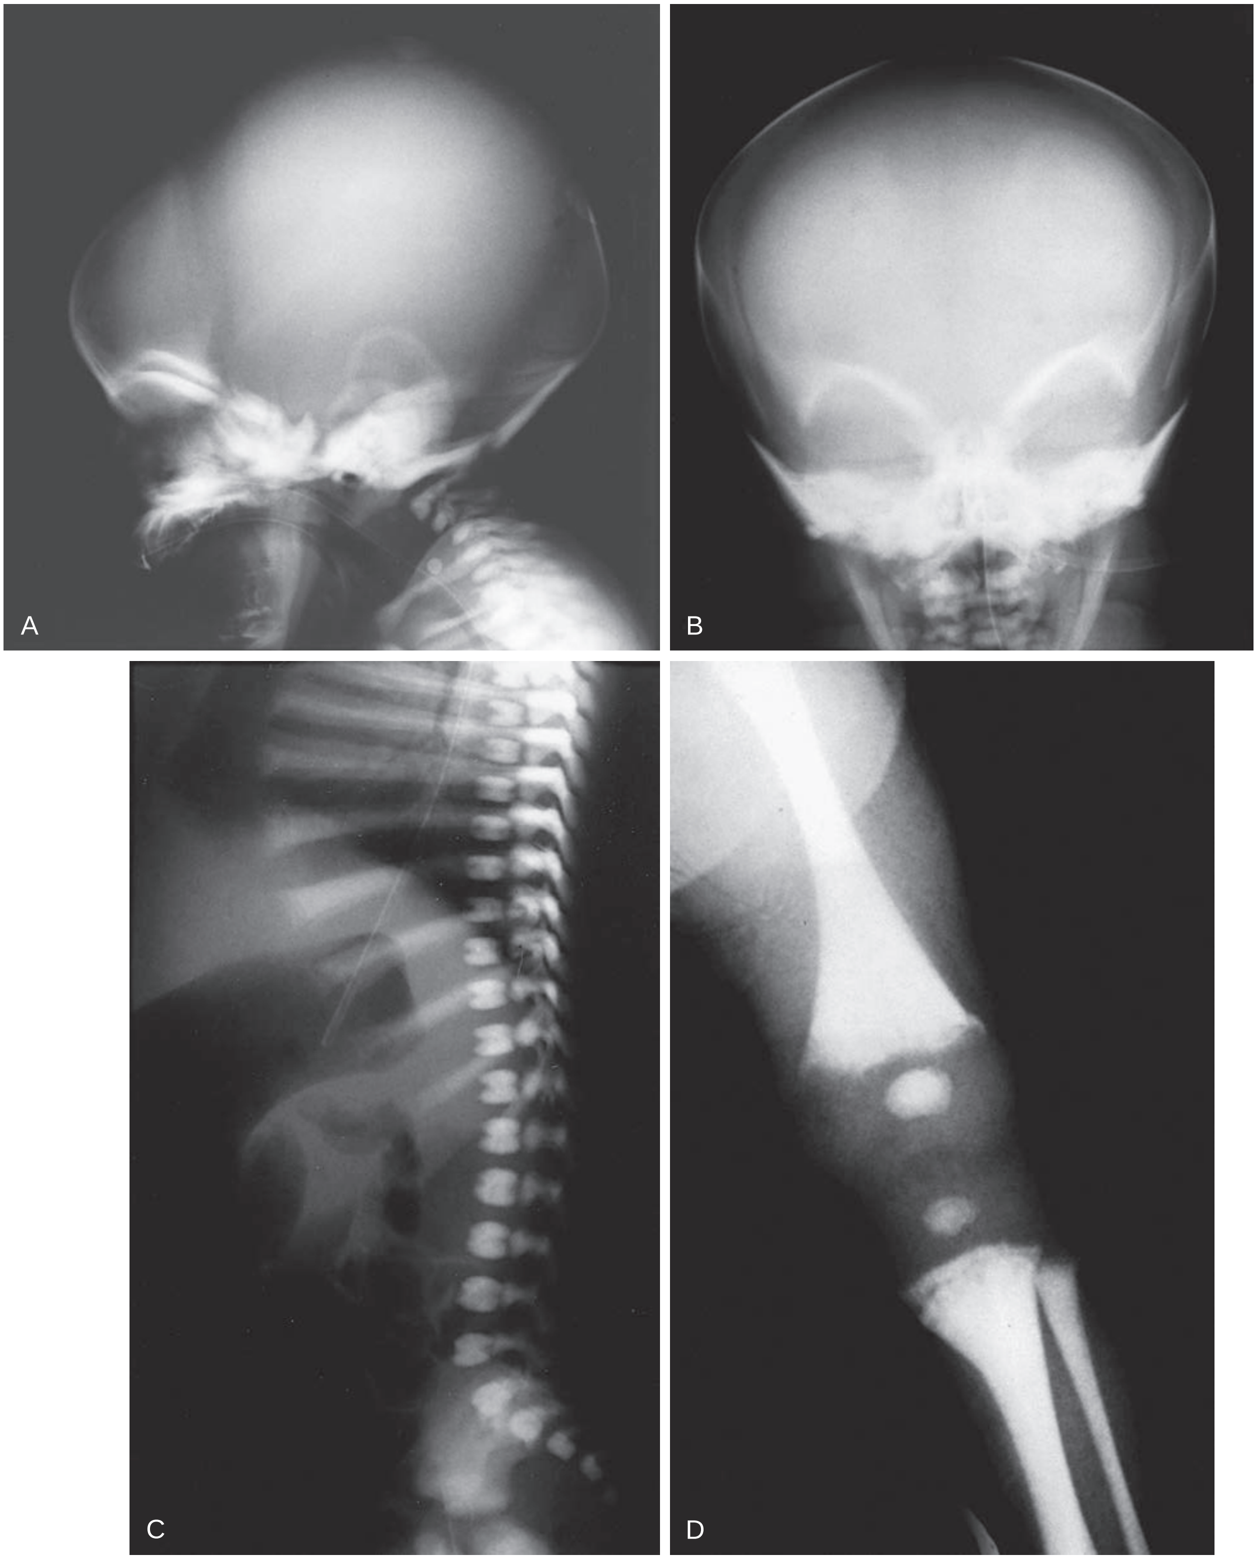
This is an asymptomatic sporadic condition, but when associated with cranial sclerosis, it is an X-linked dominant disorder. It is often identified on routine radiographs as a “normal variant.” It can be seen, however, as a manifestation of other discrete disorders such as the dysplasia of spondylar changes, nasal anomaly, and striated metaphyses (SPONASTRIME).

***Radiologic Findings*** (Fig. 132.35)

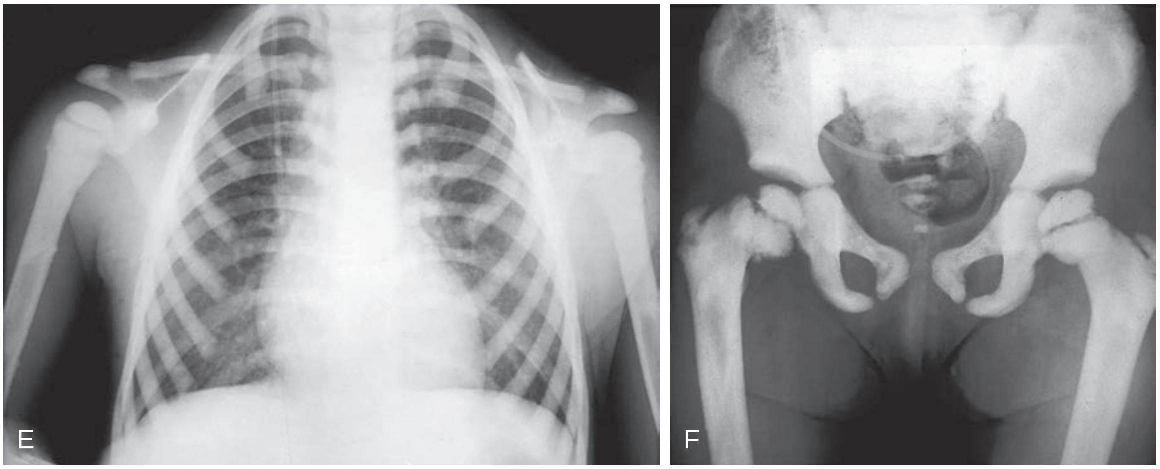
1. Vertical, fine, dense, linear striations
2. Most common at the ends of the long tubular bones, skull and clavicles unaffected
3. No uptake on bone scan

## Melorheostosis

This is often sporadic but can be seen as an autosomal dominant entity in families with an *LEMD3* gene mutation, similar to osteopoikilosis. Patients can experience bone pain and joint stiffening, as well as limb asymmetry.



**e-Figure 132.31. Precocious-type osteopetrosis (autosomal recessive).** (A–C) Radiographs from a newborn. (A and B) Dense skull and face, especially skull base. (C) Dense spine and ribs. (D) At 3 months, very dense long bones, medullary obliteration, and frayed metaphyses (rickets) are present. Precocious-type osteopetrosis (autosomal recessive). (E and F) Radiographic findings at 4 years. *Continued*



**e-Figure 132.31, cont'd.** (E) Dense thorax (ribs, clavicles, scapulas) and upper extremity long bones (*note:* less medullary obliteration). (F) Dense pelvis and lower extremity long bones (including capital femoral epiphyses), and bilateral pathologic femoral neck fractures.

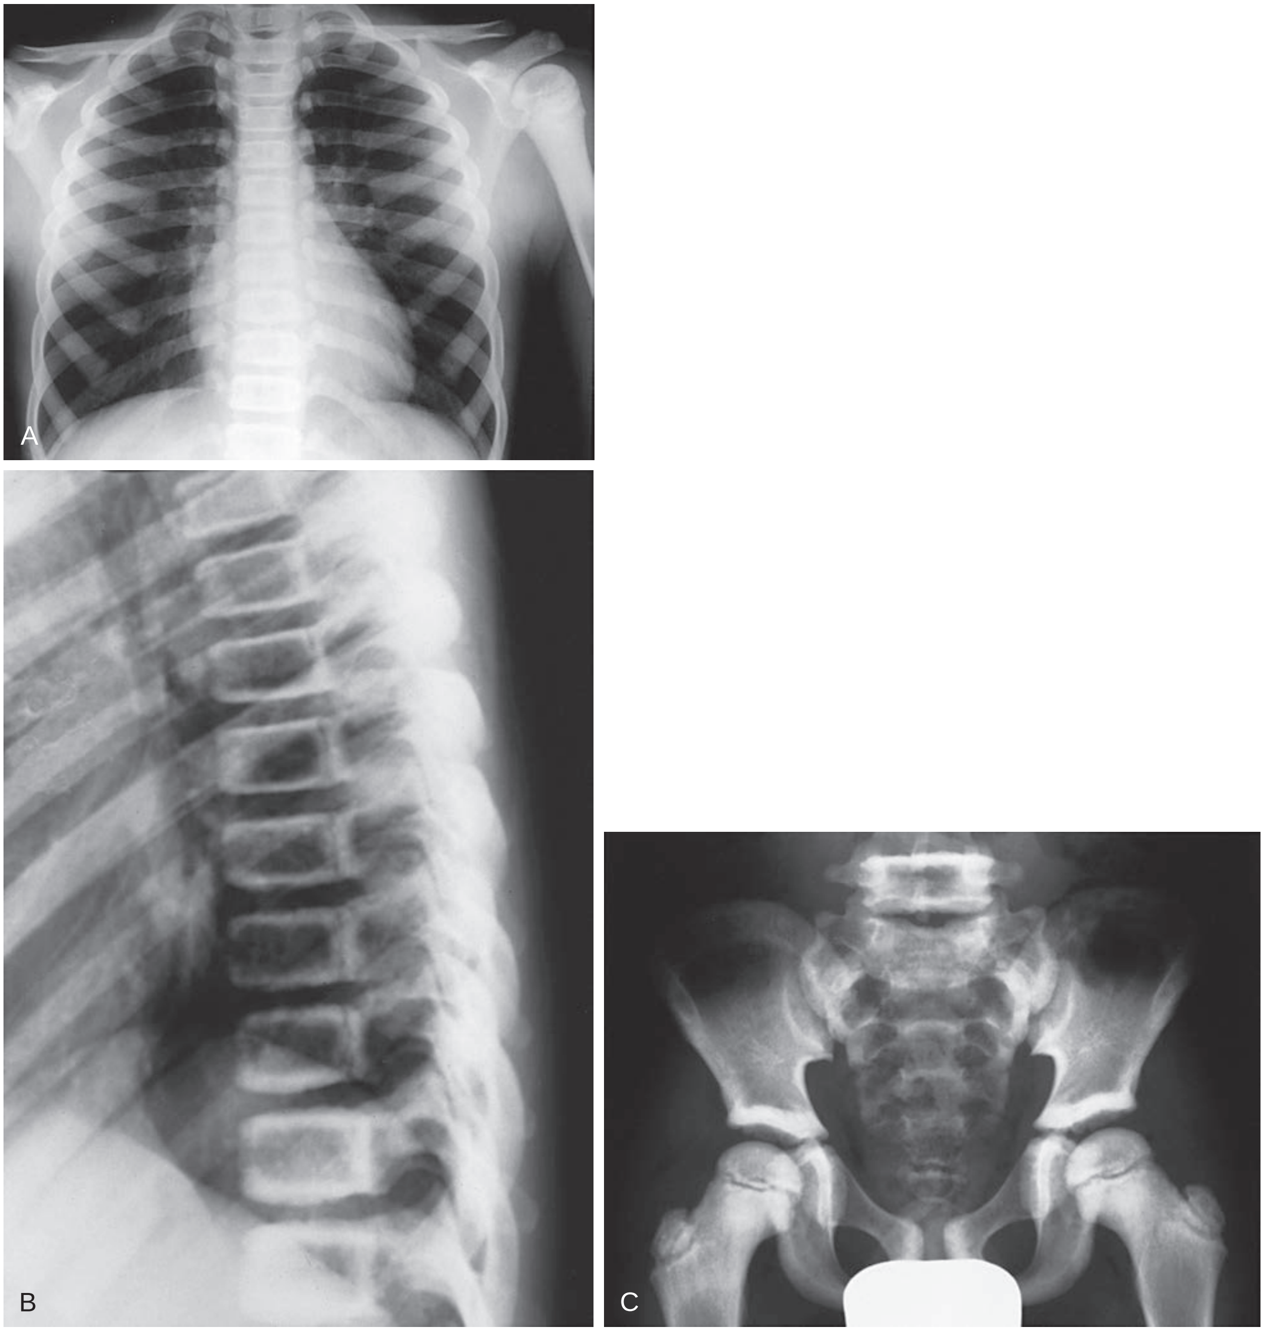


**Figure 132.32. Delayed-type osteopetrosis (autosomal dominant) in an 8 year old.** (A) Radiographs reveal dense thoracic bones without medullary encroachment of left humerus. (B) "Sandwich," almost "picture frame" vertebral bodies (dense outer borders). (C) Increased bone density outlining ileum, including supraacetabular regions, and pubic symphysis region, as well as dense proximal femoral epiphyses and femoral necks with sparing of lower medullary space.

***Radiologic Findings*** (Fig. 132.36)

1. Monostotic or polyostotic usually affecting the same extremity
2. Linear dense cortical hyperostosis following the long axis of bones that resembles melting or dripping candle wax
3. Can be present across joint space
4. Increased uptake on bone scan

## INCREASED BONE DENSITY GROUP WITH METAPHYSEAL AND DIAPHYSEAL INVOLVEMENT

This group includes the craniotubular dysplasias. The hallmark is sclerosis of the long bones with either a diaphyseal or a metaphyseal focus and abnormal calvarial thickening and sclerosis. Craniodiaphyseal dysplasia, craniometaphyseal dysplasia, and Pyle dysplasia are described here.

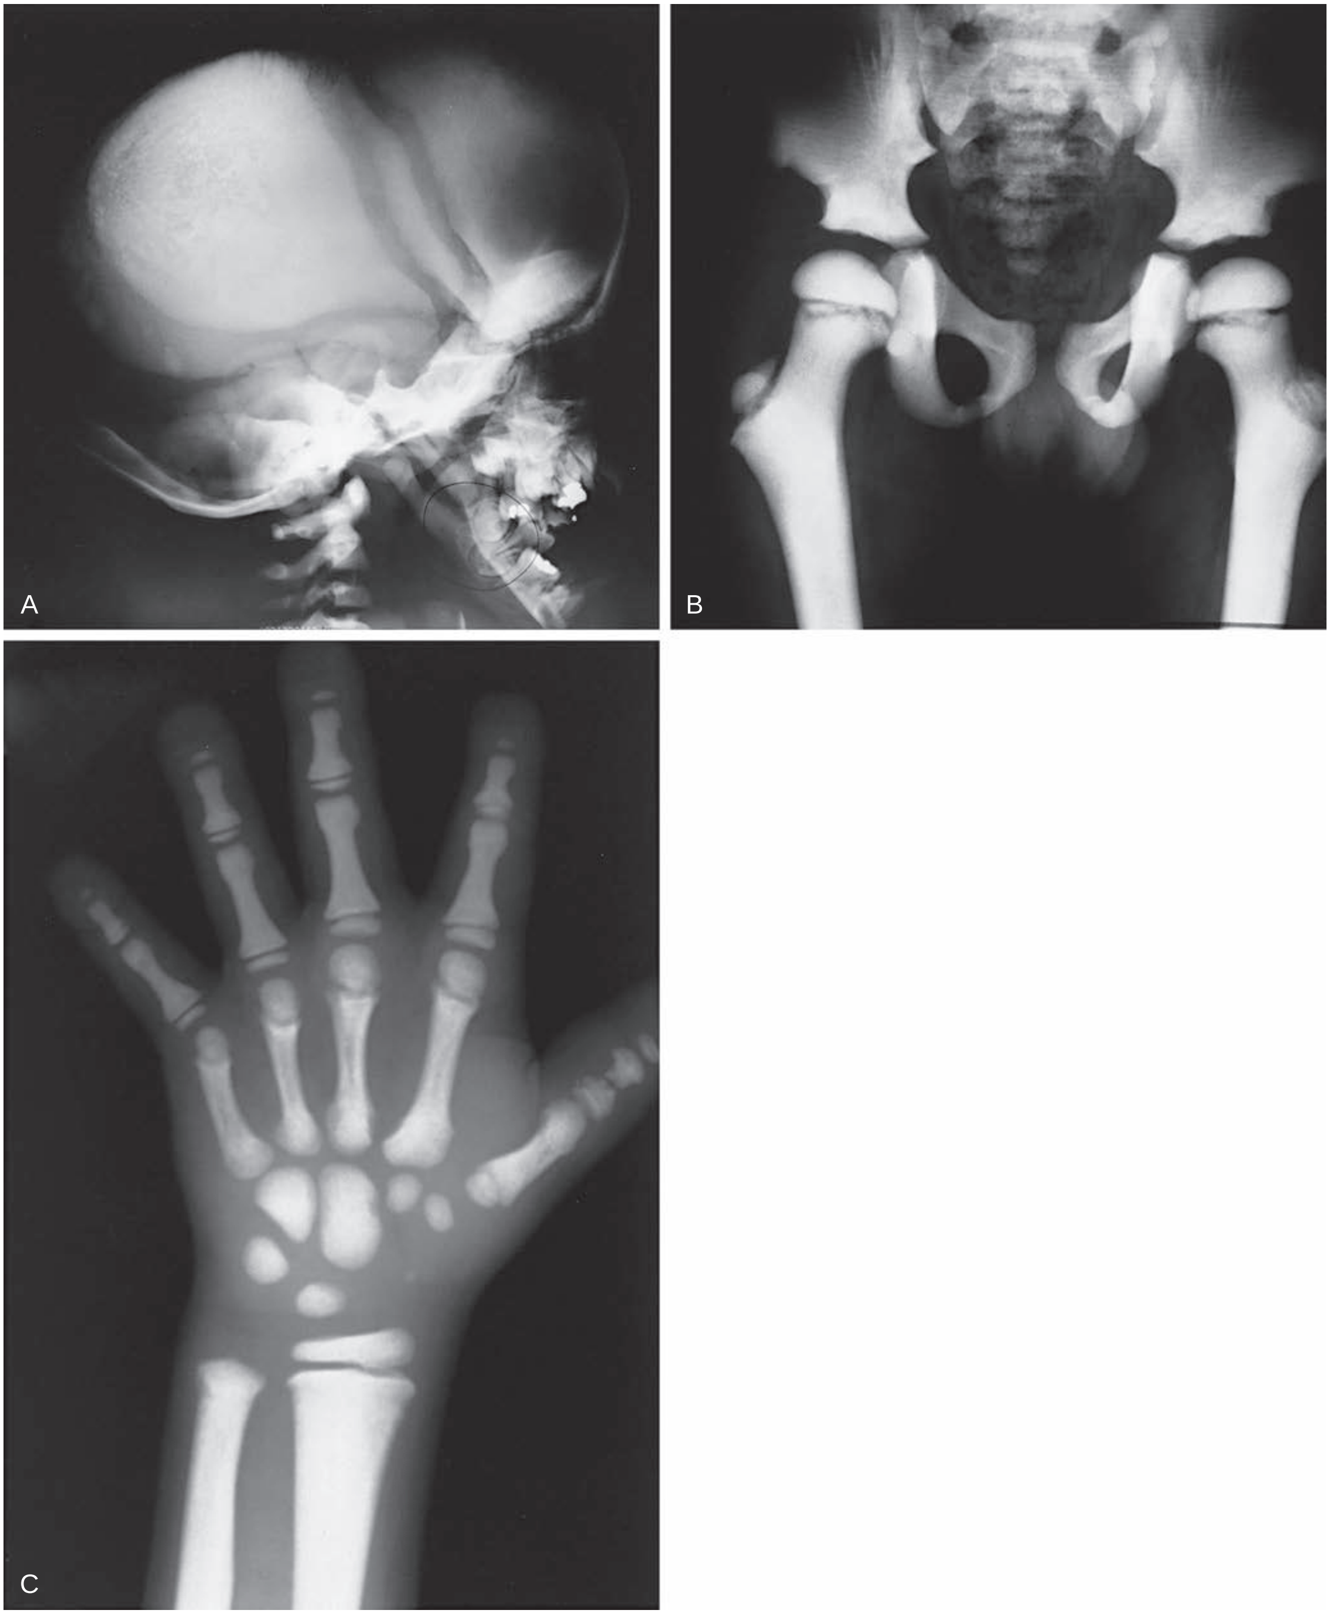

**Figure 132.33. Pyknodysostosis in an 8 year old.** (A) Radiographs reveal dense skull convexity and base, widely separated sutures with open fontanel, and absence of mandibular angle. (B) Hip and pelvis: generalized increased bone density with long, overmodeled (resorbed) femoral necks. (C) Hands: dense bones, overmodeled metacarpals and phalanges, phalangeal tuft resorption.

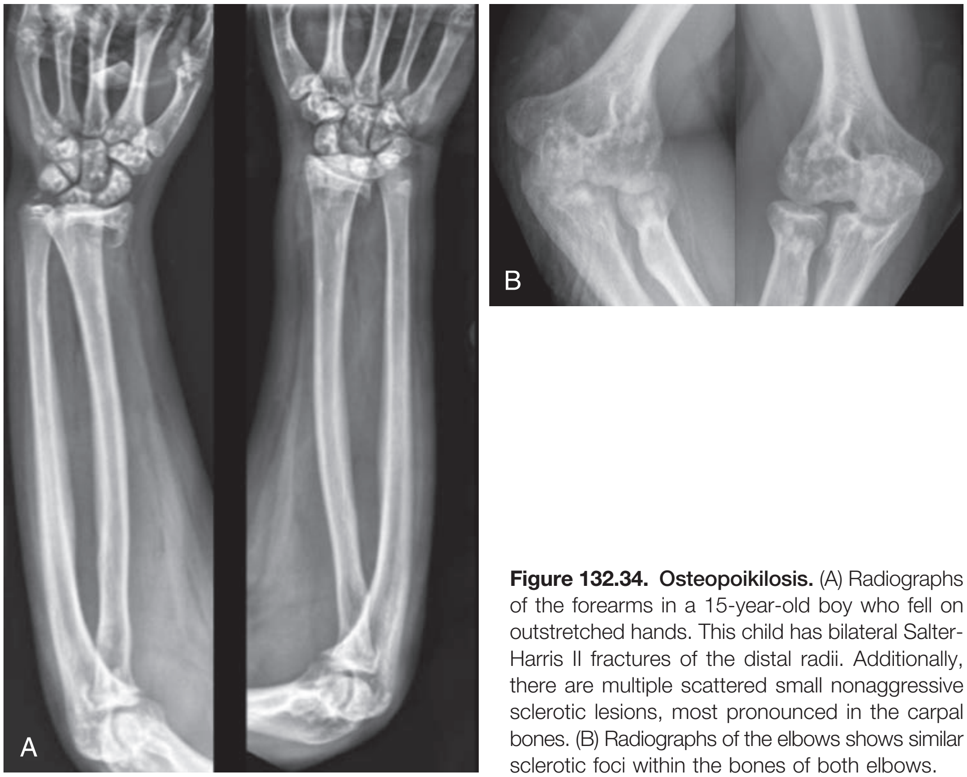

**Figure 132.34. Osteopoikilosis.** (A) Radiographs of the forearms in a 15-year-old boy who fell on outstretched hands. This child has bilateral Salter-Harris II fractures of the distal radii. Additionally, there are multiple scattered small nonaggressive sclerotic lesions, most pronounced in the carpal bones. (B) Radiographs of the elbows shows similar sclerotic foci within the bones of both elbows.

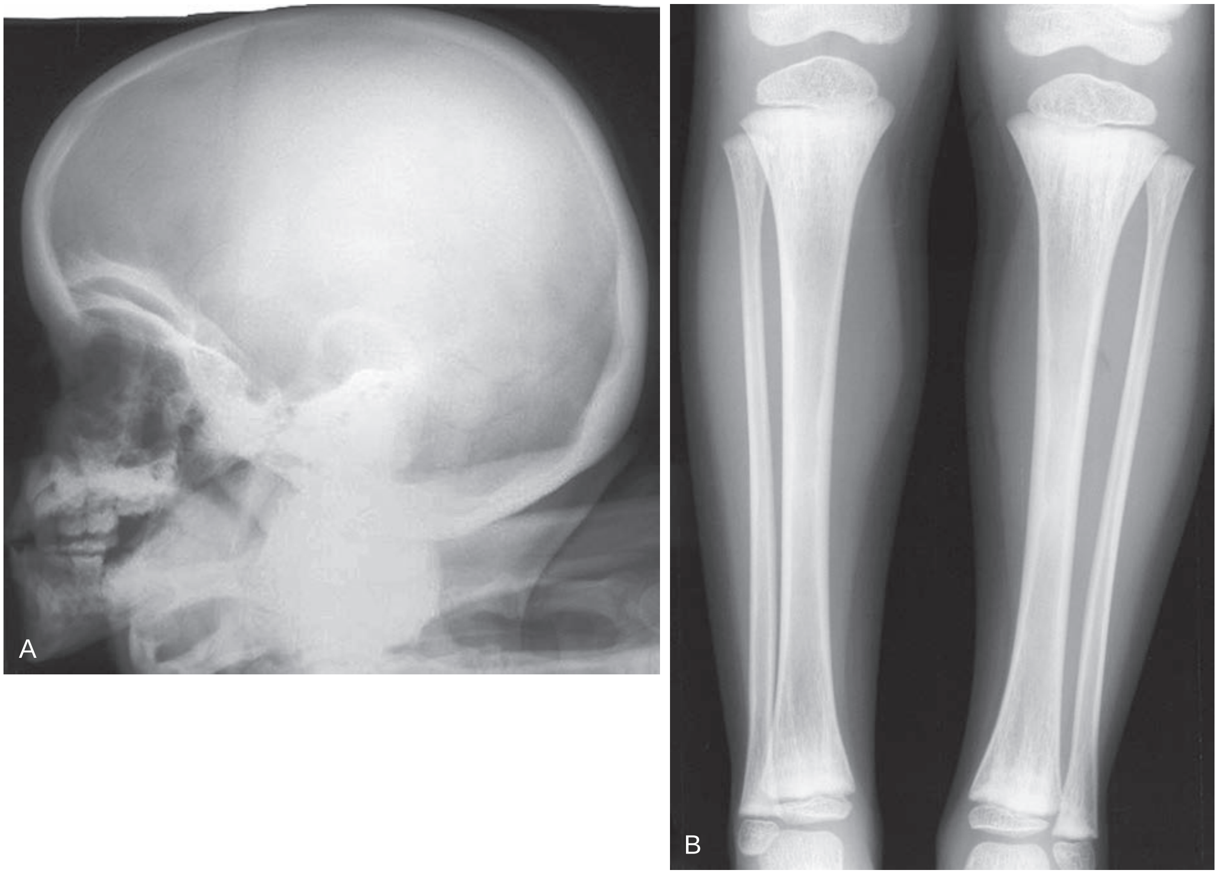

**Figure 132.35. Osteopathia striata with cranial sclerosis.** (A) Lateral skull film revealing dense thickening of the calvaria with increased basilar and orbital sclerosis. (B) An anteroposterior radiograph of the lower extremity reveals linear striations of the metadiaphyseal regions of both ends of the tibias and fibulas.

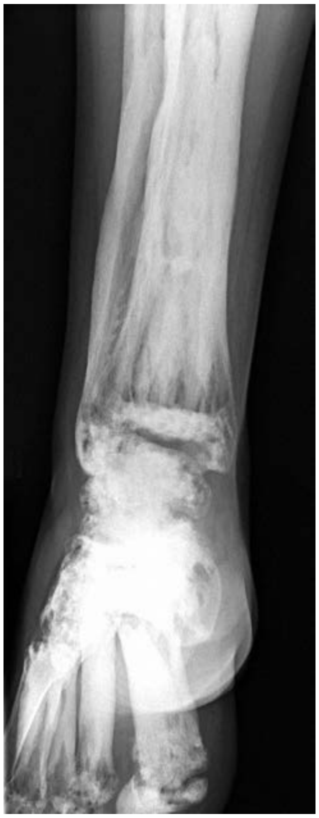

**Figure 132.36. Melorheostosis in a 14-year-old boy.** The image of the tibia and fibula and the ankle shows dense "candle-wax dripping" changes involving both tibia and fibula, extending into the epiphyses and present across the joint into the tarsal–metatarsal bones.

## Craniodiaphyseal Dysplasia

This rare autosomal-recessive condition manifests in early infancy with progressive facial and calvarial thickening. Sudden death, as the result of cranial foraminal narrowing, is frequent.

***Radiologic Findings*** (Fig. 132.37)

1. *Skull:* marked thickening and sclerosis of calvaria and facial bones, obliteration of foramina and sinuses
2. *Thorax:* diffusely widened, sclerotic ribs and clavicles
3. *Extremities:* straightened, undermodeled long bone with diaphyseal widening with metaphyseal sparing; "flame" sclerosis (cortical thickening) of the short-tubular bones (hands)

## Craniometaphyseal Dysplasia

Two forms of this disease are described on two different gene loci. Both are similar but the autosomal-recessive form is more severe and manifests as cranial and facial thickening, often with nasal obstruction. Improvement may occur with age. Cranial encroachment–induced neurologic abnormalities may develop.

***Radiologic Findings*** (e-Fig. 132.38)

1. *Skull:* diffuse hyperostosis of cranial vault base and facial bones, obliterated paranasal sinuses
2. *Extremities:* sclerosis of diaphyses with normal metaphyseal modeling (early), undermodeled flared metaphyses of long bones with normal diaphyses (later)

## Pyle Dysplasia

This autosomal-recessive entity, also known as *familial metaphyseal dysplasia*, is somewhat similar to craniometaphyseal dysplasia but differs in its minimal craniofacial involvement. Patients are often asymptomatic or develop genu valgum (knock knee).

***Radiologic Findings*** (Fig. 132.39)

1. *Skull:* mild skull and facial involvement, minimal base-of-skull sclerosis, prominent supraorbital ridging
2. *Thorax:* mildly thickened clavicles and ribs, mild platyspondyly
3. *Pelvis:* thickened ischium and pubis
4. *Extremities:* marked undertubulation of long bones, especially distal femurs (Erlenmeyer flask deformity); distal flaring of metacarpals and proximal flaring of phalanges

## OSTEOGENESIS IMPERFECTA AND DECREASED BONE DENSITY

The cardinal feature of OI is increased bone fragility. Clinically, a bluish hue to the sclerae may be seen.

OI is classified according to the Sillence classification. Originally including only four types, many types have now been described. The Sillence classification describes a spectrum of disease rather than a strict system based on objective scientific identities such as molecular genetics. In fact, we know now that multiple allelic mutations affect collagen I and cause OI, although other OI types are unrelated to collagen I abnormalities.

***Radiologic Findings, Severe Type*** (Fig. 132.40)

1. *Skull:* very poor to no ossification
2. *Thorax:* small, narrow chest; beaded ribs from healing fractures
3. *Spine:* severe deossification, collapsed vertebral bodies
4. *Extremities:* generalized osteoporosis with or without fractures; shortened, widened long bones with thin cortices; accordion-shaped femurs

***Radiologic Findings, Mild Types*** (e-Fig. 132.41)

1. *Skull:* abnormal number of wormian bones (>8–10), variable decrease in ossification
2. *Spine:* wedged or collapsed vertebrae
3. *Extremities:* at least some osteoporosis, variable number of fractures (especially pathologic fractures)

## ABNORMAL MINERALIZATION GROUP

Among the dysplasias with defective mineralization, one important entity to recognize and discuss is hypophosphatasia.

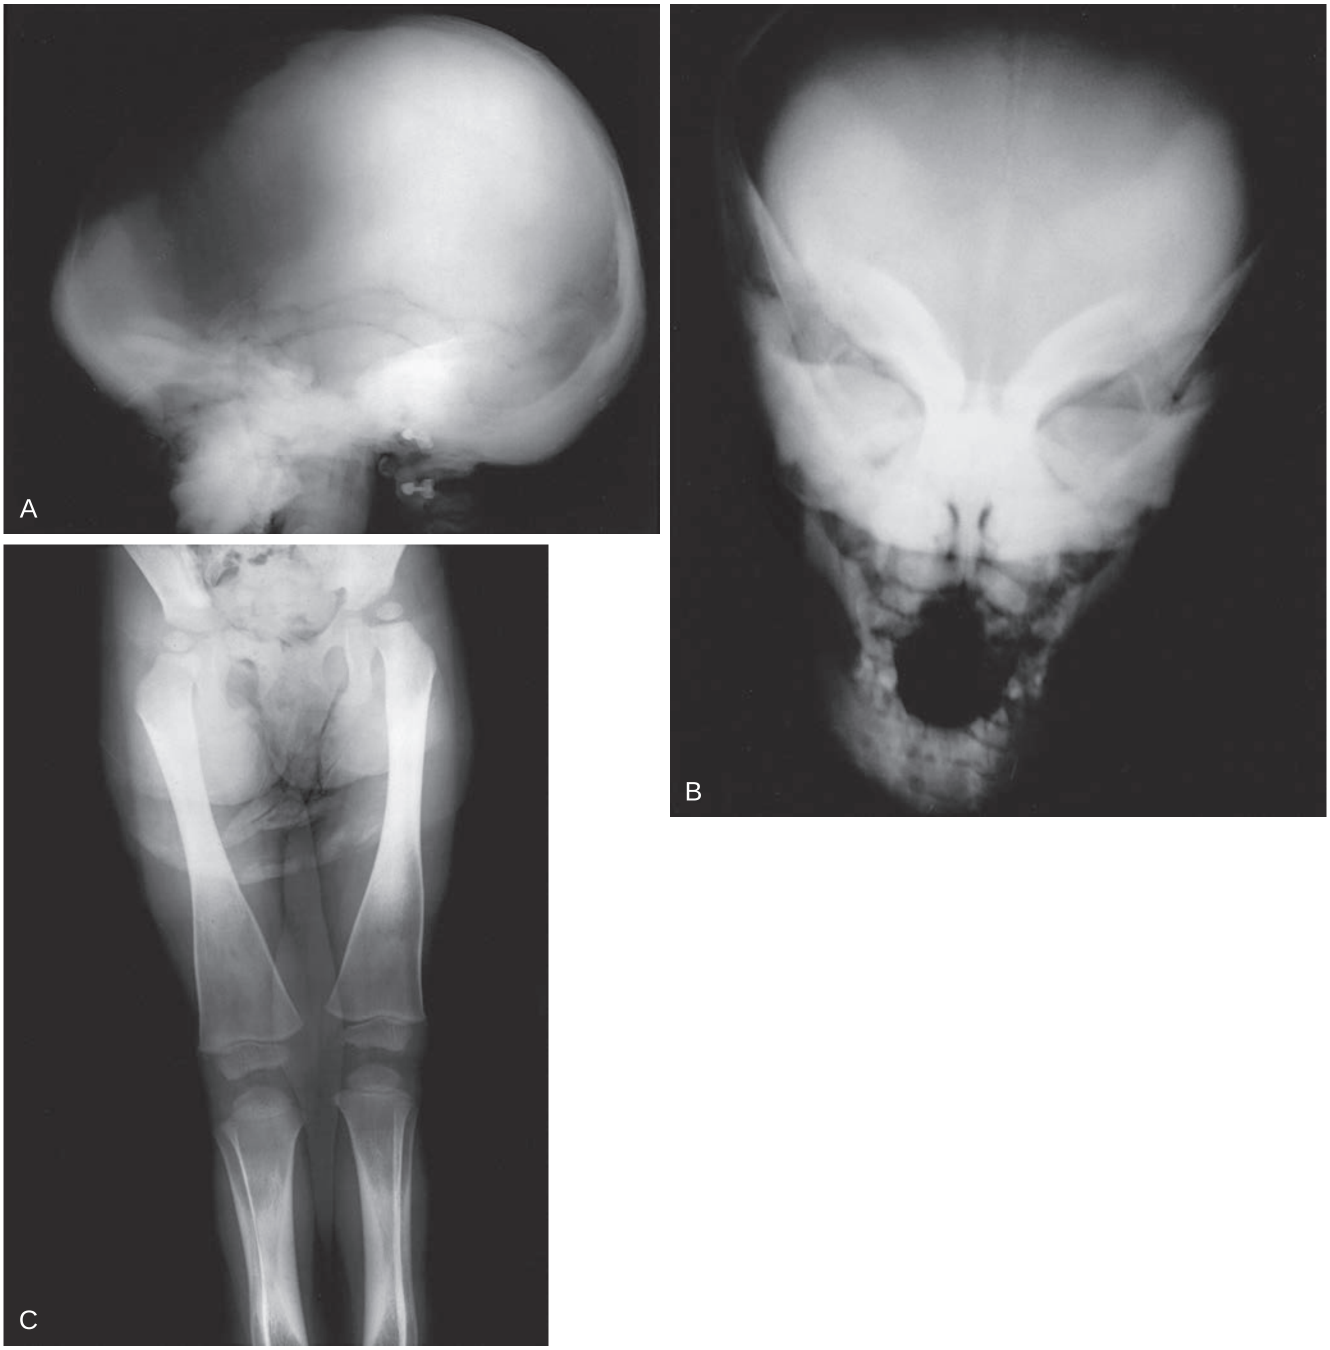
## Hypophosphatasia

The two distinct genetic forms of hypophosphatasia are (1) the autosomal-recessive perinatal lethal or infantile type and (2) a later-onset autosomal-dominant adult type. Both result from an abnormality of the enzyme alkaline phosphatase. The chromosome loci for both conditions are 1p36.1-34 and involve *TNSALP*. As a consequence of defective alkaline phosphatase, bone formation is impaired because of local increase in phosphate, impaired hydroxyapatite formation, and hypercalcemia with resultant rickets-like changes.

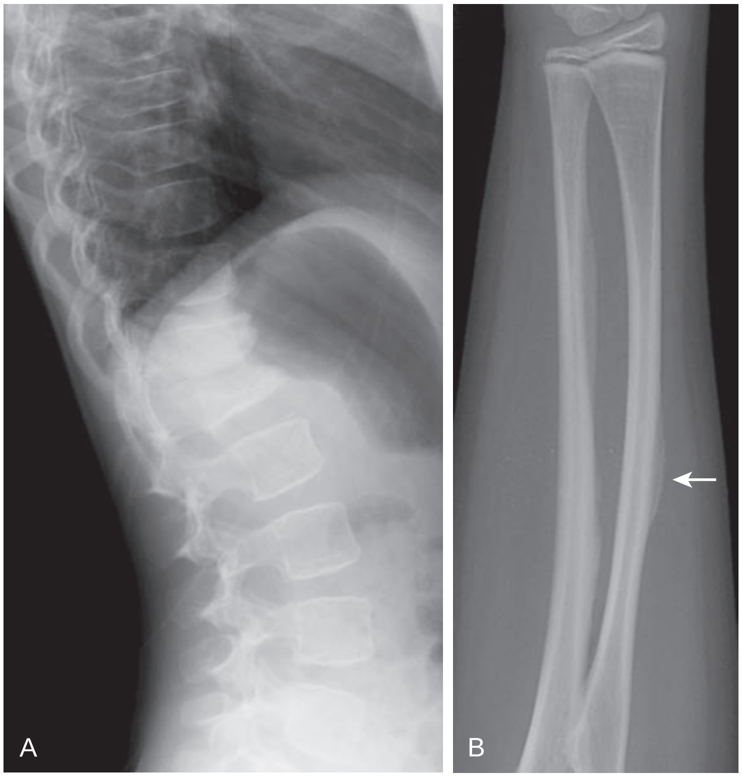
***Radiologic Findings*** (e-Fig. 132.42)

Perinatal lethal/infantile form:

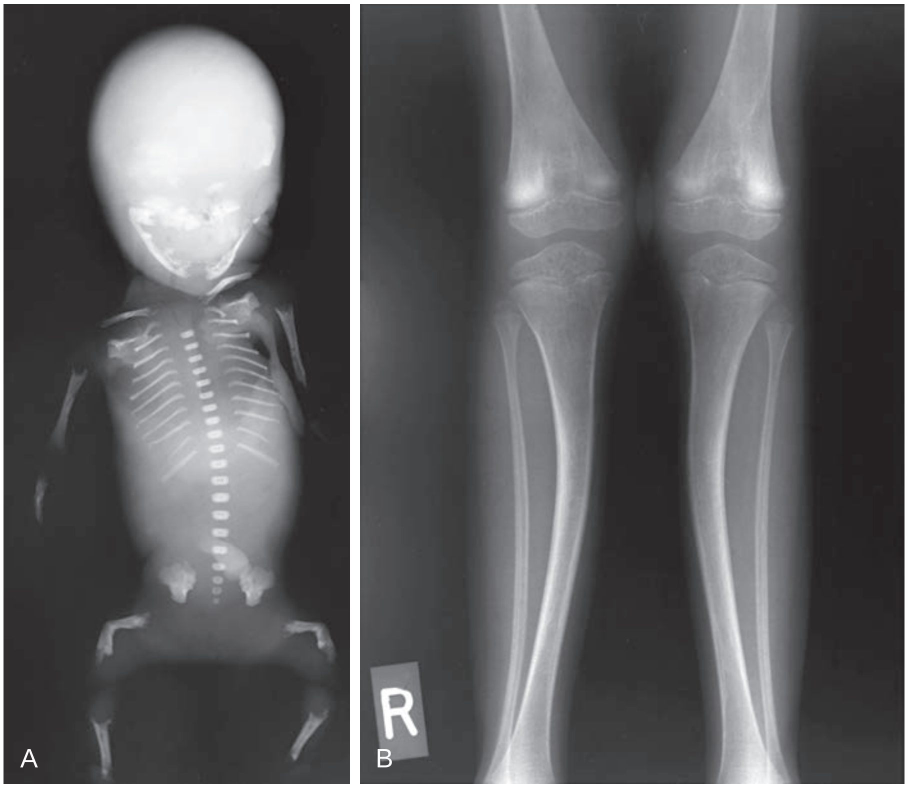
1. *Skull:* decreased ossification with single island-like centers for frontal occipital and parietal bones
2. *Thorax:* poorly ossified ribs; thin, wavy, fractured ribs; clavicles not affected



**e-Figure 132.38. Craniometaphyseal dysplasia in a 2 year old.** (A and B) Marked increased bone density of cranial base and vault, and dense facial bones with obliteration of sinuses. (C) Undermodeled flared metaphyses (Erlenmeyer flask deformity) of distal femurs.



**e-Figure 132.41. Osteogenesis imperfecta type 5 in a 12-year-old girl.** (A) Lateral view of the spine showing multiple vertebral body compression fractures. (B) The anteroposterior view of the forearm shows areas of hyperostosis *(arrow)* and increased density at the zones of provisional calcification at the metaphyses of the distal radius and ulna.



**e-Figure 132.42. Hypophosphatasia.** (A) The radiograph from a fetus with perinatal lethal type demonstrates island-like skull ossification (parietal); thin, wavy ribs; platyspondyly and missing cervical vertebrae ossification; no pedicles; and bent femurs. (B) The radiograph from a 7 year old with adult-type hypophosphatasia demonstrates osteopenia, bent tibias, and punched-out metaphyseal lesions.

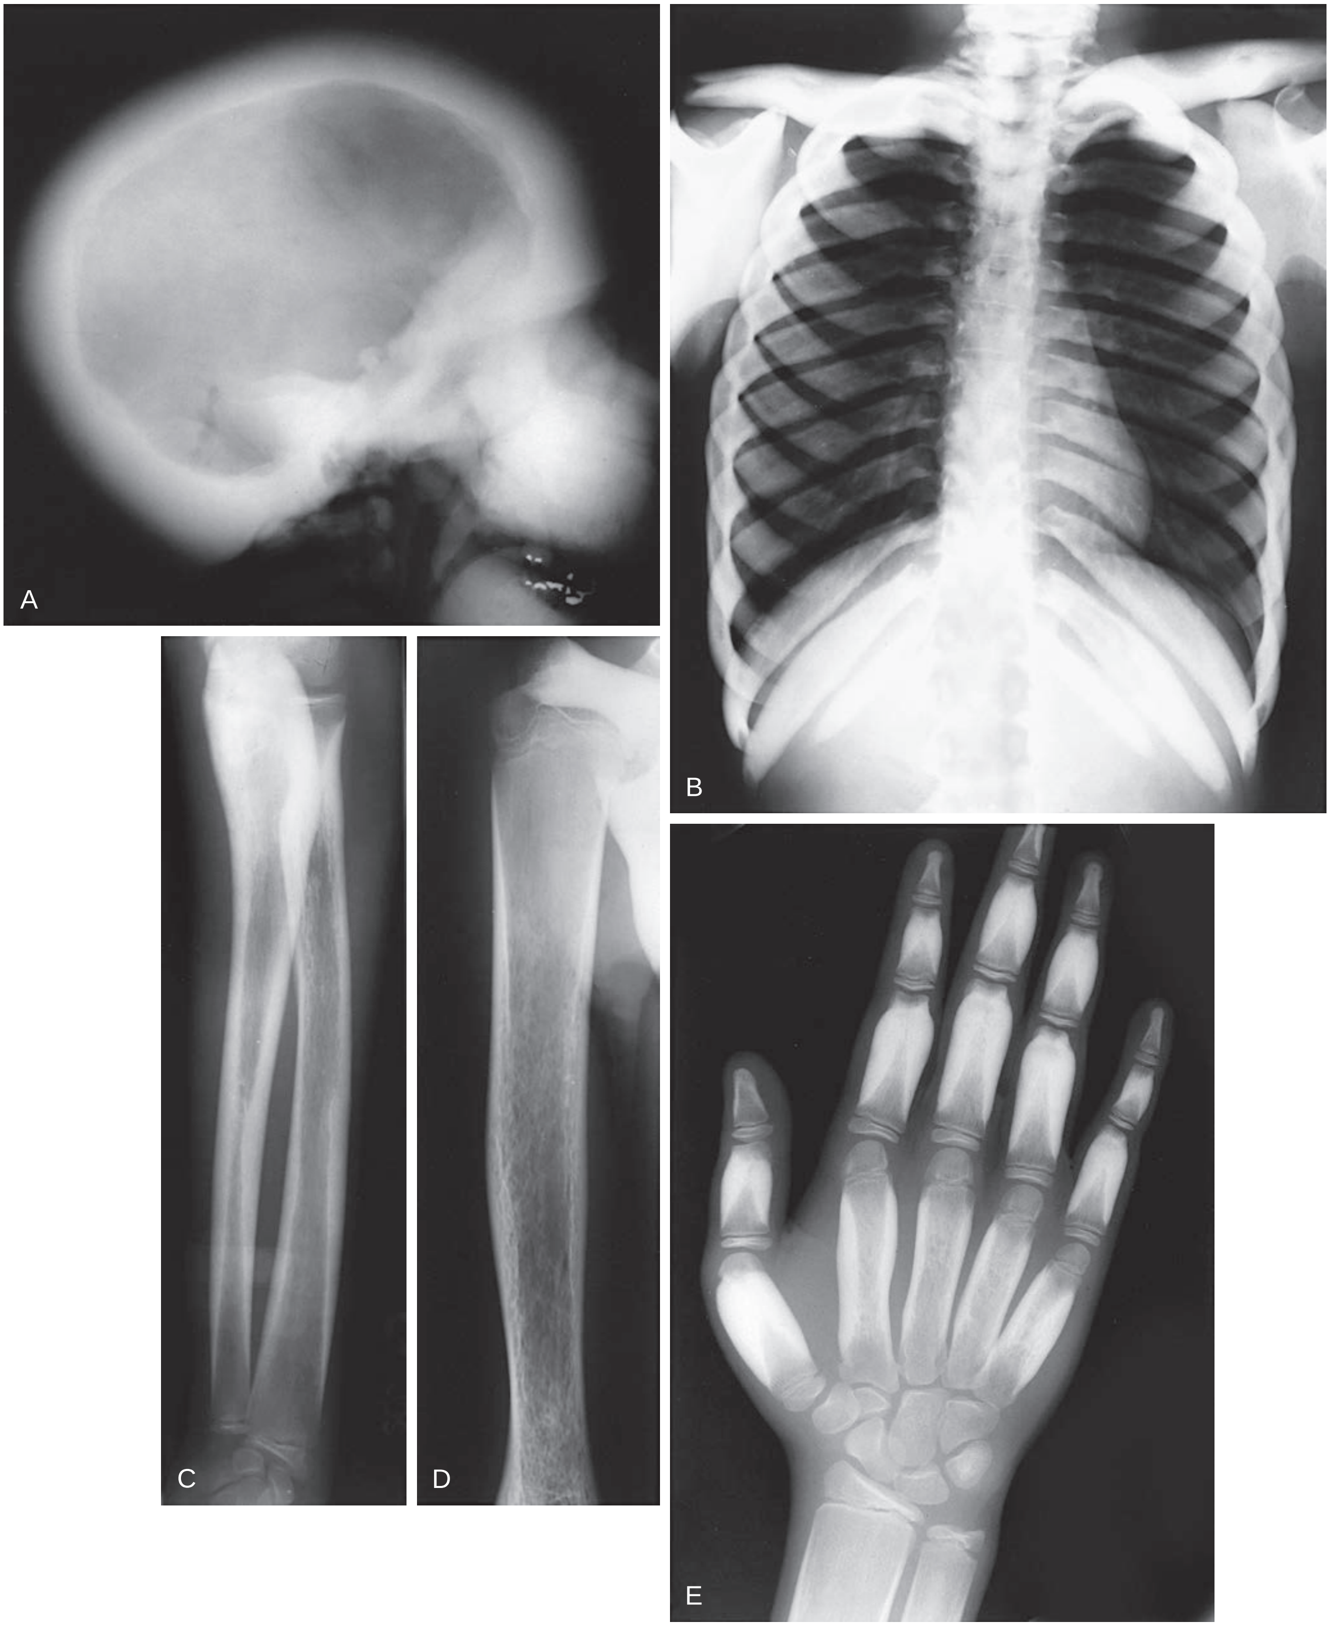


**Figure 132.37. Craniodiaphyseal dysplasia in a 13 year old.** (A) Extremely dense bone filling in the facial region and thickening the diploic space. (B) Diffusely dense, thickened ribs and clavicles. (C and D) Diffuse cortical long bone diaphyseal thickening and diaphyseal undermodeling. (E) “Flame” sclerosis (cortical thickening) of the tubular bones of the hand.

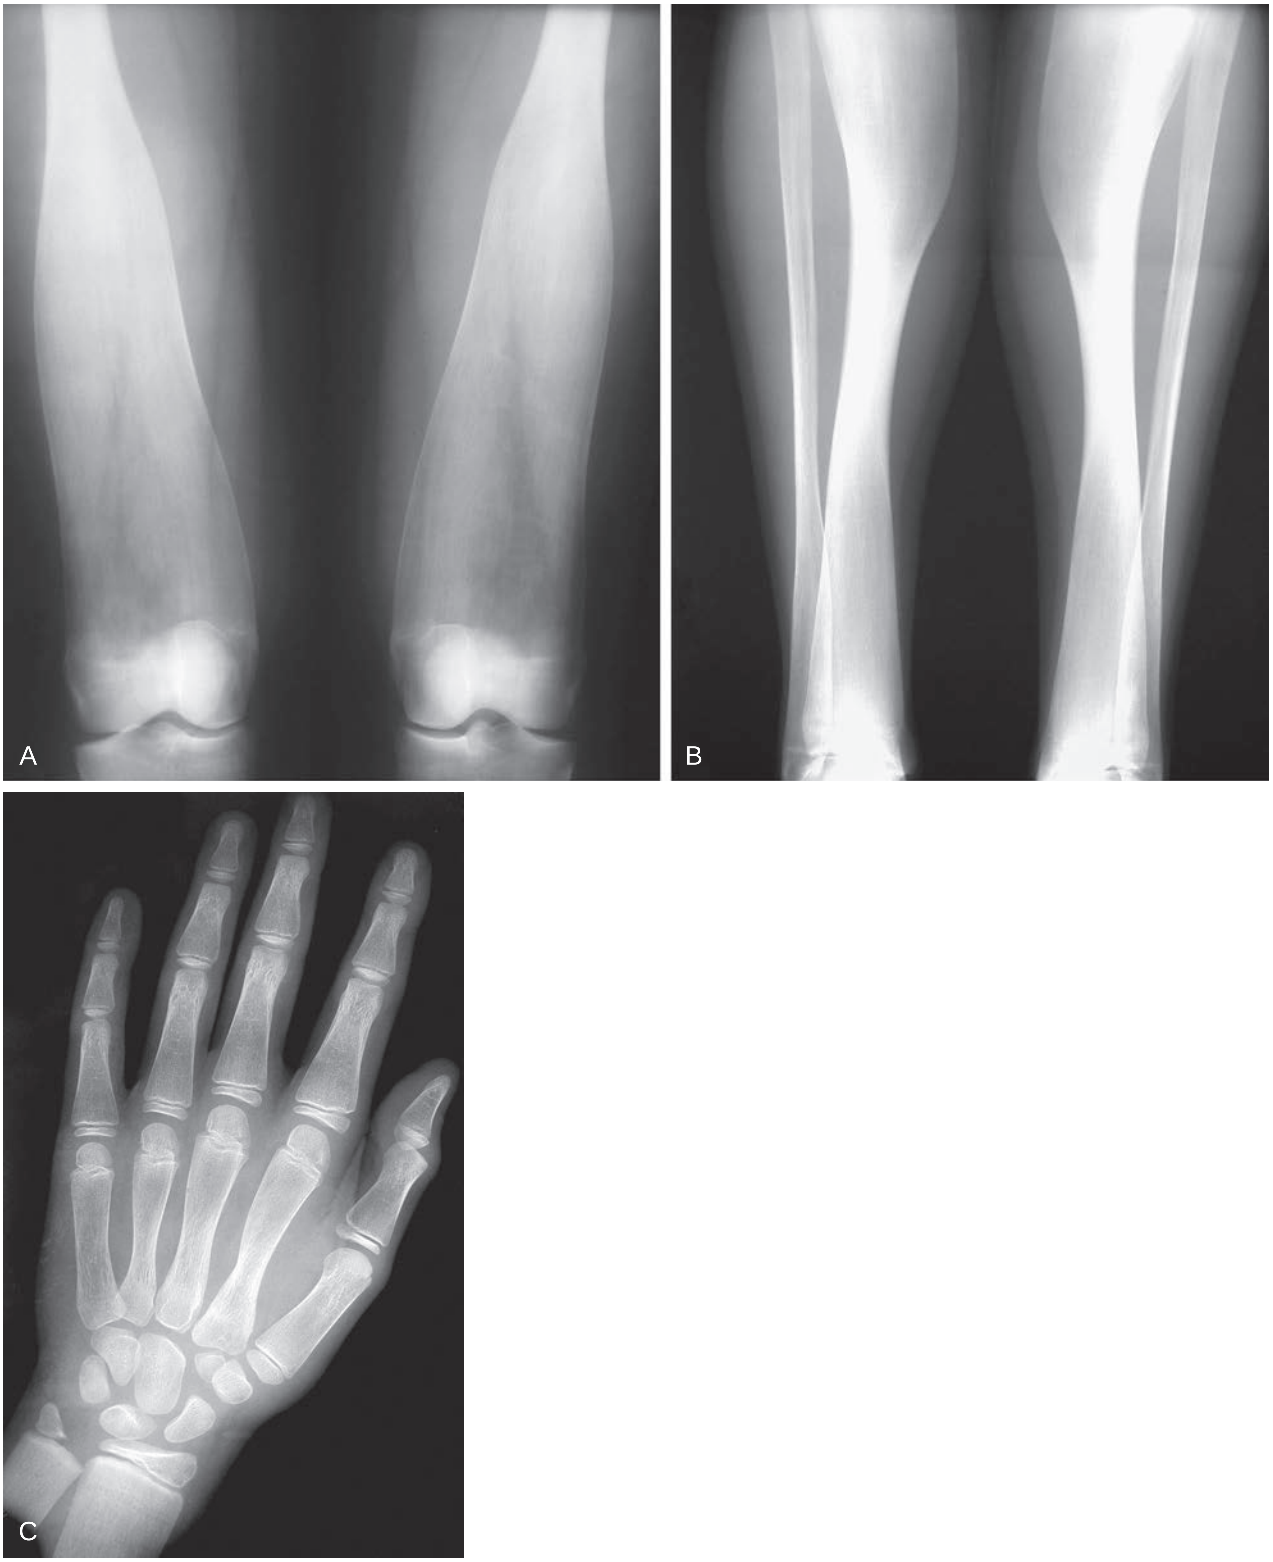

**Figure 132.39. Pyle dysplasia.** (A and B) In an affected 17 year old, markedly broad, undertubulated distal femurs (A) and markedly broad, undertubulated proximal and distal tibias with mild medial bowing proximally (B). (C) In a different patient, distal flaring of metacarpals and proximal flaring of phalanges are seen. The distal radial and ulnar metaphyses are broadened.

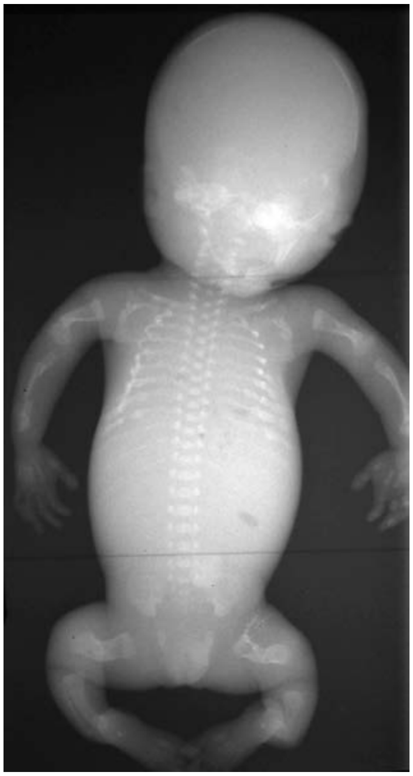

**Figure 132.40. Osteogenesis imperfecta type II in a stillborn full-term fetus.** Findings include generalized osteoporosis, absence of skull ossification, beaded ribs, and crumpled long bones.

3. *Spine:* sporadic unossified vertebral bodies, dense and osteopenic vertebrae, sporadic platyspondyly, butterfly-shaped vertebral bodies, sporadic missing pedicles
4. *Extremities:* generalized decreased ossification, chromosome-shaped femurs, metaphyseal cupping and irregularity, central lucent defect, "campomelic femurs," sporadic "missing" short tubular bones of hands and feet

Adult form:

1. Generalized osteopenia
2. *Extremities:* metaphyseal widening (rickets-like changes), punched-out metaphyseal lesions, pathologic fractures
3. Heterotopic calcifications

## LYSOSOMAL STORAGE DISEASES

The dysostosis multiplex group contains all the mucopolysaccharidoses (MPSs), mucolipidoses, and multiple other storage diseases that produce a skeletal dysplasia. The abnormalities in this entire group consist of well-described enzymatic defects that can be diagnosed by appropriate urine, blood, or fibroblast culture analyses. These diseases act similarly on the skeleton to produce abnormalities of varying severity, termed *dysostosis multiplex*. The real role of the radiologist is to suggest the likelihood of one of these disorders; the geneticist biochemically determines which exact dysplasia is present. Hurler or Hunter syndrome (MPS types IH and II) may be used as stereotypical examples of this group. Morquio syndrome (MPS types IVA and IVB) can often be differentiated from other MPS entities radiographically, as it has very prominent epiphyseal changes. In Hurler or Hunter syndrome, inferior beaking of the vertebral bodies with kyphosis is centered on the thoracolumbar junctions. This is known as *gibbus type abnormality* and is related to hypotonia in affected patients. This is a secondary effect from chronic pressure and stress on the vertebral bodies at the thoracolumbar junction and causes delay in ossification of the inferior portion of the T12 and L1 disc spaces. In Morquio syndrome, the central tongue or beaked appearance is caused by the primary dysplasia from a delay in epiphyseal ossification and causes a delay in ossification at the lower and upper end plates.

### Hurler or Hunter Syndrome (Mucopolysaccharidosis Type IH & II)

The enzyme abnormality is alpha-L-l-iduronidase, located on chromosome 4p. As with all the other members of this group, the inheritance pattern is recessive. Most of the MPS entities manifest clinically in late infancy or early childhood.

***Radiologic Findings (Dysostosis Multiplex)*** (Fig. 132.43)

1. *Skull:* enlarged neurocranium, abnormal J-shaped sella
2. *Thorax:* short, thick clavicles; paddle (oar)–shaped ribs; hypoplastic glenoid
3. *Spine:* gibbus, superior notched (inferior beaked) thoracolumbar vertebral bodies, upper cervical subluxation
4. *Pelvis:* flared, small iliac wings with inferior tapering; steep acetabular roofs
5. *Extremities:* diaphyseal widening of long bones; hands characteristically exhibit brachydactyly, proximal metacarpal "pointing," diaphyseal widening of metacarpals and proximal or middle phalanges, small irregular carpal bones

### Morquio Syndrome (Mucopolysaccharidosis Types IVA and IVB)

The enzyme abnormality is in galactose-6-sulfatase, resulting in the accumulation of excess MPS material in multiple organ systems, including the skeletal system. MPS IVB patients usually have more mild radiographic and clinical findings compared with MPS IVA.

***Radiologic Findings (Differentiating Features From Other Mucopolysaccharidoses)*** (Fig. 132.44)

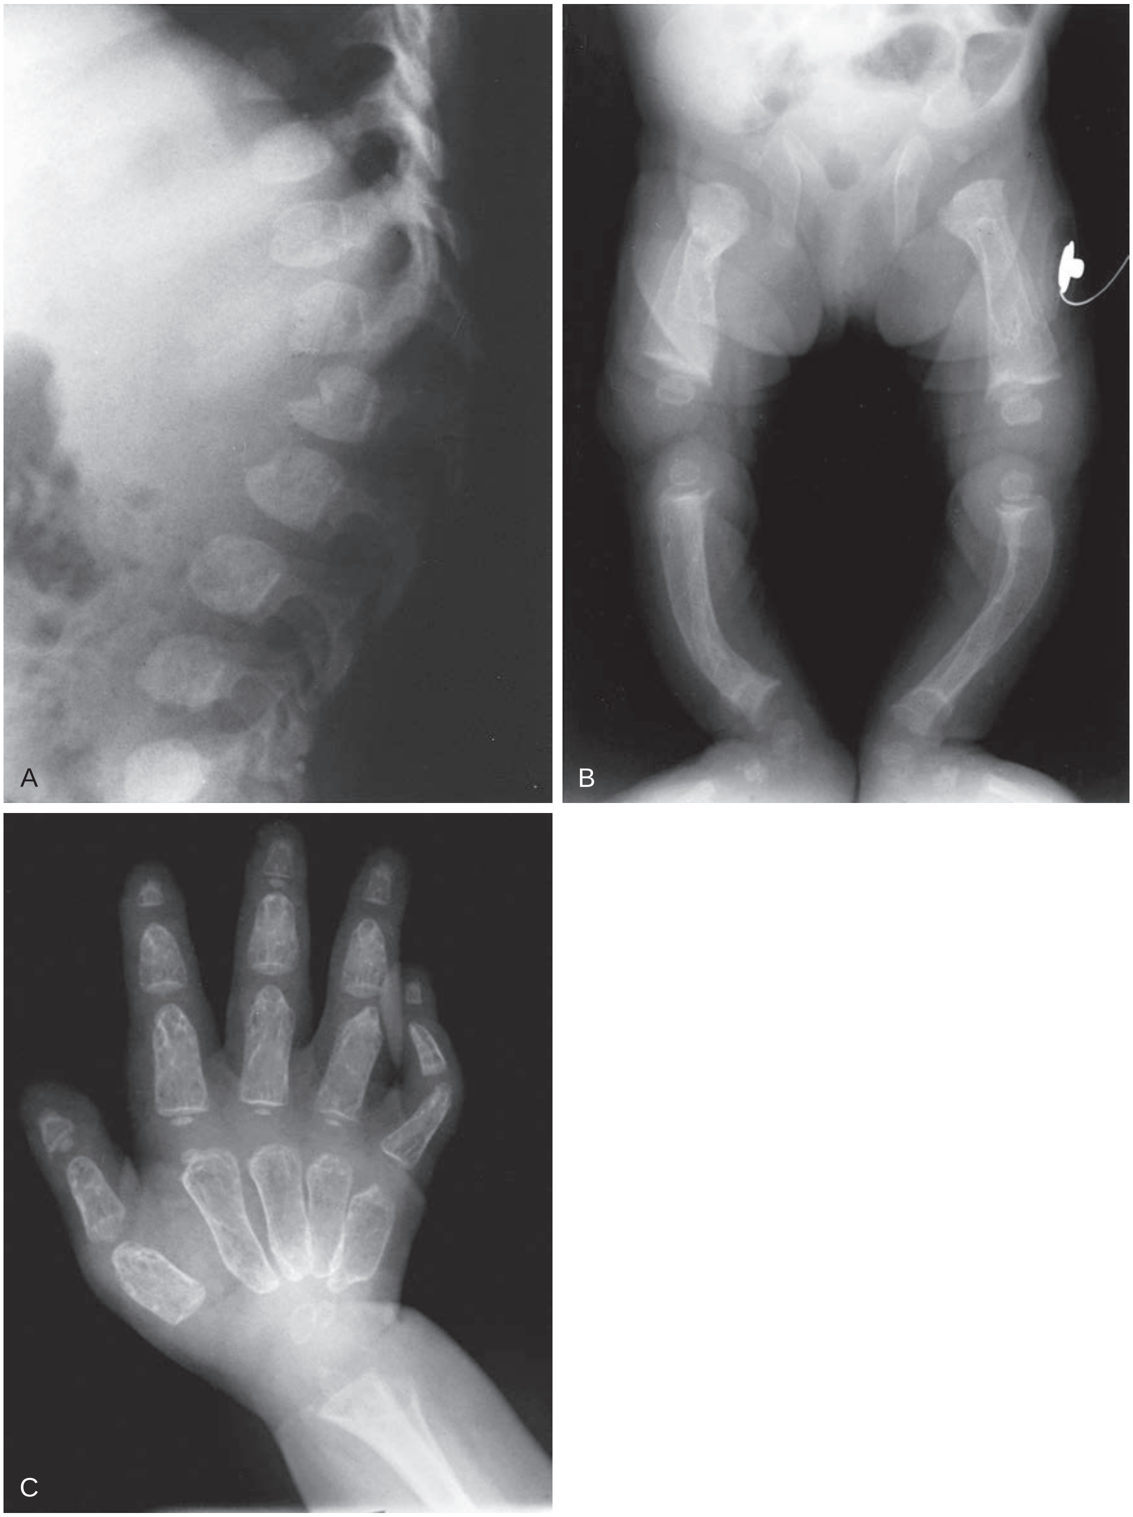
1. *Skull:* no J-shaped sella
2. *Thorax:* widened, not oar shaped, ribs
3. *Spine:* central vertebral beaking or tongue; odontoid hypoplasia and cervical instability
4. *Pelvis:* no tapering of ileum, steep acetabular roofs
5. *Extremities:* proximal metacarpal rounding, genu valgus; epiphyseal dysplasia especially at carpal bones and femoral heads

### Mucolipidosis Type II (I-Cell Disease)

Mucolipidosis type II is an enzyme abnormality of N-acetylglucosamine phosphotransferase, the gene for which is found on chromosome 4q. It clinically and radiographically manifests in the newborn and can be seen prenatally. Most affected patients die in infancy. Certain radiographic features are quite unique.

***Radiologic Findings*** (e-Fig. 132.45)

1. *Extremities:* severe osteopenia with metaphyseal cupping and fraying, poorly defined cortices, "periosteal cloaking" or reaction seen diffusely with areas of cortical bone destruction; diaphyseal expansion
2. *Pelvis:* wide iliac flare with hypoplastic lower iliac segment, steep acetabular roofs
3. *Spine:* biconvex end plates with anterior concavity of the vertebral bodies
4. The changes of dysostosis multiplex occur later



**e-Figure 132.45. Mucolipidosis type II (I-cell disease).** (A) Several hypoplastic superiorly notched vertebral bodies (mucopolysaccharidosis-like). (B) Characteristic periosteal cloaking. (C) Proximal metacarpal pointing and expanded short tubular bones with thin cortices.

## OSTEOLYSIS GROUP

This group includes a range of syndromes all with varying degrees of osteolysis present. The separate syndromes are best classified according to their primary sites of involvement.

1. Multicentric hands and feet
   a. Multicentric carpal or tarsal osteolysis with or without nephropathy
   b. Torg syndrome or Winchester syndrome or nodulosis with arthropathy syndrome
2. Acro-osteolysis
   a. Hajdu-Cheney syndrome (HCS)
   b. Mandubuloacral syndrome
3. Diaphyseal and metaphyseal
   a. Familial expansile osteolysis

## Hajdu-Cheney Syndrome

Distinctive transverse (bandlike) acro-osteolysis is present; skull features, including persistence of the skull sutures, a J-shaped sella, and wormian bones, characterize HCS. More important, however, is the progressive osteoporosis that occurs and can lead to vertebral body fractures. Many patients with confirmed HCS have an elongated and gracile twisting fibula and polycystic kidneys. Serpentine fibula polycystic kidney syndrome had been considered a separate genetic syndrome, but recently, the same genetic defect in the NOTCH2 signaling pathway has been found to cause both syndromes, unifying the picture.[29]

NOTCH2 is interesting for its effects on the skeleton and tumorogenesis. The defect in HCS causes an upmodulation in NOTCH signaling, which inhibits endochondral growth and osteoblastic differentiation resulting in osteopenia.[30] Errors in

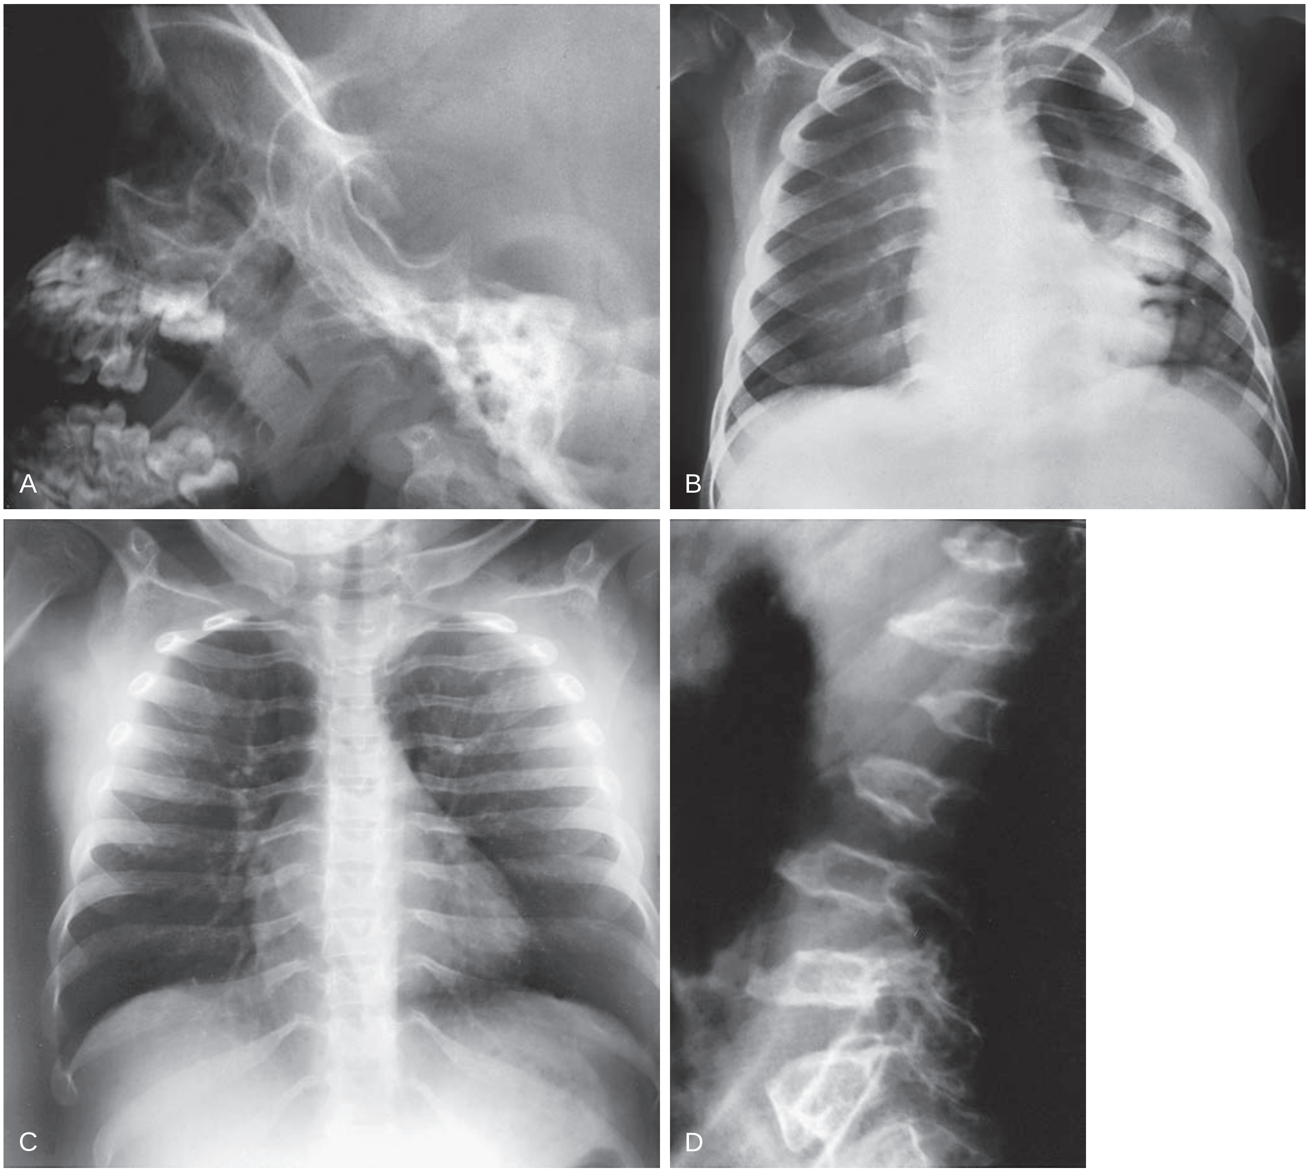


**Figure 132.43. Hurler syndrome (mucopolysaccharidosis type IH).** (A) Skull of an affected 3 year old with abnormal, excavated J-shaped sella turcica. (B) and (C) Thoraces of an affected 3 year old (B) and an affected 8 year old (C) with thick clavicles and paddle-shaped ribs (thin posteriorly and thick anteriorly). (D) Spine of an affected 8 year old with superiorly notched (inferiorly beaked) vertebral bodies. Radiographic findings in Hurler syndrome (mucopolysaccharidosis type IH). *Continued*

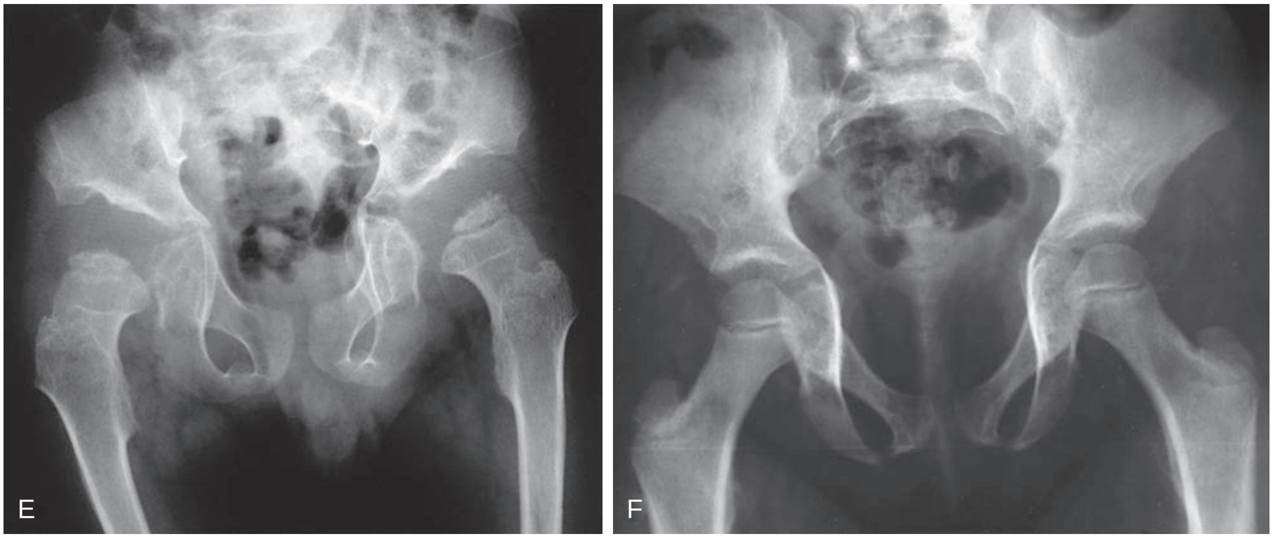

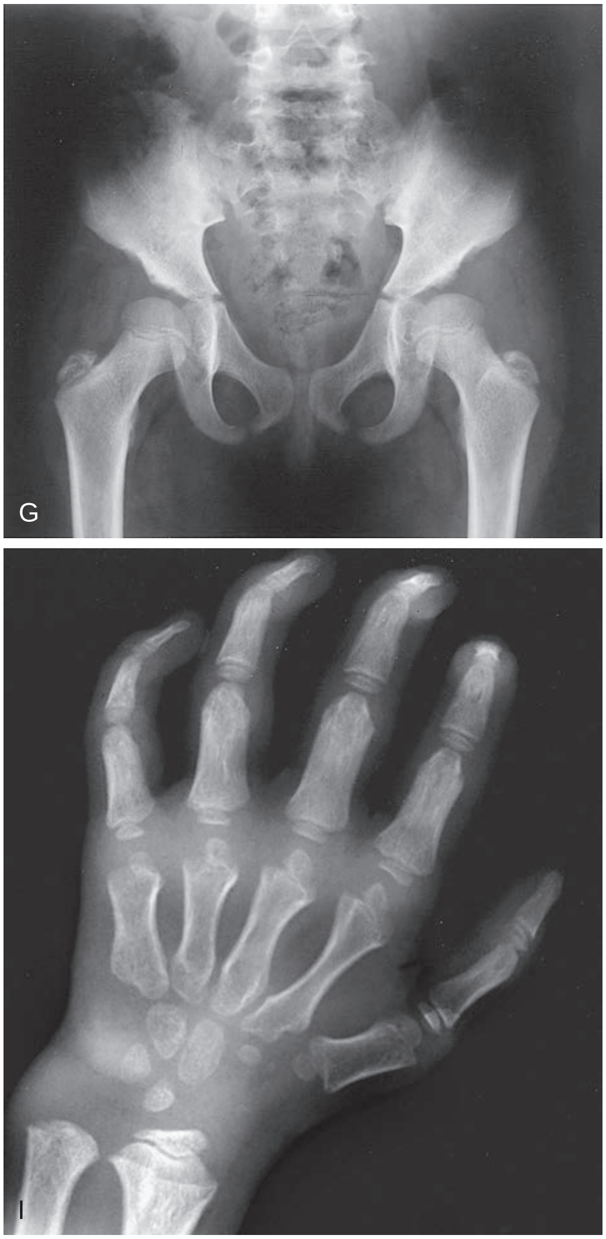

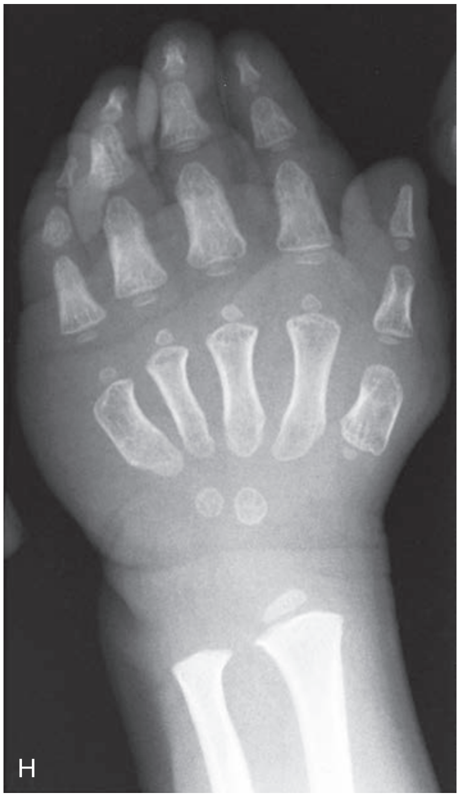

**Figure 132.43, cont'd.** (E–G) Pelvis of an affected 8 year old (E), another affected 8 year old (F), and an affected 12 year old (G) with small iliac wings with inferior tapering, and a slanted, irregular acetabular roof (E and G). (H and I) Hands of an affected 6 year old (H) and an affected 10 year old (I) with proximal metacarpal pointing and epiphyseal ossification delay.

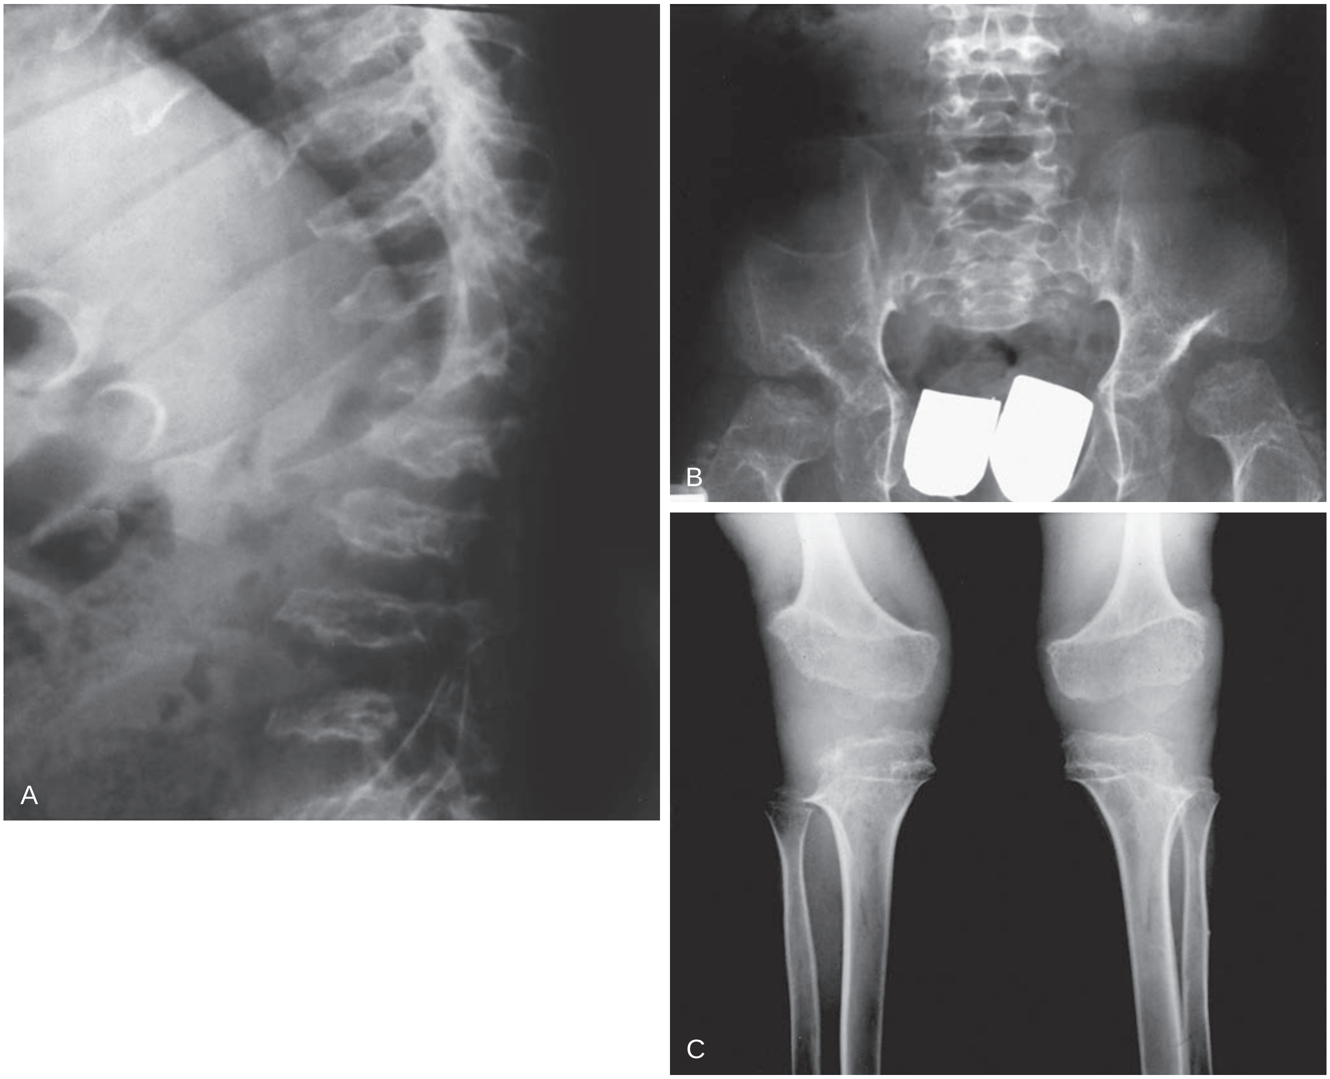

**Figure 132.44. Morquio syndrome (mucopolysaccharidosis types IVA and IVB).** (A) Radiograph from an affected 7 year old with platyspondyly with central beaking (tongue). (B) Radiograph from an affected 18 year old with severe capital femoral epiphyseal and acetabular dysplasia but no inferior iliac tapering. (C) Radiograph from an affected 15 year old with lateral distal femoral and proximal tibial epiphyseal ossification defects with genu varum.

the NOTCH signaling pathway have been associated with T-cell leukemia and lymphoma (NOTCH1).[31] Dysregulated NOTCH signaling is known to occur in multiple myeloma. Recently, enhanced NOTCH2 signaling has been associated with osteosarcoma and is associated with greater tumor invasiveness.[32]

***Radiologic Findings*** (Fig. 132.46)

1. *Skull:* wormian bones; cranial sutures remain open through adult life, hypoplastic sinuses, edentulous mandible
2. *Extremities:* bandlike acro-osteolysis; progressive osteopenia

## OVERGROWTH SYNDROMES WITH SKELETAL INVOLVEMENT

Important members of this group include Marfan syndrome, congenital contractural arachnodactyly (CCA), and Proteus syndrome.

### Marfan Syndrome and Congenital Contractural Arachnodactyly

These two congenital syndromes are caused by errors in fibrillin. Fibrillin is a glycoprotein that functions as a structural scaffold for elastic microfibrils. It can be found in abundance in the connective tissues of the walls of large vessels, lungs, bones, and eyes. The marfanoid body habitus is a constant feature along with long spidery fingers (hence the term *arachnodactyly*) and tall stature. The loss of normal fibrillin may allow liberation of transforming growth factor-β from the connective tissues, thereby allowing greater expressivity as tall stature.[33–35]

Dislocation of the lens of the eye occurs since fibrillin is found in the supportive connective tissues of the lens. The lack of normal fibrillin damages the elastic walls of the large vessels. Aortic root dilatation and rupture are the leading cause of death.

Marfan syndrome is a fibrillin 1 abnormality, whereas CCA is a fibrillin 2 abnormality. The two are phenotypically similar, each

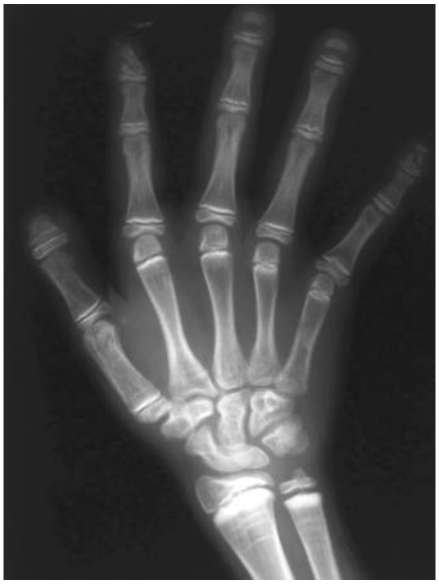

**Figure 132.46. Hajdu-Cheney syndrome in a 14-year-old boy.** Anteroposterior view of the hand shows transverse acro-osteolysis of the distal phalanges. Note the dense sclerosis at metaphyses—the patient takes bisphosphonates to enhance bone mineral density.

manifesting the typical marfanoid body habitus. However, patients with CCA also have joint contractures at the proximal interphalangeal joints, elbows, and knees. Although joint contractures can occur in Marfan syndrome, it is not a hallmark.

***Radiographic Features*** (e-Fig. 132.47)

1. *Skull:* dolicocephaly, arched palate
2. *Thorax:* scoliosis, pectus deformities, dural ectasia
3. *Pelvis:* acetabular protrusion deformity
4. *Extremities:* dolichostenomelia (long thin limbs or bones), arachnodactyly, joint hyperextensibility, osteopenia
5. *Other:* aortic root dilatation, spontaneous pneumothorax

### Proteus Syndrome

Proteus syndrome is named for the Greek god Proteus, who was able to change his shape at will. Proteus syndrome is a congenital hamartomatous disorder, which may be autosomal dominant. Affected patients have overgrowth of the hands and feet, limb asymmetry, gross cranial hyperostosis, and facial asymmetry leading to a frequently grotesque appearance. Patients with Proteus syndrome may also have mixed vascular malformations. Some have suggested that Joseph Merrick, also known as *the elephant man*, may have had Proteus syndrome rather than neurofibromatosis as was originally thought.

The radiographic findings of Proteus syndrome reflect what is seen clinically, namely, overgrowth of limbs and digits from both bone and soft tissues. Several types of tumors are associated with Proteus syndrome, including lipomas that tend to grow aggressively, ovarian cystadenoma, monomorphic parotid adenoma, testicular tumors, and central nervous system tumors (especially meningiomas).

***Radiologic Findings*** (e-Fig. 132.48)

1. *Skull:* macrocrania with cortical hyperostosis, dolichocephaly, and facial asymmetry
2. *Thorax:* scoliosis, kyphosis, large and asymmetric vertebral bodies
3. *Extremities:* asymmetric bone and soft tissue overgrowth
4. *Other:* mixed vascular malformations, hydrocephalus, emphysematous lung disease (12%)

## OTHER DISORDERS

### Cleidocranial Dysplasia

In this autosomal-dominant disorder, the chromosome locus is at 6p21 coding for a gene called *CBFA1* (core binding factor a1), also known as *RUNX2*. This dysplasia is quite common, with marked clinical variability and is often diagnosable at birth. The clinical findings include enlarged skull with large, late-closing fontanels; dental abnormalities; drooping, hypermobile shoulders; mild short stature; and a narrow chest.

***Radiologic Findings*** (Fig. 132.49)

1. *Skull:* large, brachycephalic; wormian bones; wide sutures; persistently open anterior fontanel
2. *Thorax:* absence or hypoplasia of clavicles, mildly shortened ribs with downward slope, 11 ribs
3. *Spine:* significant posterior wedging of thoracic vertebrae
4. *Pelvis:* high narrow iliac wings, absence or hypoplasia of pubic bones
5. *Extremities:* numerous pseudoepiphyses of metacarpals and tapered distal phalanges in the hands

## BRACHYDACTYLY GROUP

### Rubinstein-Taybi Syndrome

Rubinstein-Taybi syndrome is characterized by short stature; distinctive facial features; mental retardation; and broad, short thumbs and great toes. It is caused by sporadic mutations, the majority affecting the CREB-binding protein, which plays an important role in embryonic development. In slightly more than half of the patients, a cytogenetic abnormality can be identified. Radiographically, a delta-phalanx (longitudinal epiphyseal bracket) is seen at the first proximal phalanx (Fig. 132.50). The first distal phalanx is short and broad. At times, it may have a central lucency indicating an attempt at duplication. Other findings include congenital heart defects, agenesis of the corpus callosum, and vertebral and sternal anomalies. Patients have an increased risk of tumors, mainly meningioma, leukemia, and lymphoma.

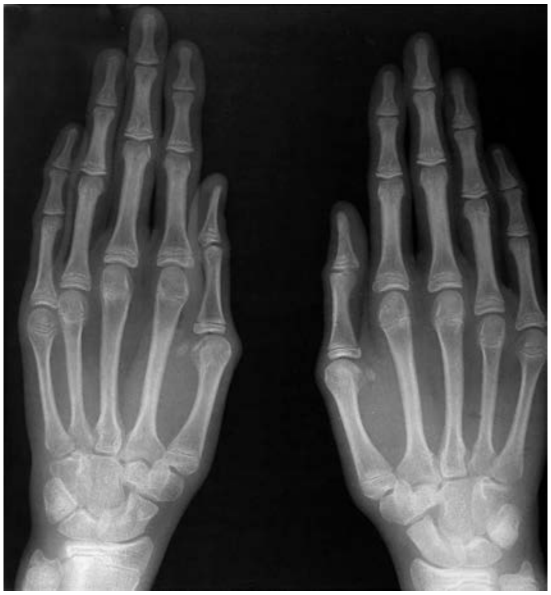
### Poland Syndrome

Poland syndrome includes a spectrum of abnormalities that includes absence or hypoplasia of the pectoralis major muscle and variable deformities of the ipsilateral upper extremity. In the mildest form, absence or hypoplasia of the pectoralis major muscle is seen. In the most severe presentations in the chest, absence of some ribs, scoliosis, absence of the latissimus dorsi, and mammary hypoplasia are seen. The entire hemithoracic cavity may be shortened with a low-riding clavicular head and high-riding insertion of the rectus abdominus. In the hands, ipsilateral shortening of fingers 2 to 4, with cutaneous syndactyly, is seen.

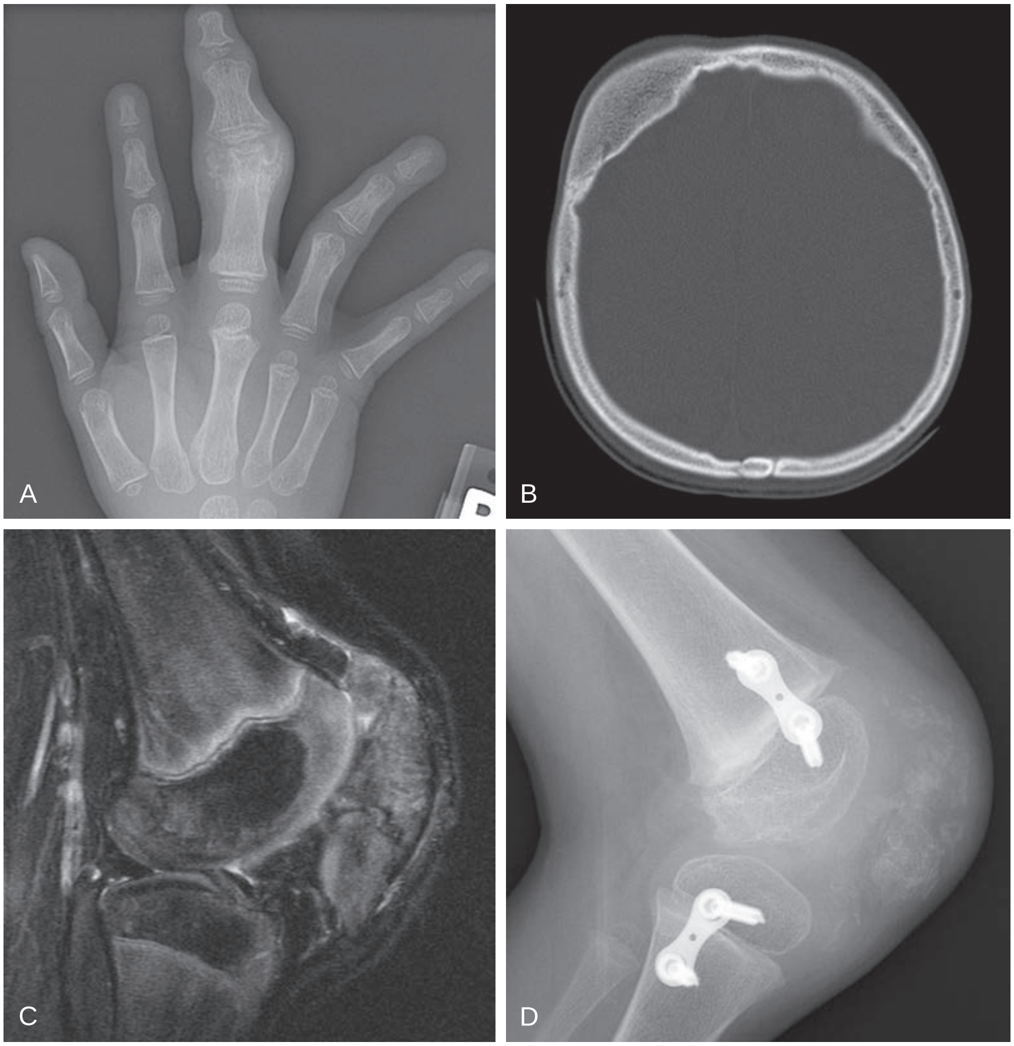
The cause is thought to be an interruption of the embryonic vascular supply during the sixth week of gestation, at a time when the chest wall musculature and hand are differentiating. Generally, the sternal head of the pectoralis major muscle is affected, as the clavicular head is known to form first and is, therefore, usually present.

***Radiologic Findings*** (Fig. 132.51)

1. Hyperlucent hemithorax and absent axillary fold related to absence of the pectoralis major muscle
2. Syndactyly and polydactyly of ipsilateral upper extremity
3. Brachymesophalangy (brachydactyly of the middle phalanges)



**e-Figure 132.47. Marfan syndrome.** The posteroanterior radiograph of the hand shows arachnodactyly.



**e-Figure 132.48. Proteus syndrome in a 5-year-old male.** (A) Anteroposterior view of the hand with osseous and soft tissue overgrowth of the third finger. (B) An axial computed tomography scan shows osseous overgrowth of the right frontal bone. (C) Sagittal proton density fat-saturated MRI of the knee shows the cartilaginous patella is enlarged and very irregular. (D) The lateral radiograph of the knee shows irregular ossification and overgrowth of the patella.

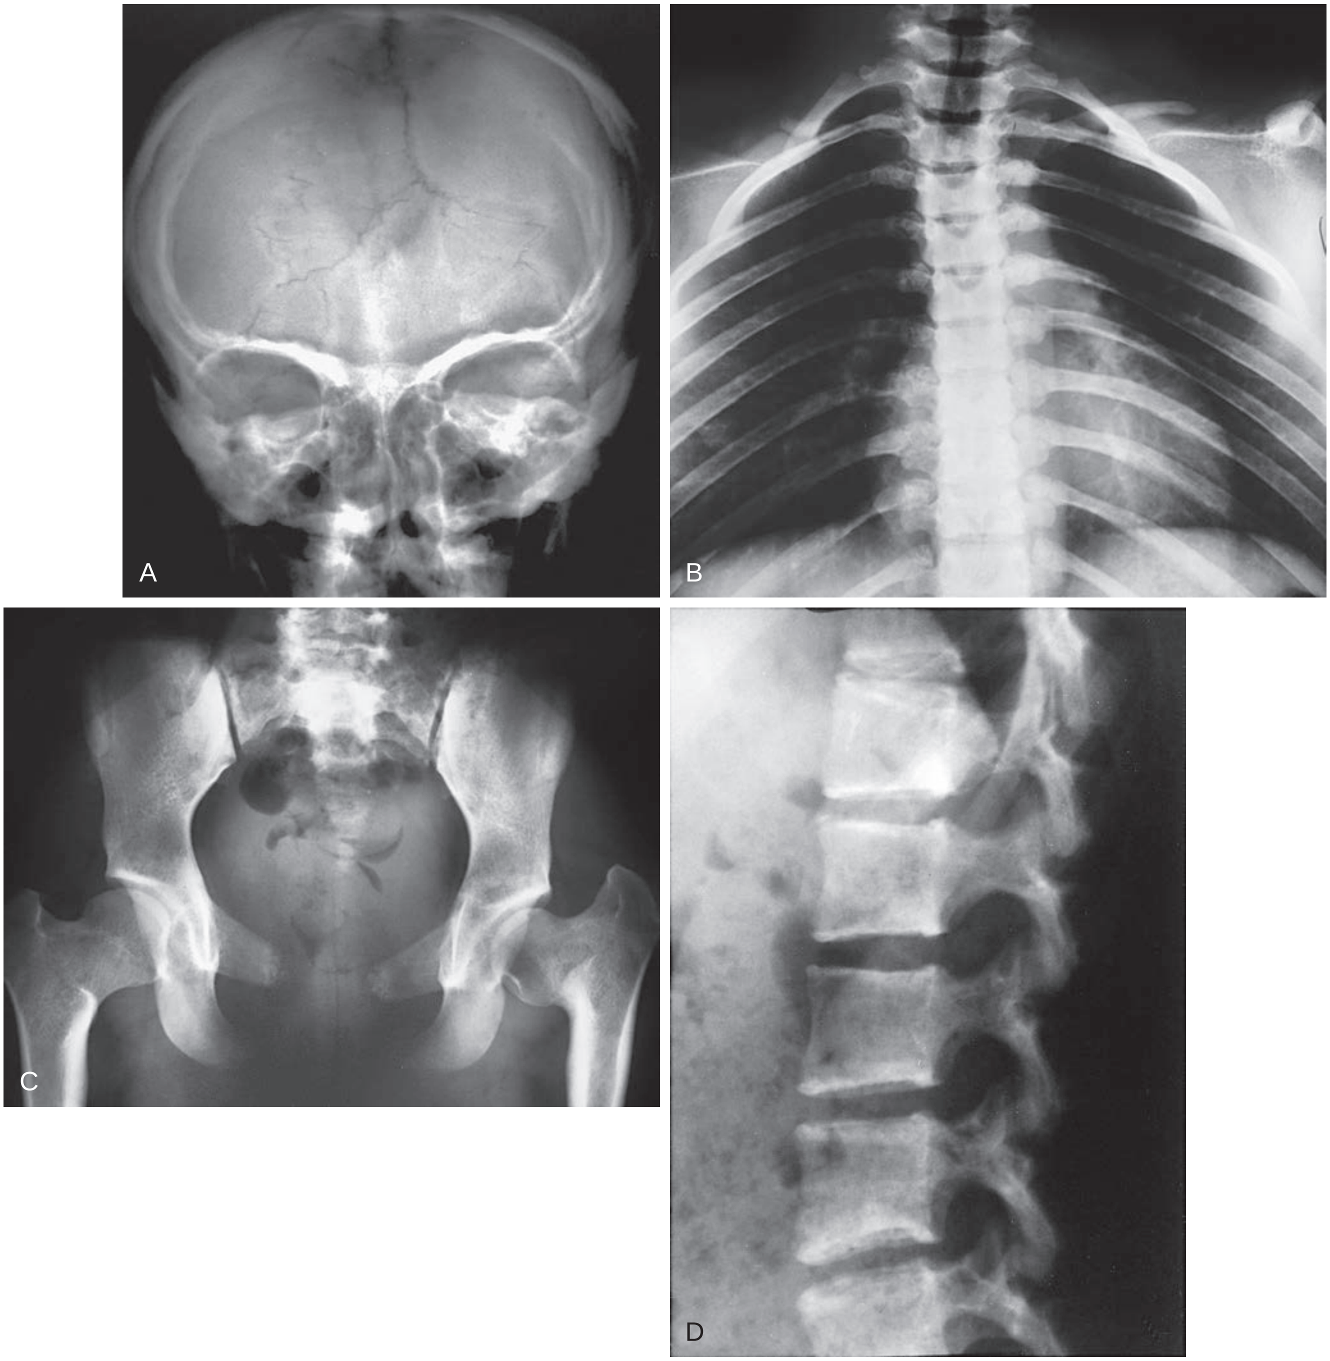


**Figure 132.49. Cleidocranial dysplasia in a 15 year old.** (A) Skull: large open anterior fontanel and multiple wormian bones. (B) Thorax: asymmetric hypoplastic or absent clavicles and downward-sloping ribs. (C) Pelvis: tall, narrow ilia and hypoplastic pubic bones. (D) Spine: posteriorly wedged but otherwise normal vertebral bodies.

## LIMB HYPOPLASIA—REDUCTION DEFECTS GROUP

### Brachydactyly A-E

The brachydactyly classification system most commonly used was described by Bell in 1951 and refined by Temtamy and McKusick in 1978. Since these descriptions, the genetic loci associated with many of the types of isolated brachydactyly have been elucidated. Some of the patterns of shortening of the bones of the hand will be easily recognized by the practicing radiologist. Brachydactyly type A3 in which the fifth middle phalanx is short is especially common. This can be differentiated from (1) Kirner deformity, with palmar/radial bowing of the distal phalanx, and (2) camptodactyly, with a flexion contracture of the interphalangeal joints.

Brachydactylies are usually isolated genetic abnormalities, but some may have associated syndromes or metabolic conditions. Variable shortening of the metacarpals is classified as brachydactyly type E, which most commonly affects the fourth and fifth rays. A short fourth metacarpal is also a well-known feature of many syndromes, including Turner syndrome and pseudohypoparathyroidism or pseudopseudohypoparathroidism (PHP/PPHP). Many

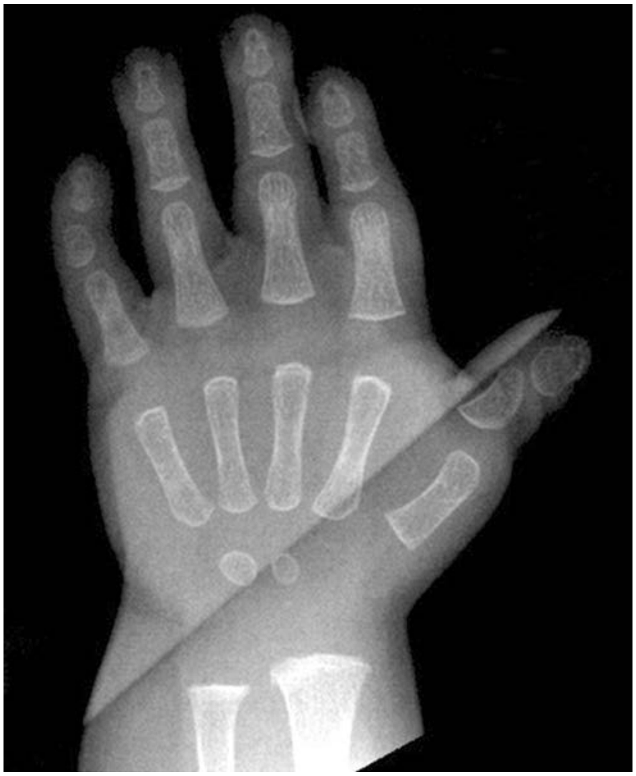

**Figure 132.50. Rubinstein-Taybi syndrome in an 8-month-old boy.** The anteroposterior view of the hand exhibits the classic delta phalanx at the first proximal phalanx.

patients with brachydactyly type E are short and, as such, may be indistinguishable from those with PHP/PPHP.

## Holt-Oram Syndrome

Holt-Oram syndrome, also called *heart–hand syndrome*, is caused by a completely penetrant mutation involving *TBX5* at 12q2. *TBX5* encodes a protein that plays a role in heart development and limb identity and patterning. It is part of the T-box gene family, which encodes transcription factors important in body development.

The disease is familial in 60% to 70% of cases; new mutations account for the remainder. Limb anomalies range from phocomelia with absent or hypoplastic humerus (10% of patients in some series) to triphalangeal thumbs. The most common limb anomalies are radial ray anomalies. These include absence of hypoplasia of the radius, bipartite or hypoplastic scaphoids of abnormalities of the thumb. Because radial ray abnormalities commonly involve the most distal part of the radial ray, the syndrome is well marked for the common occurrence of the triphalangeal thumb. The triphalangeal thumb is an interesting anomaly. In the normal first metacarpal, the epiphysis is proximal in contrast to the metacarpals 2 to 5, in which a distal epiphysis is seen. In the phalanges, however, the epiphyses are always proximal. In the most common form of triphalangeal thumb, in which the so-called "five-fingered hand" is seen, the thumb recapitulates fingers 2 to 5 with a distal metacarpal epiphysis and three phalanges each with basilar epiphyses. In this form, the thumb is frequently not opposable and articulates in the same plane as fingers 2 to 5.

The most common heart defects are septal defects, both atrial (58%) and ventricular (28%). *TBX5* appears to play a significant role specifically in the septation of the heart into four chambers. In addition, it plays a role in determining electrical conductive pathways between the chambers, giving rise to occasional conduction defects (18%).

## MISCELLANEOUS ASSOCIATIONS, SYNDROMES, AND CHROMOSOMAL DISORDERS

### VACTERL Association

VATER association, now expanded to VACTERL association, refers to a specific combination of anomalies in multiple organ systems, which is believed to represent a developmental defect arising during the fifth week of gestation. The acronym indicates the following:

V: vertebral (fusion and segmentation anomalies)
A: anorectal (imperforate anus)
C: cardiac (septal defects, tetralogy of Fallot, transposition of the great vessels)
T: tracheoesophageal (esophageal atresia/tracheoesophageal fistula)
R: renal (agenesis, hypoplasia, horseshoe kidney)
L: limb (especially radial ray anomalies)

VACTERL is referred to as an *association* rather than a syndrome, indicating that the cause is uncertain. The various organ defects occur together and are associated. They are probably caused by a problem in blastogenesis around the fifth week of gestation. It is not associated with facial dysmorphism, learning disability, growth failure, or abnormal head size or shape. If any of these features is present, a genetic condition associated either with esophageal atresia such as Feingold syndrome or CHARGE association or with imperforate anus such as Townes-Brocks syndrome needs to be excluded.

In those patients with imperforate anus, sacral anomalies and posterior spinal fusion defects, including tethered cord and lipomyelomeningocele, are common.

Hydrocephalus associated with the VACTERL association is known to have a high rate of recurrence in subsequent pregnancies. This is referred to as *VACTERL-H association*, with hydrocephalus added to the acronym. VACTERL-H is frequently an X-linked disorder, particularly when aqueductal stenosis is present and the prognosis is poor (e-Fig. 132.52).

### Klinefelter Syndrome

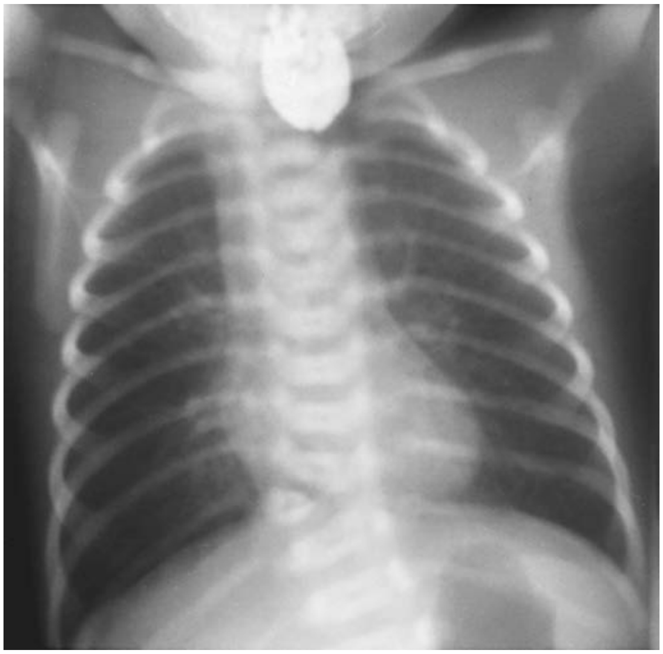
The addition of one or more X chromosomes in the male results in Klinefelter syndrome. Affected patients have greater expression of female characteristics, including gynecomastia, a feminine body fat distribution, small testes, and elevated levels of follicle-stimulating hormone. An increased incidence of male breast cancer, mediastinal germ cell tumor, leukemia, non-Hodgkin lymphoma, and lung cancer is seen, but the risk of prostate cancer is decreased.

Osseous changes are inconstant and include kyphoscoliosis, radioulnar synostosis, and a short fourth metacarpal. Skeletal findings are more apparent when more than two X chromosomes are present.

Other organ systems also may be affected. The risk of lupus, diabetes mellitus, mitral valve prolapse, bronchiectasis and emphysema, and situs inversus is increased.

### Trisomy 13 (Patau Syndrome)

Trisomy 13 occurs as a pure trisomy as well as a mosaic syndrome. Survival beyond the age of 10 years is rare and most die in infancy. Severe intracranial abnormalities, including holoprosencephaly, Dandy-Walker malformation spectrum, agenesis of the corpus callosum, and anencephaly, are often present. Congenital heart disease with various renal anomalies is often present. Additional



**e-Figure 132.52. VACTERL association (*v*ertebral, *a*norectal, *c*ardiac, *t*racheo*e*sophageal, *r*enal, *l*imb).** The chest radiograph of a newborn with tracheoesophageal fistula and esophageal atresia. Contrast medium is in the proximal esophageal pouch. Air in the stomach indicates the presence of a distal tracheoesophageal fistula. A hemivertebra is noted. The patient also had a pelvic kidney.

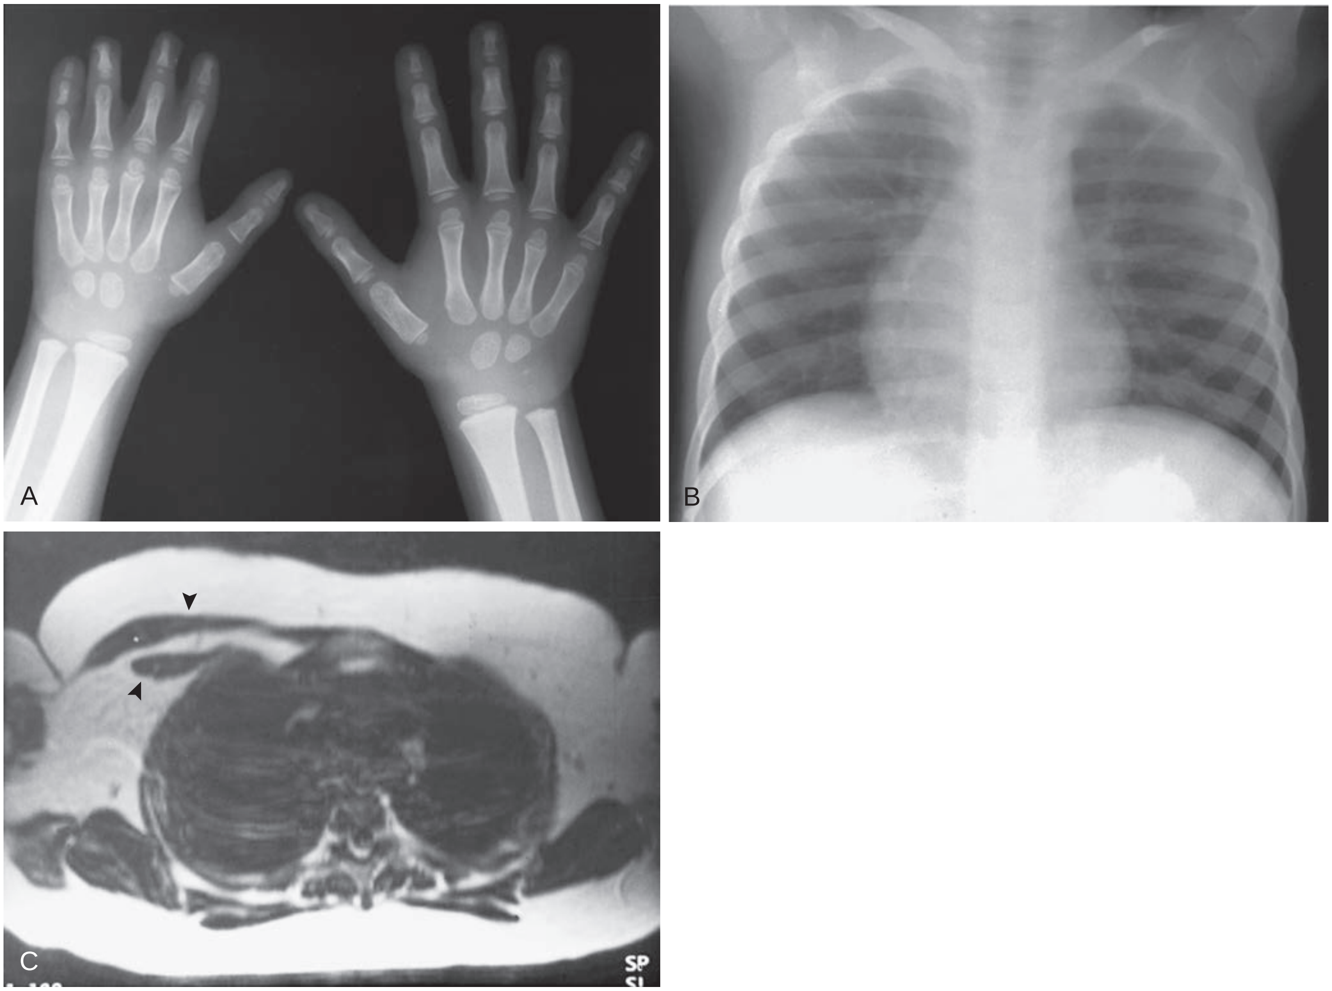


**Figure 132.51. Poland syndrome.** (A) Hand radiograph shows generalized hypoplasia of the left hand, with soft tissue syndactyly affecting the second through fourth digits. (B) The anteroposterior chest radiograph on a different patient shows relative lucency of the left hemithorax with loss of the pectoral shadow. (C) Axial T1-weighted magnetic resonance (MR) image shows absence of the left anterior chest wall musculature (*arrowheads* indicate normal musculature on the right).

components of the syndrome include congenital vertical talus (rocker-bottom foot), digital anomalies, micropthalmia, micrognathia, and cleft palate.

## Trisomy 18 (Edwards Syndrome)

Abnormalities in trisomy 18 include severe central nervous system changes such as holoprosencephaly and nonspecific migrational disorders, congenital heart disease, clubfeet or rocker-bottom feet, and digital anomalies. The hands are clenched in utero, and at birth, the first finger is adducted, and the second finger overlaps the third. Multiple other organ systems, including genitourinary, gastrointestinal, and biliary systems, are also affected. Life expectancy is short. Very few cases survive childhood. Mosaics may be less affected.

## Trisomy 21 (Down Syndrome)

Trisomy 21 is the most common chromosomal syndrome. A host of anomalies involving virtually all organ systems are well described. The most common cause of trisomy 21 is a nondisjunction event during gametogenesis, usually in the mother. At times, a trisomy 21 mosaic situation can occur when the nondisjunction event occurs in an embryo during early cell division. Rarely, trisomy 21 can occur as a result of an unbalanced translocation in one parent when the long arm of chromosome 21 attaches to the long arm of chromosome 14.

Both occipitoatlantal and atlantoaxial instability is found in Down syndrome. Anteroposterior occipitoatlantal instability is defined as more than 2 mm of motion on extension of the occipitoatlantal joints. If present, a neck MRI is recommended to evaluate for signal changes in the cord. An atlantoaxial distance of 4.5 mm or less is considered normal. With a distance from 4.5 to 10 mm and a normal neurologic exam, avoidance of high-risk sports (diving, football) is recommended. If more than 4.5 mm and with a neurologic deficit, activities are restricted and MRI recommended to evaluate for cord changes.[36] However, the poor reproducibility of findings and both intraobserver and interobserver variability may make it difficult to base surgical and clinical treatment protocols for upper cervical spine instability on measurements alone.

The brains of trisomy 21 patients have smaller than normal volumes, but no other consistent changes occur. The level of intellectual performance of affected individuals varies, but many are able to function normally in society with some assistance.

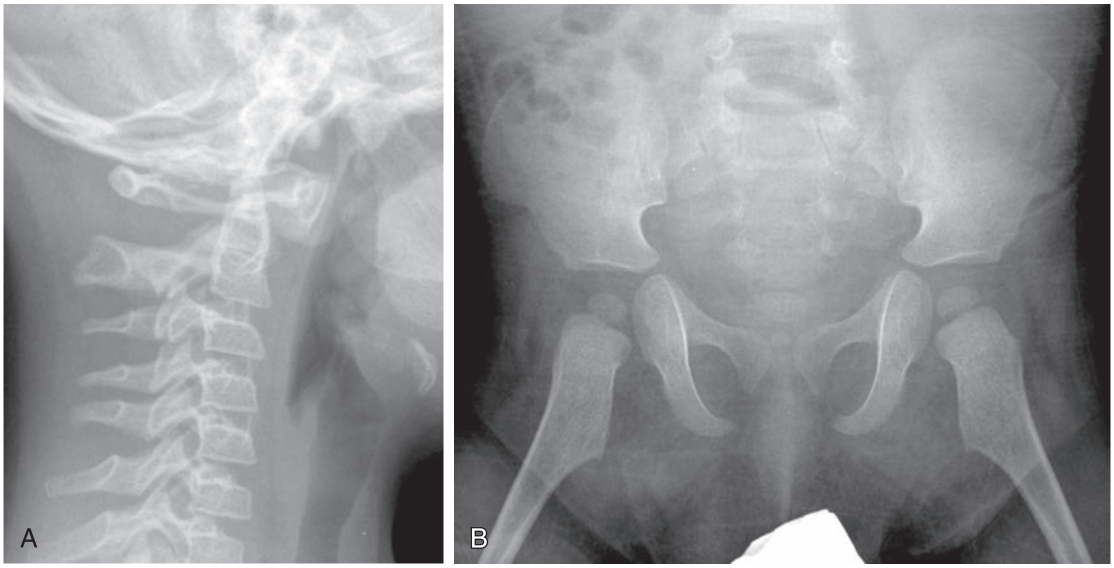

**Figure 132.53. Down syndrome.** (A) Lateral cervical spine radiograph shows abnormal widening between the anterior arch of C1 and the dens. (B) Frontal view of the pelvis in another patient shows flared iliac wings and flat horizontal acetabular roofs.

***Clinical and Imaging Findings*** (Fig. 132.53)

- *Skull:* brachycephaly
- *Spine:* occipitoatlantal and atlantoaxial instability
- *Thorax:* hypersegmented manubrium, 11 rib pairs, small bell-shaped chest with short ribs
- *Pelvis:* flared iliac wings, flat acetabular roofs
- *Gastrointestinal tract:* duodenal atresia, Hirschsprung disease, malrotation, tracheoesophageal fistula, and imperforate anus
- *Cardiac:* endocardial cushion defect most common but other types also occur
- *Other:* increased risk for leukemia (acute lymphoblastic leukemia)

## Turner Syndrome

Turner syndrome is most commonly caused by a 45,XO chromosomal pattern. In 15% of cases, one full X chromosome is present as well as an X isochromosome that contains only the long arms of chromosome X. Although originally it was thought that in the normal 46,XX female, complete inactivation of the second X chromosome occurs, some genes on the short arm of the inactivated X chromosome remain activated and are necessary for proper development, which explains why a patient with an X isochromosome and the classic XO are phenotypically similar.[37] The locus involved on the short arm of the X chromosome is in the pseudoautosomal region at Xp22 at a gene termed the *short stature homeobox gene (SHOX)*. *SHOX* was originally determined to be associated with some patients with idiopathic short stature syndrome who have a significantly short stature (>2 SDS), a persistently low growth rate for age, and no identifiable cause of a specific metabolic growth retarding condition.[38] Subsequently, *SHOX* has been found to be active in Turner syndrome.[39] Later, homozygous loss was found to be the cause of Langer mesomelic dysplasia and heterozygous loss the cause of dyschondrosteosis (Leri-Weill syndrome). In each of these last three conditions, the common thread of short stature, a short fourth metacarpal, and a varying degree of Madelung deformity is present.

Turner syndrome, or monosomy X, was initially described as a triad of infertility, webbing of the neck, and cubitus valgus deformity of the elbow. Since that time, a multitude of associated radiographic findings have been described involving most organ systems:

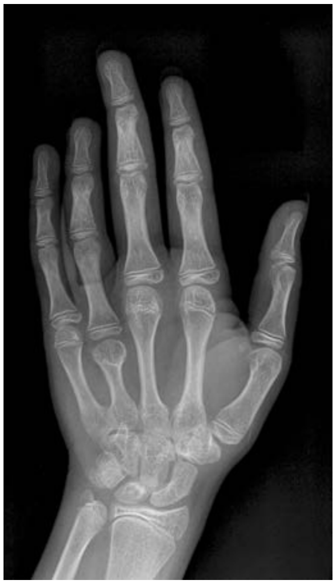
1. *Skull:* brachycephaly
2. *Spine:* platyspondyly
3. *Thorax:* pectus carinatum, thin lateral clavicles
4. *Pelvis:* sacral hypoplasia
5. *Extremities:* elbow valgus, overtubulation of long bones, flattening of the medial femoral condyle and patellar dislocation, proximal tibial exostosis, phalangeal abnormalities

Hand radiographs demonstrate typical changes with osteopenia, shortening of the fourth and fifth metacarpals (e-Fig. 132.54), delayed maturation, phalangeal predominance, a V-shaped deformity of the distal radiocarpal joint (Madelung deformity), and drumstick-shaped distal phalanges.

The classic cardiovascular finding is postductal coarctation of the aorta, but septal defects, aortic coarctation and dissection, and mitral valve prolapse are also common. Renal anomalies include rotational anomalies, bifid renal pelvis, horseshoe kidney (common), and multicystic dysplastic kidney. Autoimmune conditions, including hypothyroidism, diabetes, and juvenile rheumatoid arthritis, have been associated with Turner syndrome. Genital abnormalities, best evaluated with pelvic ultrasound or MRI, include ovarian and uterine absence or hypoplasia. Vascular abnormalities also include intestinal telangiectasia, lymphedema, and an increased incidence of vascular tumors (hemangioma, lymphatic malformation).

### KEY POINTS

- An ordered segmental approach to the radiographs of a patient with skeletal dysplasia is the key to proper diagnosis.
- Abnormalities should be generally classified as to the area of abnormality. Are the epiphyses or metaphyses involved? Is there vertebral body involvement? Are the findings rhizomelic, mesomelic, or acromelic?
- Following a general classification, a search should be made for any more peculiar or specific changes.
- After appropriate analysis, consultation with any of the excellent referral texts included in this chapter will be very helpful.



**e-Figure 132.54. Turner syndrome.** Frontal radiograph of the hand shows marked shortening of the fourth metacarpal.

# 133 Alignment Disorders

Matthew R. Hammer, Yassine Kanaan, and Peter J. Strouse

## OVERVIEW

Malalignment of extremity bones may be congenital or acquired. Primary bone or secondary soft tissue or neuromuscular disorders can result in abnormal alignment. Malalignment is often seen with congenital deformities characterized by embryologic failure of development, discussed in Chapter 131. One of the most common alignment disorders is developmental dysplasia of the hip, discussed in Chapter 135.

## UPPER EXTREMITIES

### Neonatal Brachial Plexus Palsy/Glenohumeral Dysplasia

***Etiologies, Pathophysiology, and Clinical Presentation.*** Neonatal brachial plexus palsy (also know as *Erb palsy* or *brachial plexopathy*) is caused by injury to the cervicothoracic nerve roots during birth. It is associated with prolonged, difficult delivery (dystocia) and with larger infants. Infants present with decreased motion of the involved extremity. Children with a persistent defect will hold their arms in internal rotation with pronation of the forearm and flexion of the wrist (waiter's tip arm). This is the most common insult leading to secondary glenohumeral dysplasia.

***Imaging.*** At birth, radiographs can exclude fractures of the clavicle and humerus. Ultrasonography (US) and magnetic resonance imaging (MRI) have been used to directly evaluate the brachial plexus; however, the primary goal of advanced imaging is to evaluate orthopedic anatomy to determine function and orthopedic treatment as primary repair of the brachial plexus injury is difficult.[1–3]

Progressive deformity with secondary glenohumeral dysplasia manifests as a small, flattened humeral head, which may sublux, usually in the posterior direction relative to a small, shallow, abnormally retroverted glenoid (Fig. 133.1).[4] In normal shoulders, glenoid version is near neutral, often mildly retroverted by approximately 5 degrees relative to a line perpendicular to the axis of the scapular body.[5] With brachial plexus palsy, glenoid retroversion averages 25 degrees. The scapula is hypoplastic and elevated; the acromion is tapered and inferiorly directed, as is the coracoid; and the clavicle is shortened.

Many of these findings are seen on radiography. Computed tomography (CT) or MRI can be used to quantify the degree of glenoid retroversion, deformity of the glenoid and humeral head, glenoid–humeral head congruence, and relative muscle volume and quality of the affected shoulder.[6–10] Ultrasound is useful, particularly in infants because no sedation is required, to evaluate muscle bulk, degree of glenoid and posterior labral abnormality, and dynamic alignment of the shoulder. The alpha angle can be measured to assess the degree of humeral head subluxation (e-Fig. 133.2).[11–13] The glenoid normally has a concave shape. With glenohumeral dysplasia, the glenoid becomes progressively flat, convex, or biconvex with a pseudoarticulation with the humeral head. MRI is preferred in young children (<5 years old) (e-Fig. 133.3) to evaluate the cartilaginous glenoid; CT is sometimes preferred in older children to evaluate cortical bone.

***Treatment.*** Microsurgery techniques may be attempted to address the underlying traumatic neural injury.[14] Controversy exists as to their role and proper timing. Typical treatment focuses on the reconstructive surgical techniques of the shoulder and distal upper extremity to preserve joint integrity and maximize function.[14,15]

### Madelung Deformity

***Etiologies, Pathophysiology, and Clinical Presentation.*** In Madelung deformity, the radius is short and its distal articular surface tilted toward to ulna.[16] The cause of the deformity is usually unknown. Madelung deformity occurs more often in girls.[17] Patients may have pain; however, treatment is more often sought because of deformity or limited range of motion. Bilateral involvement is more common in the setting of an associated syndrome. Madelung deformity is occasionally seen with Turner syndrome and is a characteristic of Léri-Weill syndrome.[16] Among these cases, 10% to 15% are familial. A Madelung-like deformity may also be seen in patients with hereditary osteochondromatosis or enchondromatosis, also suggesting a defect in normal distal radial maturation. It may also occur as a complication of infection or trauma that results in medial and volar radial physeal growth disturbance.[18]

***Imaging.*** The distal articular surface of the radius is tilted in an ulnar and volar direction.[19,20] The radius is short and bowed dorsally and laterally ("bayonet deformity") (Fig. 133.4). Secondary distortion of the carpus is observed with an abnormally narrow carpal angle and proximal lunate migration.[19,20] The distal ulna is subluxed. The distal radial growth plate may prematurely fuse along its ulnar and volar aspect. CT or MRI may be used to assess the extent of distal radial physeal fusion.[21] MRI can also identify an anomalous radiolunate ligament (Vickers ligament) which is present in true, idiopathic Madelung deformity.[22]

***Treatment.*** Treatment is aimed at relieving pain caused by ulnocarpal impingement and improving wrist mobility.[18] Ulnar shortening and radial wedge osteotomies are common techniques.[18]

### Ulnar Variance

***Etiologies, Pathophysiology, and Clinical Presentation.*** Trauma, infection, inflammatory arthropathy (juvenile idiopathic arthritis), or other causes of premature fusion may lead to shortening of the ulna relative to the radius (negative ulnar variance) or shortening of the radius relative to the ulna (positive ulnar variance) (Fig. 133.5).[23] Most cases are idiopathic. Hyperemia resulting from fracture healing, infection, or vascular anomalies may lead to single bone over growth. Osteochondromas of either the radius or ulna can also lead to shortening of the affected bone.

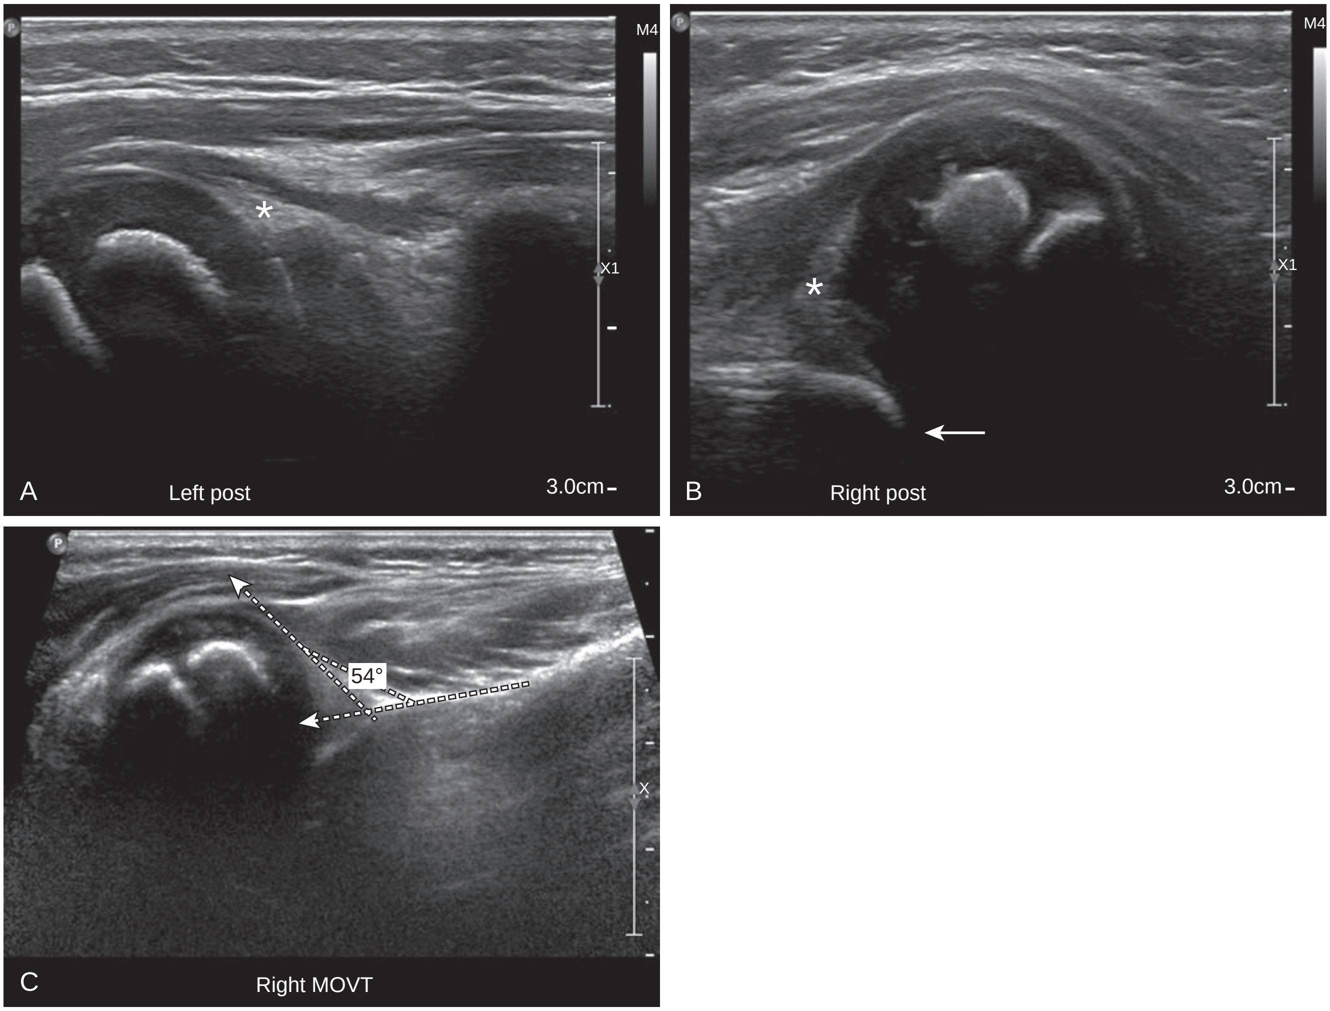
***Imaging.*** At skeletal maturity, the distal radial and ulnar articular surfaces are nearly at the same level, and the radial styloid projects 9 to 12 mm distal to the ulnar articular surface.[23,24] With negative ulnar variance, the ulna ends more proximally, and with positive ulnar variance, the ulna ends more distally (e-Fig. 133.6).[23,25] Ulnar variance may be exaggerated with forearm pronation and decreased with forearm supination.

## Abstract:

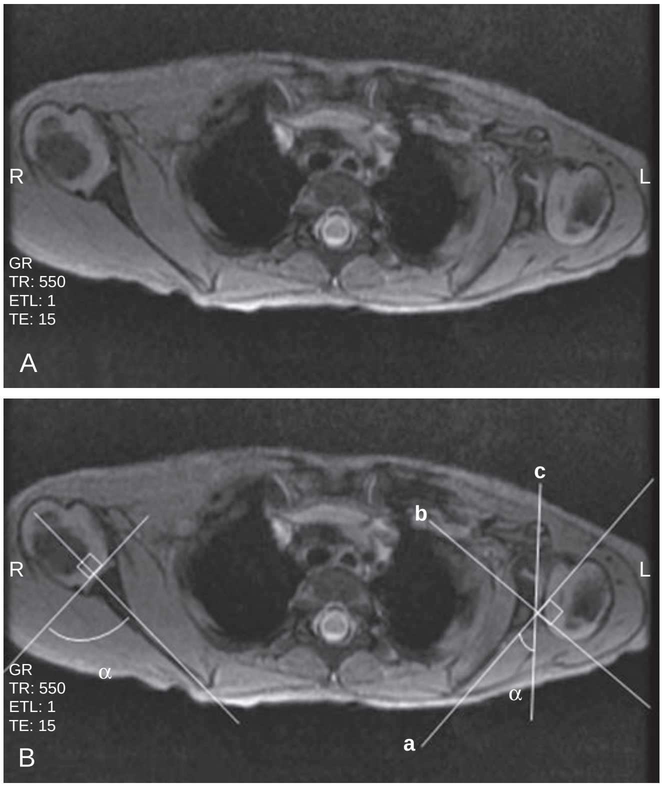
Imaging plays a key role in the evaluation of alignment disorders involving the axial and appendicular skeleton. This chapter explores various imaging modalities and illustrates numerous disorders of alignment in the pediatric population. Abnormal alignment of each joint as well as the tibia and femur can initially be evaluated by radiography. However; advanced cross-sectional imaging techniques can play a key role in the evaluation of potential underlying causes and treatment planning in these patients. This chapter also discusses how imaging plays a role in surveying progression of alignment disorders, including systemic conditions including cerebral palsy and myelomeningocele. Finally, there is guidance to identify treatment outcomes and complications of treatment.

## Keywords:

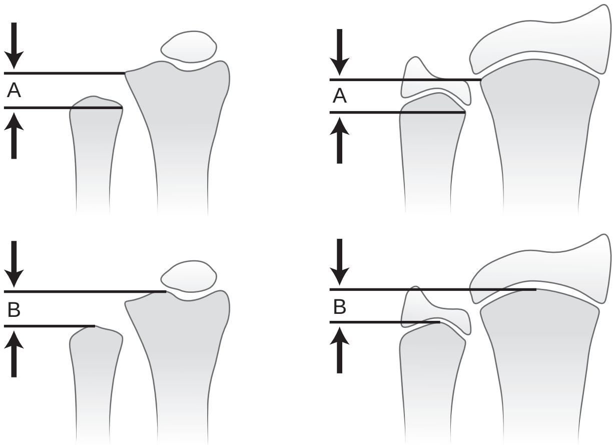
alignment
cerebral palsy
Madelung
glenohumeral dysplasia
femoral version
tibial torsion
clubfoot



**e-Figure 133.2. Glenohumeral dysplasia and shoulder subluxation in a 10-month-old boy with brachial plexopathy.** (A) Normal shoulder ultrasound imaged posteriorly. Normal small triangular posterior labrum *(asterisk)* and normal articulation and contour of proximal humeral epiphysis with the glenoid. (B) Abnormal contralateral shoulder with dysplasia. The posterior labrum is enlarged and thickened *(asterisk)* and there is posterior subluxation of the humerus with respect to the rounded glenoid *(arrow)*. (C) Posterior subluxation with an alpha angle of 54 degrees. The alpha angle is the angle between the posterior margin of the scapula and a line drawn tangentially to the humeral head and posterior edge of the glenoid. The normal value is 30 degrees or less.



**e-Figure 133.3. Left glenohumeral dysplasia from brachial plexus palsy in a 2-year-old girl.** (A) Gradient recalled echo axial sequence magnetic resonance (MR) image demonstrates severely dysplastic left glenoid that is retroverted, a posteriorly subluxed humeral head and global left shoulder girdle muscle atrophy. (B) Same sequence with glenoid version measurements. Glenoscapular angle is the angle between a line drawn along scapula *(a)* and a line along the articular surface of the glenoid *(c)*. The glenoid version angle is the glenoscapular angle minus 90 degrees. If the glenoid is directed posteriorly with respect to scapula, the glenoid is in retroversion (negative angle). If the glenoid is directed anteriorly, the glenoid is in anteversion.



**e-Figure 133.6. Methods of measuring ulnar variance in skeletally immature children.** Method *A* measures the distance from the most proximal point of the ulnar metaphysis to the most proximal point of the radial metaphysis. Method *B* measures the distance from the most distal point of the ulnar metaphysis to the most distal point of the radial metaphysis. *(Modified from Hafner F, Poznanski AK, Donavan JM. Ulnar variance in children—standard measurements for evaluation of ulnar shortening in juvenile rheumatoid arthritis, hereditary multiple exostosis and other bone and joint disorders of childhood.* Skeletal Radiol. *1989;18:513–516.)*

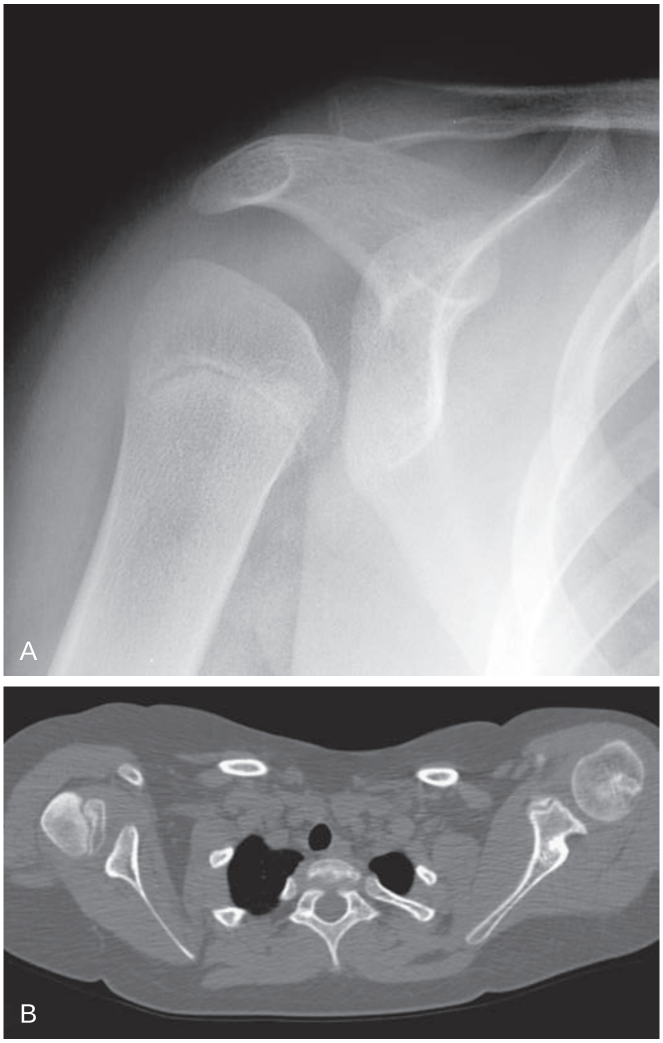


**Figure 133.1. Glenohumeral dysplasia secondary to brachial plexopathy in a 9-year-old girl.** (A) On radiography, the humeral head appears small and abnormally contoured, the glenoid margins are indistinct, and the acromion is curved. (B) Axial CT image shows the right glenoid to be small and retroverted. The right humeral head, which is small and squared in contour, is posteriorly positioned but aligned with the glenoid. Note the asymmetric muscle volume of the right shoulder girdle compared with the left shoulder girdle.

***Treatment.*** Osteotomy with ulnar or radial shortening may be indicated to reduce symptoms and avoid complications. Negative ulnar variance is associated with the development of avascular necrosis of the lunate (Kienböck disease).[26] Positive ulnar variance is associated with ulnolunate impaction syndrome (Fig. 133.7) and triangular fibrocartilage complex degeneration.

## LOWER EXTREMITIES

### Hip/Femur

### Coxa Vara

***Etiologies, Pathophysiology, and Clinical Presentation.*** The normal neck-shaft angle of the proximal femur is approximately 150 degrees at birth and decreases to 120 to 130 degrees in adulthood.[27] External or internal rotation of the hip or femoral anteversion may affect this measurement.[28]

Functional coxa vara occurs with disorders that result in femoral neck shortening, as in trauma, infection, or epiphyseal osteonecrosis.[29] This can result in abnormal growth at the proximal femoral physis that produces abnormal angulation. Coxa vara also occurs as a congenital anomaly that is caused by bone softening (e.g., rickets, osteogenesis imperfecta, fibrous dysplasia) or abnormal growth (e.g., spondyloepiphyseal dysplasia congenita, spondyloepimetaphyseal dysplasia, cleidocranial dysplasia, proximal focal femoral deficiency).[30,31] Children will present with a limp (unilateral deformity) or a waddling gate (bilateral deformities). With infantile or developmental coxa vara, the hip is normal at birth, and deformity is noted when the child begins to walk and can be self-limited.[30,32] Acquired coxa vara is caused by other processes such as trauma.[30]

***Imaging.*** In coxa vara, the femoral neck-shaft angle is decreased from normal. A measurement below 120 degrees is considered coxa vara.[33,34] Fragmentation and sclerosis may be seen at the medial margin of the proximal femoral metaphysis (Fig. 133.8).[32] The Hilgenreiner epiphyseal angle is the angle between the Hilgenreiner line and a line drawn through the proximal femoral physis (e-Fig. 133.9).[30,33] The normal angle is less than 30 degrees. If it is less than 45 degrees, progression is unlikely. If over 60 degrees, progression is likely. If 45 to 60 degrees, prognosis is less predictable.

***Treatment.*** Surgical management may be warranted for progressive disease, especially if asymmetric or associated with pain or leg length discrepancy.[30] Valgus osteotomy is performed, and physeal fixation or tendon transfers may also be performed to deter progression and improve mechanical function.

### Coxa Valga

***Etiologies, Pathophysiology, and Clinical Presentation.*** With coxa valga, the neck-shaft angle of the proximal femur is increased.[35] Coxa valga is most often seen in patients who are nonambulatory and nonerect, such as those with cerebral palsy and other neuromuscular disorders (Fig. 133.10).[28,36]

***Imaging.*** The femoral neck-shaft angle is measured on frontal radiographs. External rotation may mimic coxa valga; with external rotation, the greater trochanter projects through the femur and the lesser trochanter is visualized in profile, whereas with true coxa valga in appropriate position, the appearance of the trochanters are reversed.[28] Increased femoral anteversion may also cause the femoral neck-shaft angle to be overestimated.[35] Acetabular dysplasia and hip subluxation are frequently concomitant findings.

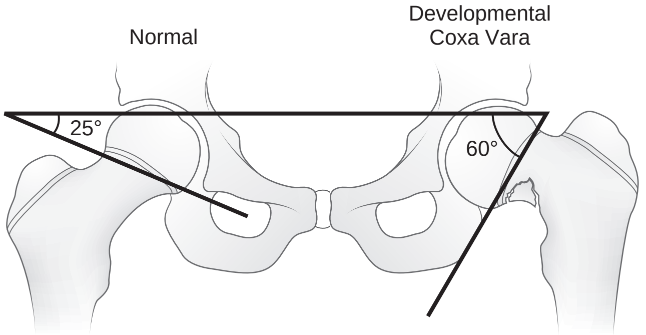
***Treatment.*** Varus osteotomy and iliac osteotomy are often performed together in patients with cerebral palsy to better direct the femoral head into the acetabulum.

### Femoral Anteversion

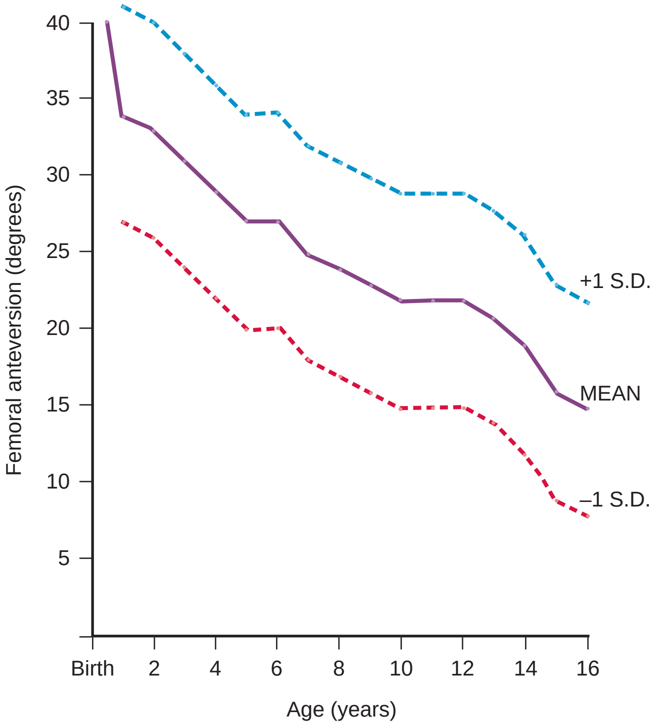
***Etiologies, Pathophysiology, and Clinical Presentation.*** Femoral version is the angulation of the femoral neck in the transverse plane measured relative to the femoral condyles distally (Fig. 133.11). If the femoral neck is anteriorly angulated with respect to the femoral condyles, the femur is anteverted. If the femoral neck is posterior with respect to the femoral condyles, the femur is retroverted. Normal femoral anteversion is around 35 to 50 degrees at birth, decreasing steadily to around 8 to 15 degrees in adulthood (e-Fig. 133.12).[29]

Increased femoral anteversion may hinder proper localization of the femoral head relative to the acetabulum. Increased femoral anteversion may be idiopathic or seen in hip deformities caused by developmental hip dysplasia, Legg-Calvé-Perthes disease, and cerebral palsy.[35] Increased anteversion is associated with in-toeing of feet.

***Imaging.*** On CT, femoral anteversion is the angle between the axis of the femoral neck and the transcondylar axis at the distal femur (Fig. 133.13).[37–39] Limited low-dose axial images are usually performed; however, axial oblique or three-dimensional



**e-Figure 133.9. Hilgenreiner epiphyseal angle.** This angle is created by a single line through the triradiate cartilage and its intersection with another line through the proximal femoral physis. The normal angle is about 25 degrees. *(From Beals RK. Coxa vara in childhood: evaluation and management.* J Am Acad Orthop Surg. *1998;6:93–99.)*



**e-Figure 133.12. Normal femoral anteversion.** The mean value is an average of those reported by Shands and Steele (1958), Crane (1959), and Fabry and associates (1973). Standard deviations are only an approximation and are based on the range of those determined by Fabry and associates. *(From Ozonoff MB:* Pediatric orthopedic radiology, *2nd ed, Philadelphia: WB Saunders; 1992.)*

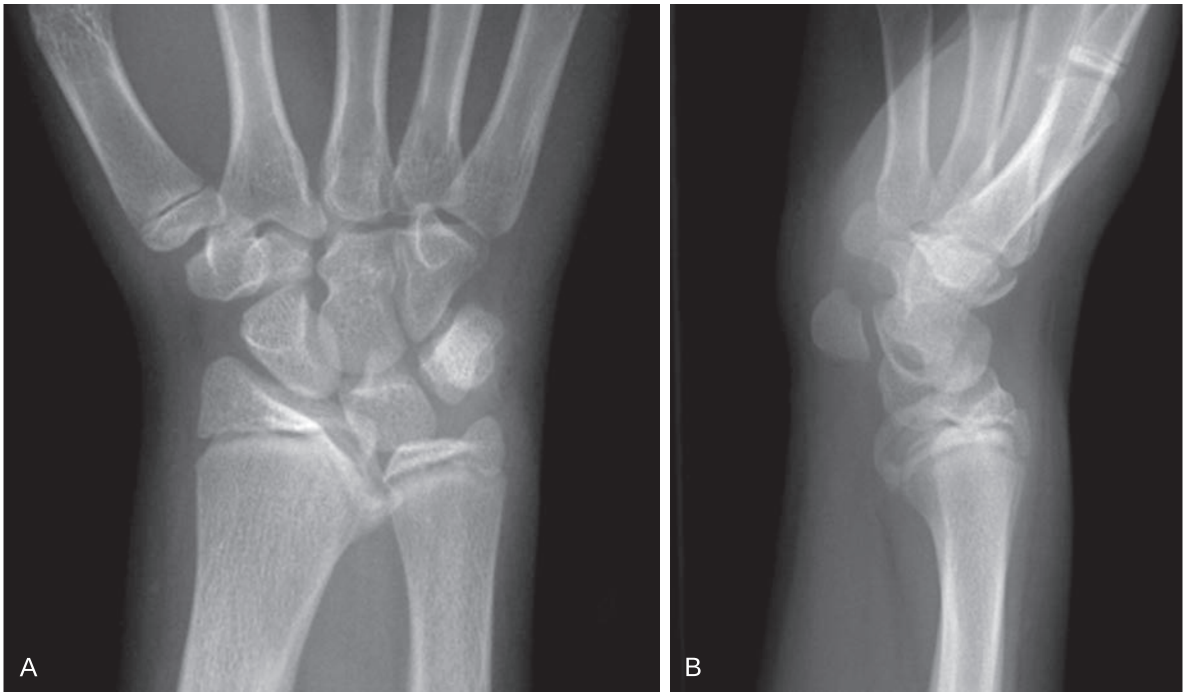


**Figure 133.4. Madelung deformity in a 10-year-old girl who presented with right wrist pain.** (A) Posteroanterior radiograph shows medial tilt of the distal radial articular surface and physis with thinning of the medial aspect of the distal radial epiphysis. Also note the proximal migration of the lunate. (B) Lateral radiograph shows anterior tilt of the distal radial articular surface with mild anterior displacement of the carpus.

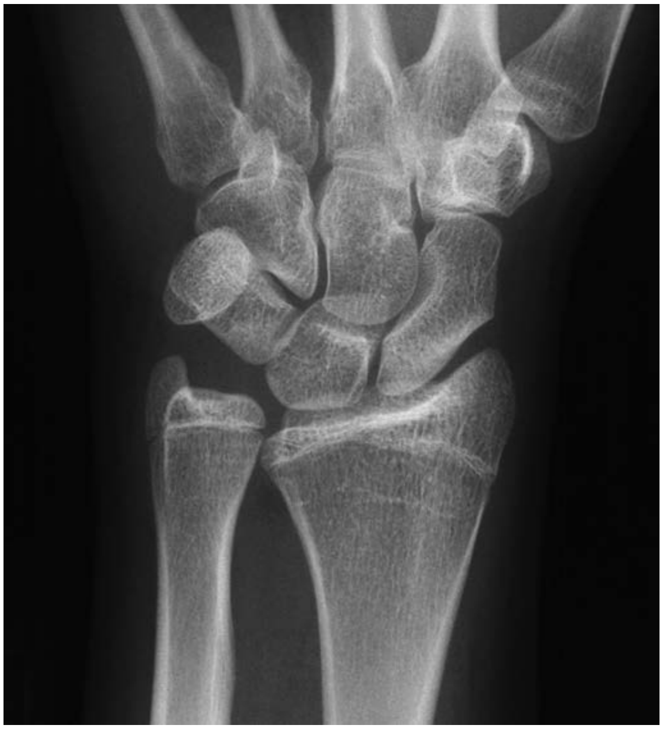

**Figure 133.5. Positive ulnar variance in a 14-year-old girl with a history of prior osteomyelitis of the ulna.** Presumably, resultant overgrowth of the ulna occurred. The patient required ulnar shortening because of clinical evidence of ulnar impaction syndrome.

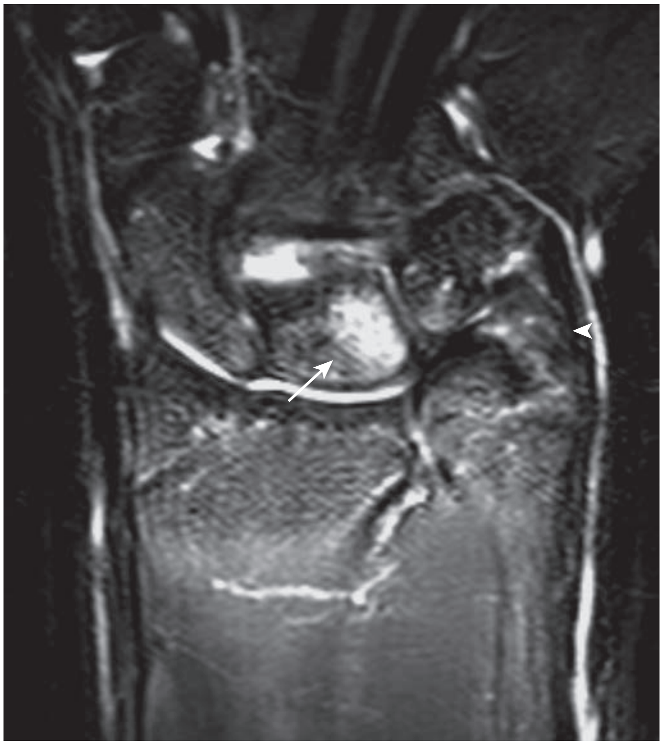

**Figure 133.7. Ulnolunate impaction syndrome in a 14-year-old boy.** Inversion recovery coronal sequence magnetic resonance (MR) image demonstrates a distally located ulna *(arrowhead)* with lunate edema *(arrow)* caused by ulnolunate impaction syndrome.

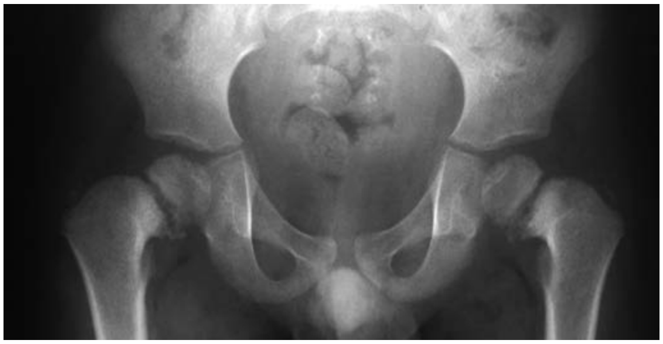

**Figure 133.8. Bilateral congenital coxa vara in a 4-year-old boy.** Proximal femoral growth plates are tilted, medial side down. Slight irregularity is noted adjacent to the medial aspects of each proximal femoral physis.

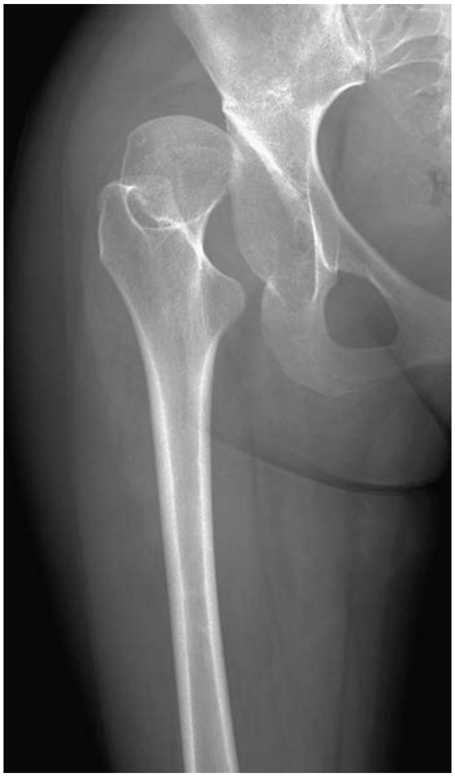

**Figure 133.10. Coxa valga in a 15-year-old girl with cerebral palsy.** The acetabulum is markedly dysplastic. The femoral head is subluxed. Coxa valga is noted.

(3D) images may improve measurement accuracy.[40,41] CT imaging can be obtained concomitantly to evaluate for femoroacetabular impingement and tibial torsion. The biplanar digital slot-scanning radiologic device (EOS Imaging, Paris, France) uses two narrow fan beam sources to acquire concurrent, high-quality, orthogonal radiographic images of the spine or entire lower extremities.[42] Frontal, lateral, and 3D views can be generated from the obtained data. Standard radiographic measurements of the lower extremities can be performed with these images. Also beneficial is lower radiation exposure with this device compared to standard radiographs and CT while maintaining image quality.

***Treatment.*** Most children with increased femoral anteversion are managed conservatively. Surgical indications for treatment include symptomatic in-toeing. Femoral rotational osteotomy may be performed to optimize femoral version.

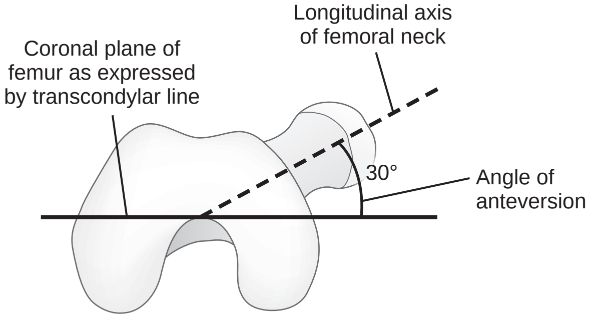

**Figure 133.11. Schematic diagram of the right femur as viewed from below.** The femoral neck is angulated anterior (anteversion) relative to the transcondylar axis of the distal femur. *(Modified from Greenspan A.* Orthopedic imaging: a practical approach*, 4th ed, Philadelphia, PA: Lippincott Williams & Wilkins; 2004.)*

## Leg

### Tibial Torsion

***Etiologies, Pathophysiology, and Clinical Presentation.*** Tibial torsion is the degree of rotation of the distal tibia relative to the upper tibia. Newborns have internal tibial torsion relative to older children and adults. Lack of normal progression leads to in-toeing. Internal tibial torsion is the most common cause of in-toeing in the preschool age group.

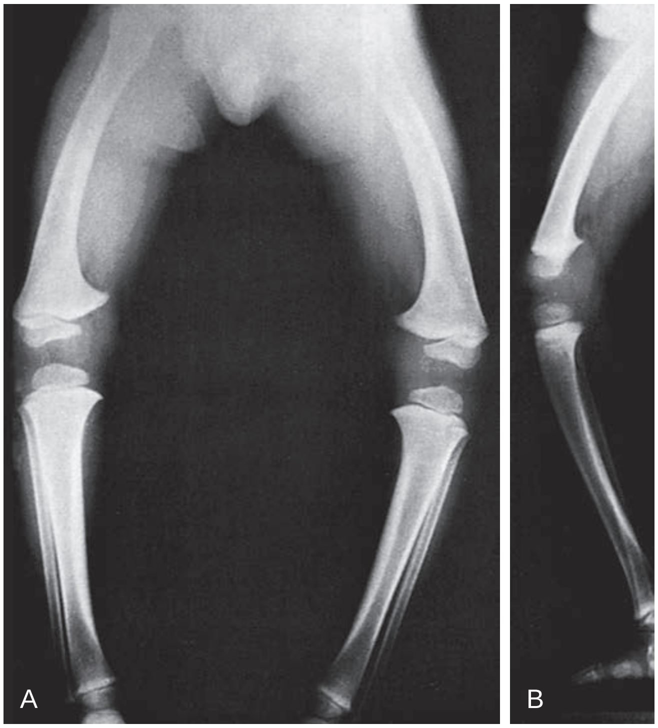
***Imaging.*** Assessment of tibial torsion is often performed with assessment of femoral version. Limited axial low-dose CT images are obtained through the proximal and distal tibias.[43,44] Tibial torsion is best measured as the angle between the posterior proximal epiphyseal cortical margin and a bimalleolar line distally. Normal values are neutral to mild (5 degrees) of external torsion in a newborn, which progresses to 18 to 47 degrees of external rotation in an adult.[43,45,46]

***Treatment.*** Surgery is rarely needed as more than 95% of cases resolve spontaneously, usually by 8 years of age. Tibial rotational osteotomy may be performed to improve alignment.

### Bowleg (Genu Varum)

***Etiologies, Pathophysiology, and Clinical Presentation.*** Bowleg deformity manifests as separation of the knees, with the legs in anatomic position. Pathologic causes include rickets, osteogenesis imperfecta, neurofibromatosis, skeletal dysplasias (i.e., campomelic dysplasia, achondroplasia), focal fibrocartilaginous dysplasia, congenital bowing, Blount disease, and growth plate injuries.[47–50] Recently, greater prevalence of bowleg and tibia vara has been noted in some adolescent athletes, most notably soccer players.[51–53] Repetitive stress on the proximal tibial physis may play a role in this.[52] Most lateral bowing in otherwise normal infants and children younger than 2 years of age is normal developmental ("physiologic") bowing and resolves without treatment.[48,54–56] Similar to Blount disease, exaggerated physiologic bowing is seen more commonly in early walkers, African Americans, and heavier children.[48]

***Imaging.*** Imaging characteristics of physiologic bowing include mild lateral and anterior bowing of the femur and tibia, exaggerated tibial torsion, small beaks along the distal femoral and proximal tibial metaphyses (Fig. 133.14), medial femoral and tibial cortical thickening, wedge-shaped and incompletely ossified distal femoral and proximal tibial epiphyses, and lateral tilting of the distal tibial growth plate.[57] Physiologic bowing is usually more marked in the tibias. Occasionally, lateral bowing may almost exclusively be seen in the distal femur (e-Fig. 133.15). A varus angulation is common in normal infants and converts to valgus between 18 and 36 months



**e-Figure 133.15. Femoral bowed legs (femora vara).** (A) Anteroposterior and (B) lateral projections show marked bowlegs, in which the tibias are straight and both femora are bowed lateral near their distal ends (femora vara). Femoral epiphyseal ossification centers are small and flattened on their medial halves.

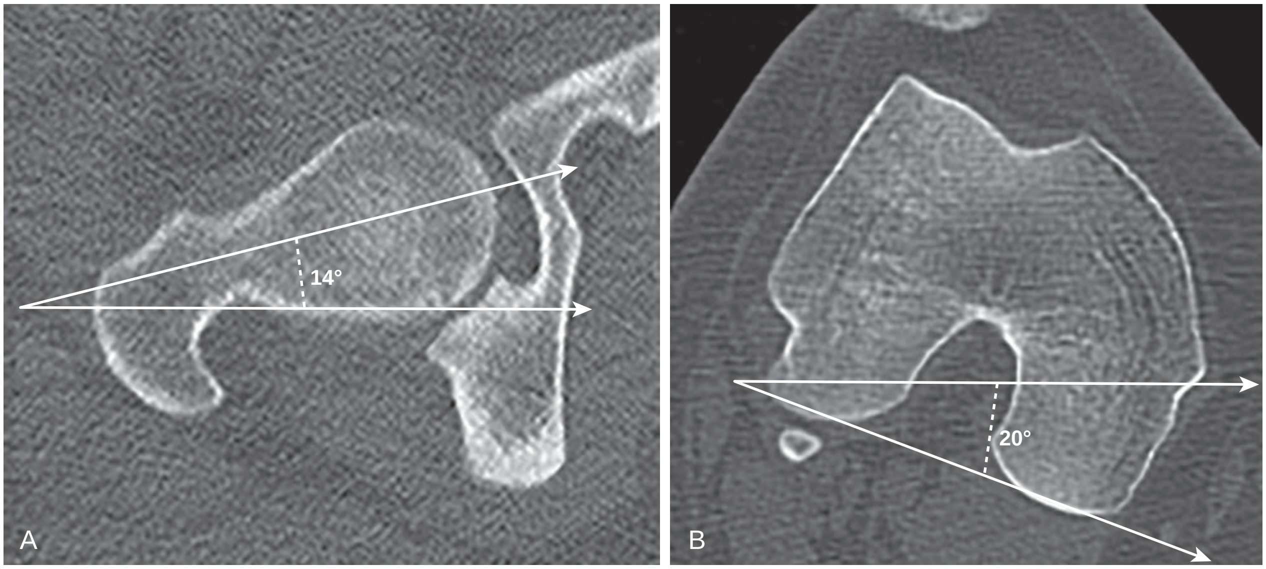


**Figure 133.13. Femoral anteversion in a 16-year-old girl with a history of right femoral fracture.** (A) Axial CT image with line denoting the axis of the femoral neck with respect to the horizontal plane. (B) Axial CT imaging with line denoting the axis of the posterior distal femoral transcondylar axis with respect to the horizontal plane. An angle of 34 degrees of right femoral anteversion was obtained by adding the two angles.

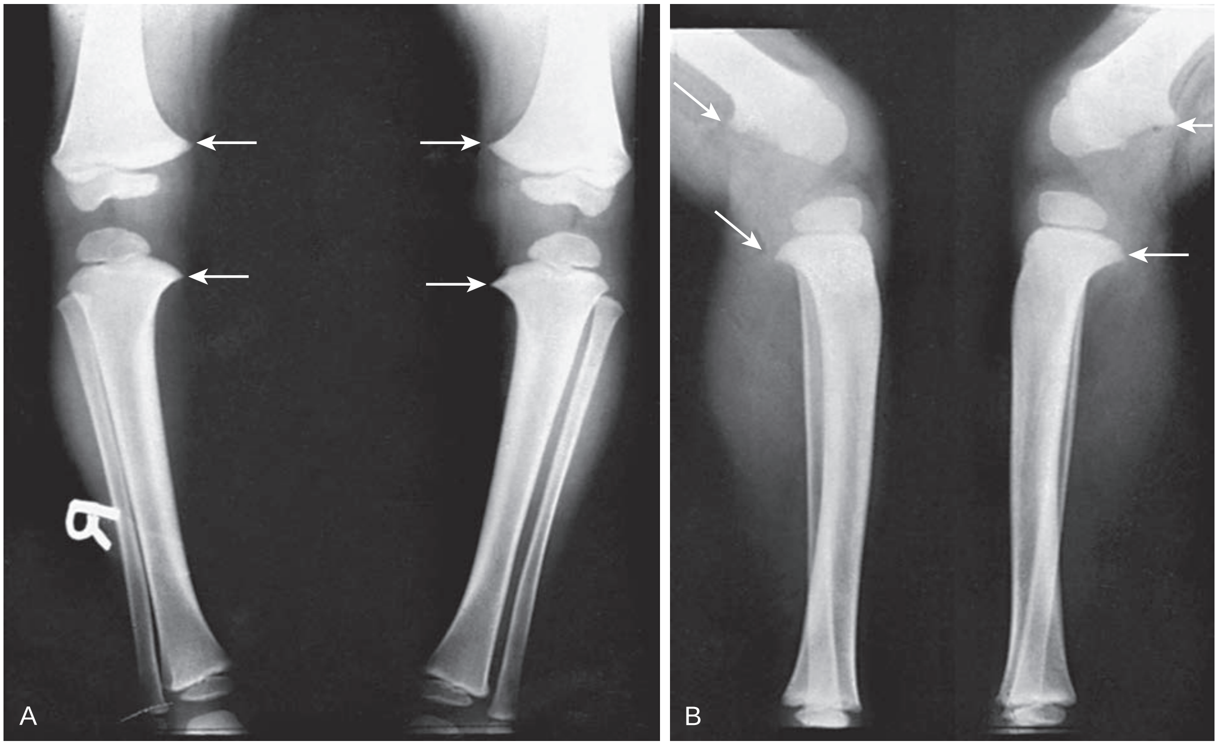

**Figure 133.14. Bilateral idiopathic bowed legs in a 22-month-old boy.** (A) Frontal projection. *Arrows* point to the medial beaking of the femoral and tibial metaphyses at the knees. The increased stress of weight bearing has thickened the medial and dorsal cortical walls of the tibias inward. The medial femoral epiphyseal ossification centers are small, which may reflect the greater stress of weight bearing when the legs are bowed. (B) Lateral projection. *Arrows* point to dorsal beaking of the femoral and tibial metaphyses. After correction of bowed legs, these “stress” phenomena disappear after several months.

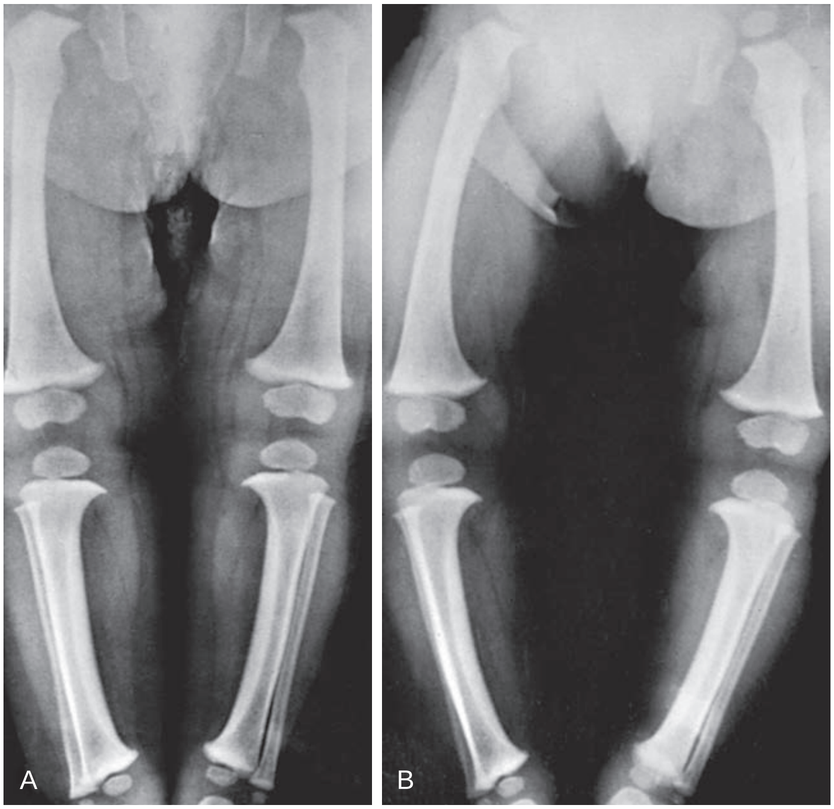

**Figure 133.17. Bowed legs of a 12-month-old girl who started to walk at 8 months.** (A) In recumbent position, the tibias and femora are bowed, but the legs are not bowed because the knees and ankles are in apposition. (B) In the erect position during weight bearing with the ankles in apposition the legs are bowed, with a gap of 12 cm at the knees. The real clinical deformity of bowed legs is shown most accurately when the patient is erect and is bearing weight.

of age. Degree of valgus reduces spontaneously by 6 to 7 years of age to a mild degree that remains throughout life. Approximate normal angles are 17 degrees varus in a newborn, 9 degrees varus at 1 year, 2 degrees valgus at 2 years, 11 degrees valgus at 3 years, and 5 to 6 degrees valgus at 13 years (e-Fig. 133.16).[56,58,59]

Radiographs should be taken with the patient bearing weight as soon as he or she is able to stand (Fig. 133.17). The metaphyseal-diaphyseal angle can help distinguish physiologic bowing from Blount disease (tibia vara), as described in the next section. The radiographs may suggest an underlying disorder such as rickets or a dysplasia.

***Treatment.*** Persistent varus with delayed conversion to valgus may indicate that the varus is not physiologic. In the second year, it may be difficult to distinguish normal physiologic bowing from Blount disease.[60] Exaggerated varus during the second year is likely developmental or physiologic and does not require treatment.[54,55,58] Persistent varus at the knee after 2 years of age should raise concern and prompt monitoring of these children to exclude progression to Blount disease.[59,61] Realignment surgery is rarely needed in isolated bowleg without underlying dysplasia, metabolic bone disease, or Blount disease.

## Blount Disease (Tibia Vara)

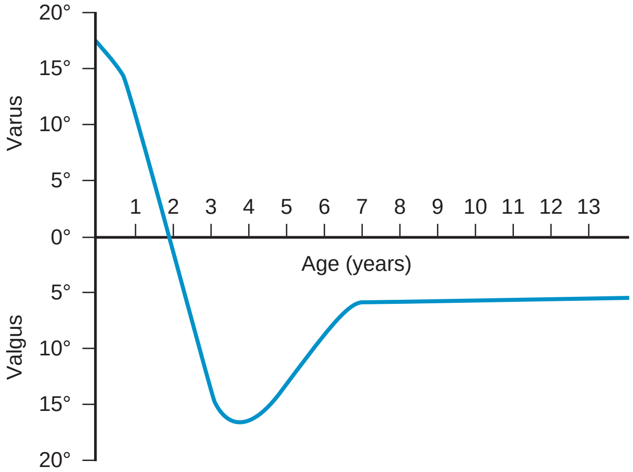
***Etiologies, Pathophysiology, and Clinical Presentation.*** Blount disease (tibia vara; osteochondrosis deformans tibiae) is a progressive deformity affecting the proximal tibia (Fig. 133.18).[62–64] It is theorized that stress on the posteromedial proximal tibial physis causes growth suppression.

The infantile form of Blount disease, which develops in children between 1 and 3 years of age, must be differentiated from developmental bowing.[65] Infantile Blount disease may represent normal developmental bowing that fails to correct. The diagnosis is made when progressive clinical bowing is seen in the presence of characteristic radiographic changes in the proximal tibia.[65] The disease is typically bilateral (60%–80%) but often asymmetric and occasionally unilateral (Fig. 133.19). A family history is often reported. The disorder is more common in early walkers, African Americans, and obese children.[48,64,66]

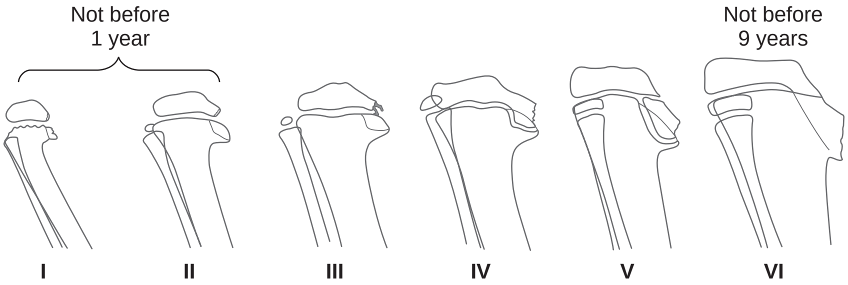
Adolescent or late-onset Blount disease is a separate entity. It occurs in children 8 to 14 years of age; obese African American males of normal height are at particular risk (Fig. 133.20).[47] It is commonly unilateral but may be bilateral. Adolescent Blount disease is slowly progressive and probably results from the repetitive trauma of weight bearing on the medial physis of the proximal tibia.[47] Patients often present with knee pain.

***Imaging.*** The characteristic radiographic feature of infantile Blount disease is deformity of the medial metaphysis of the proximal tibia (Fig. 133.21).[48] Irregularity with a more vertically oriented growth plate creates a beaked appearance. The severity of radiographic changes has been described by the six-stage Langenskiöld classification (e-Fig. 133.22).[67] Higher stage denotes greater abnormality; bone bridging across the physis is seen with stage IV and higher. The medial portion of the epiphyseal ossification center is often smaller than the lateral portion. The tibia may have lateral subluxation.

The metaphyseal–diaphyseal angle (MDA) is measured by drawing a single line through the widest portion of the proximal



**e-Figure 133.16. Development of the tibiofemoral angle during growth.** This graph shows the normal physiologic progression of varus to valgus and then less pronounced valgus angulation at the knee during childhood. *(From Bruce RW Jr. Torsional and angular deformities.* Pediatr Clin North Am*. 1996;43:867–881.)*



**e-Figure 133.22. Radiographic changes seen in infantile tibia vara with increasing age.** *(From Langenskiöld A, Riska E. Tibia vara [osteochondrosis deformans tibiae].* J Bone Joint Surg Am*. 1964;46:1405–1420.)*

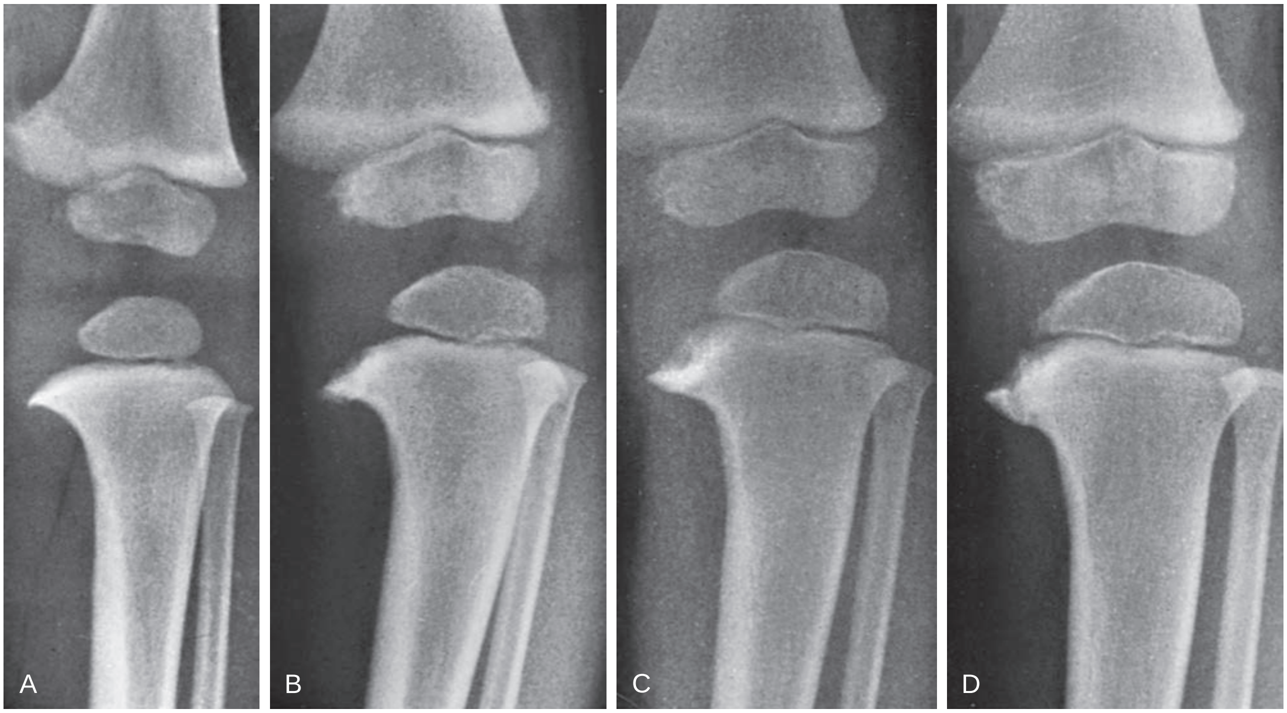


**Figure 133.18. Progressive changes in Blount tibia vara.** (A) At 17 months, the medial segment of the tibial metaphysis is widened and sharpened into a short beak or spur that is bent slightly caudad. (B) At 26 months, the spur is longer, sharper, and more bent; a radiolucent strip on its upper edge represents noncalcified cartilage. (C) At 32 months, the amount of cartilage is increased and the spur thickened. (D) At 38 months, the beak of the spur is displaced caudad, possibly owing to trauma; the medial edge of the epiphyseal ossification center is flattened, and the femur has shifted medial in relation to the tibia.

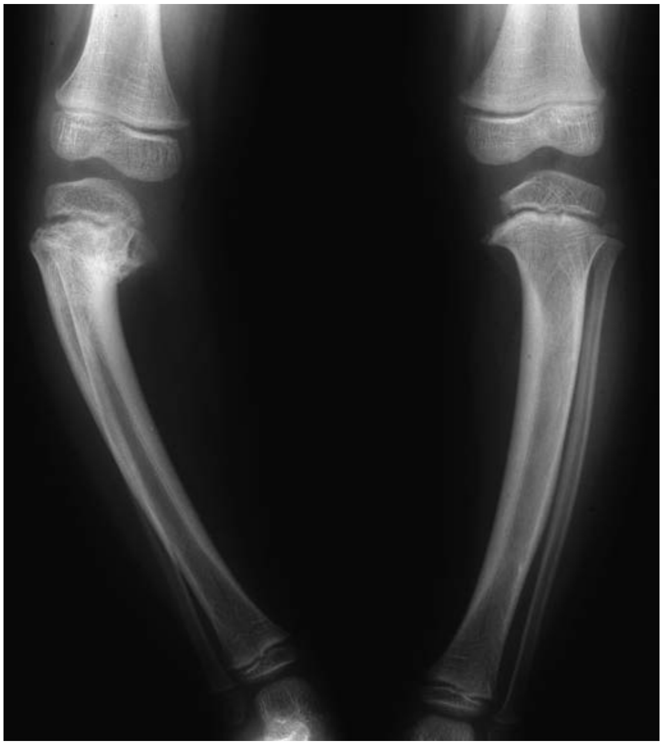

**Figure 133.19. Bilateral Blount disease in a 3-year-old girl.** Abnormality is greater on the right, where more sclerosis and irregularity of the proximal tibial metaphysis are evident.

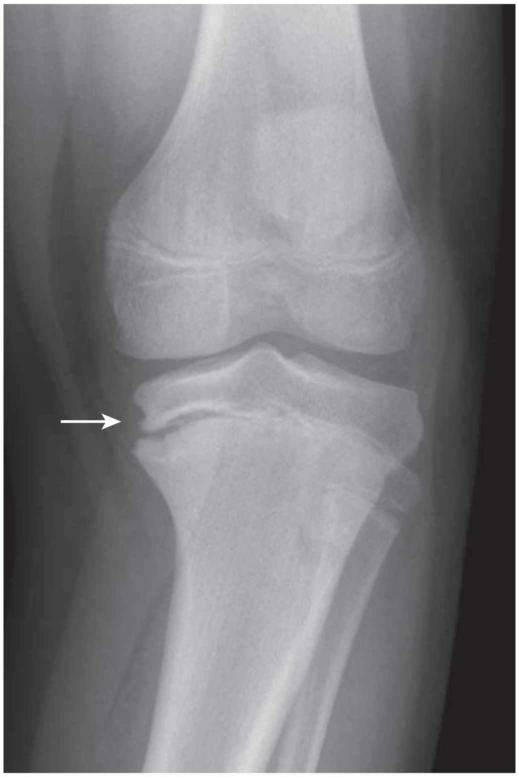

**Figure 133.20. Adolescent Blount disease in a 13-year-old boy.** Note the medial tibial physeal widening, metaphyseal fraying, and diminished medial epiphyseal height *(arrow)*.

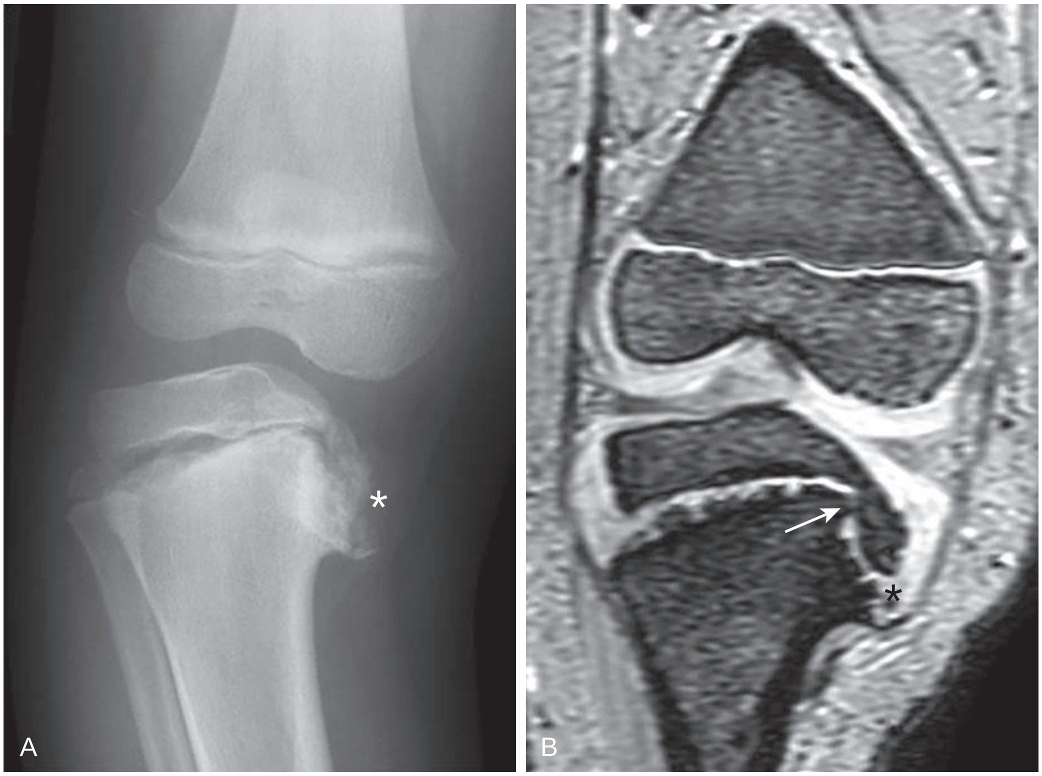

**Figure 133.21. Infantile Blount disease in a 5-year-old girl.** (A) Unlike adolescent Blount disease, sharp metaphyseal angulation *(asterisk)*, beaking, and markedly diminished and near-absent medial epiphyseal ossification of the proximal tibia are seen. (B) MRI cartilage visualization sequence (T1-weighted water selective WATS) in the same patient demonstrates thickened unossified cartilage in the region of metaphyseal irregularity *(asterisk)* and small transphyseal osseous bridge *(arrow)*.

tibial metaphysis (between the medial and lateral beaks) and another line perpendicular to the long axis of the tibial diaphysis.[55] In physiologic bowing, this angle is typically less than 11 degrees (averaging 5 degrees), whereas in Blount disease this angle is typically greater than 11 degrees (averaging 16 degrees) (e-Fig. 133.23). However, there is overlap of the MDAs in these entities in the 8 to 11 degree range, which should be considered borderline and may warrant follow-up.[48–55] Several studies have questioned the validity of the MDA, and measurement may be affected by tibial rotation. Additional angle measurements have been described for the femur and tibia to evaluate deformities in other planes including proximal tibia procurvatum (anterior bowing) and recurvatum (posterior bowing).

Changes related to infantile Blount disease should be distinguished from those of adolescent Blount disease (see Fig. 133.20). The metaphyseal angular deformities, diminished medial epiphyseal height, and degree of tibia vara are typically less severe with adolescent Blount disease.

CT or MRI can assess the degree of proximal tibial growth plate fusion. MRI also allows assessment of associated epiphyseal cartilage abnormalities, stress changes around the knee, meniscal and ligamentous abnormalities (see Fig. 133.21).[68–70]

***Treatment.*** Although spontaneous resolution of infantile Blount disease is reported in some instances, treatment with bracing is begun usually between ages 18 and 24 months and is continued during waking hours for an average of 2 years. If conservative management fails, the patient may undergo a realignment osteotomy, which is most effective when performed before 5 years of age. For adolescent Blount disease, a lateral tibial epiphyseodesis may be performed if sufficient growth potential remains. If the proximal tibial physis is nearly fused, a proximal tibial valgus osteotomy to produce normal alignment may be performed.[64]

## Knock-Knee (Genu Valgum)

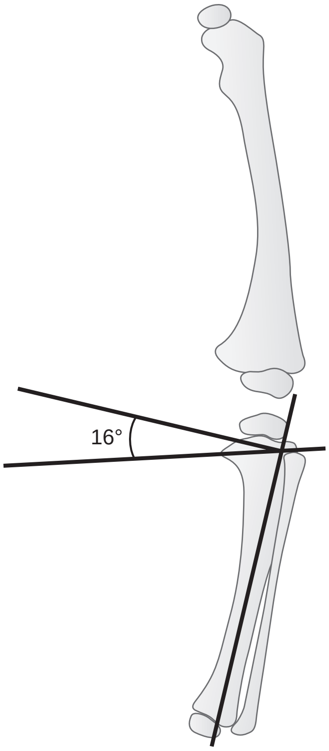
***Etiologies, Pathophysiology, and Clinical Presentation.*** Genu valgum is approximation of the knees in standing position. Physiologic genu valgum is a normal developmental phase that lasts from 2 to 12 years of age and is most apparent at 3 to 5 years of age in normal children.[56,58,59,71] Persistent genu valgum can be related to pathologic causes such as trauma, skeletal dysplasia, obesity, metabolic disease, or laxity of muscles and ligaments.

***Imaging.*** In genu valgum, the lower legs deviate laterally when in anatomic position. Wide separation is noted at the ankles (Fig. 133.24). Radiographs may show evidence of an underlying disorder or complicating process.

***Treatment.*** Treatment is conservative, particularly for children with physiologic genu valgum. Bracing is occasionally employed. Rarely, surgical osteotomies are performed for realignment.

## Leg Length Discrepancy

***Overview.*** Some degree of leg length discrepancy (anisomelia) is common and depending upon the source up to 1 to 2 cm of difference is considered within normal limits.[72] The presence of a leg length discrepancy may reflect overgrowth of the long limb or decreased size or growth of the short limb. Leg length discrepancy clinically presents with alteration of gait and pelvic tilt. With significant pelvic tilt, compensatory scoliosis may develop.



**e-Figure 133.23. Metaphyseal-diaphyseal angle.** This angle is defined as the angle between a line perpendicular to the axis of the tibia and a line through the medial and lateral beaks of the tibial metaphysis. *(From Eggert P, Viemann M. Physiological bowlegs or infantile Blount's disease: some new aspects to an old problem.* Pediatr Radiol*. 1996;26:349–352.)*

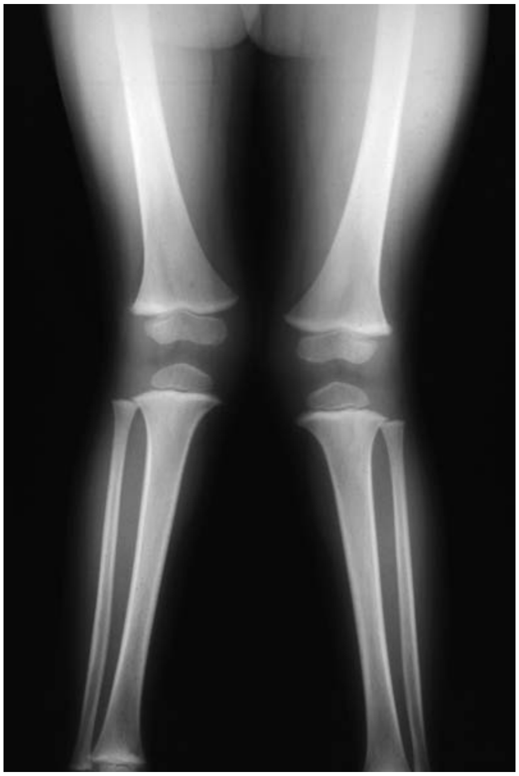


**Figure 133.24. Physiologic knock-knee (genu valgum) in a 3-year-old girl.** In follow-up, the child's legs were seen to have straightened normally, without treatment.

***Etiologies, Pathophysiology, and Clinical Presentation.*** The differential diagnoses for overgrowth and undergrowth is lengthy. Overgrowth is associated with various syndromes and vascular abnormalities. Mild overgrowth may occur as the result of fracture healing. In many cases, the cause is unknown. Undergrowth may be caused by hypoplasia or aplasia of a limb segment. Acquired shortening most often occurs as a consequence of premature growth plate fusion due to trauma, infection, or vascular insufficiency.

***Imaging.*** Radiographic techniques seek to determine bone lengths in a manner that minimizes magnification and other technical factors. Orthoroentgenography ("scanogram") uses three separate exposures collimated to the hip, knee, and ankle with a radiopaque ruler.[73] CT digital scout images may be used to measure bone length.[74,75] However, it is preferable to quantify length and alignment abnormalities with standing radiographs. The EOS 2D/3D system has also been shown to make reliable measurements.[76]

In addition to determining quantitative length and discrepancies in length of the lower extremities, leg length studies should also be evaluated and comments should be made with regard to the alignment of the hips, knees, and ankles. Any underlying cause of the leg length discrepancy such as physeal abnormalities or abnormal bowing deformities should be described.

***Treatment.*** Mild leg length discrepancy does not warrant treatment. The type of treatment varies with age, amount of projected growth remaining, site of abnormality, and degree of leg length discrepancy. Treatment may be aimed at halting growth on the longer side (i.e., epiphyseodesis) or lengthening the shorter side (i.e., lengthening osteotomy procedure).[77] With a lengthening osteotomy procedure, bone on either side of a diaphyseal corticotomy is distracted slowly utilizing an external frame or more recently with expandable intramedullary rods. New bone forms within the gap to add length.

## Feet

***Overview.*** Alignment disorders of the feet may be idiopathic or caused by an underlying disorder. The standard method of radiologic evaluation of the foot involves weight-bearing or simulated weight-bearing anteroposterior (dorsoventral) and lateral views. Diagnosing alignment abnormalities of the feet should be approached with caution when non–weight bearing radiographs are obtained.

The proximally-located talus is considered fixed at the ankle because it has no direct musculotendinous attachments. The calcaneus is linked to the midfoot and forefoot and moves as a unit with these structures relative to the talus. In a normal foot, on the anteroposterior view the axis of the talus extends through the base of the first metatarsal (Fig. 133.25). With hindfoot varus, the more distal calcaneus is angulated inward, and the axis of the talus passes lateral to the base of the first metatarsal. With hindfoot valgus, the more distal calcaneus is angulated outward, and the axis of the talus passes medial to the base of the first metatarsal.[78] The normal lateral talocalcaneal angle is approximately 45 degrees at birth, decreasing to 30 degrees in older children and adults.[78–80] With hindfoot varus, the lateral talocalcaneal angle is decreased (more parallel), whereas with hindfoot valgus, the angle is increased.

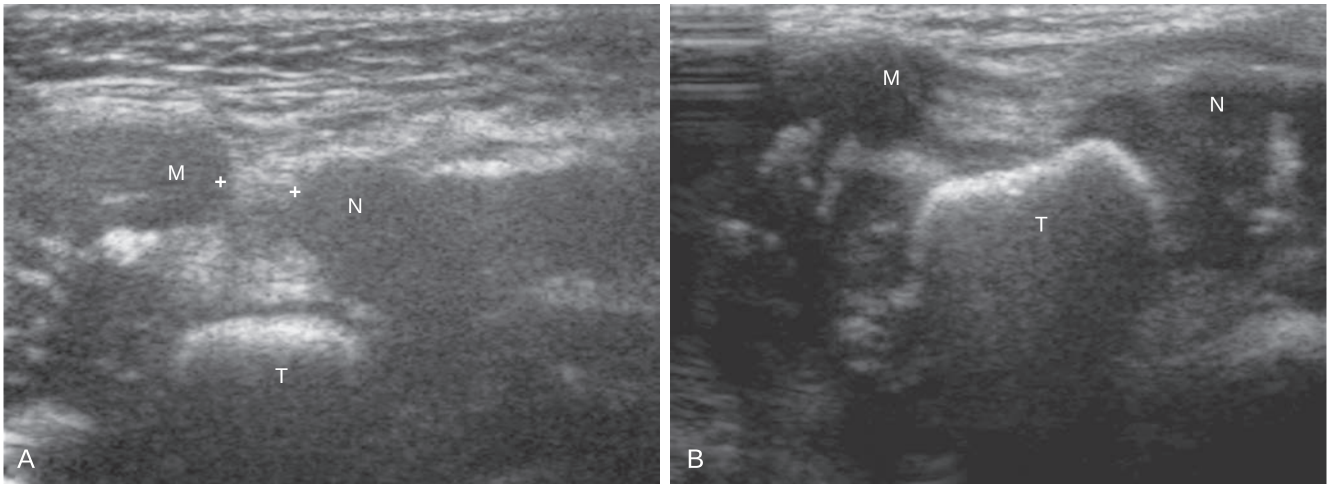
Normal elevation of the middle metatarsals relative to the fifth metatarsal reflects the transverse arch of the foot. The anterior calcaneus is slightly inclined upward. Accentuation of this upward inclination is called *calcaneus* position of the os calcis. Equinus position is downward inclination of the distal calcaneus. Normal calcaneal tilt and normal slight downward tilt of the distal metatarsals create slight longitudinal concavity in the osseous contour of the bottom of the foot.

### Clubfoot

***Etiologies, Pathophysiology, and Clinical Presentation.*** Talipes ("talus" = ankle; "pes" = foot) equinovarus, or clubfoot, is a common congenital anomaly that is clinically obvious at birth. The principal components of clubfoot deformity include plantar flexion of the ankle (equinus), inversion of the heel (varus), and adduction of the forefoot (varus) (Fig. 133.26). Abnormal intrauterine pressures contribute to the development of clubfoot.[81] Genetics also appear to play a role.

***Imaging.*** Radiographs are obtained with true or simulated weight bearing, as this is the position of best correction.[81] An anteroposterior radiograph shows superimposition and parallelism of the talus on the calcaneus with the talar axis directed lateral to the first metatarsal (hindfoot varus). Parallelism of the talus and calcaneus is also on the lateral view. The lateral view shows plantar flexion of the calcaneus (equinus) and a step-ladder arrangement of the metatarsals, with the first metatarsal highest and the fifth metatarsal at the weight-bearing surface of the foot. US has been used in select centers to assess the flexibility of clubfoot and to guide therapeutic decision making (e-Fig. 133.27).[82–85]

***Treatment.*** Current treatment approaches to clubfoot have shifted away from aggressive surgeries to manipulation and minimally invasive surgeries. Nonsurgical approaches to treatment include the Ponseti method, which involves serial casting with or without heel cord lengthening, and the French method, which involves physiotherapy, taping, and passive daily motion.[81,86–88] More invasive surgeries are typically reserved for correcting deformities that persist after conservative treatments.[88] Anatomic deformities persist after treatment of clubfoot and should be recognized as children grow. Many treated clubfeet have small, squared tali with flattened heads, decreased talocalcaneal angles, subtalar joint changes, and medial displacement of the navicular. Valgus deformity and flattening of the plantar arch may result from overcorrection.



**e-Figure 133.27. Ultrasonography of clubfoot in a 6-month-old girl: longitudinal scans at the medial aspect of the feet.** (A) In clubfoot, the cartilaginous navicular *(N)* and the medial malleolus *(M)* are closely spaced *(cursors)*. These structures overlie the talus *(T)*, which is ossified. (B) In the normal foot, the navicular and the medial malleolus are widely spaced, and the talus is not covered. The distance between the navicular and the medial malleolus is an indicator of the severity of deformity and can be monitored over time. Dynamic assessment can reveal if there is flexibility of the deformed clubfoot. *(Courtesy of Dr. M. A. DiPietro, Ann Arbor, MI.)*

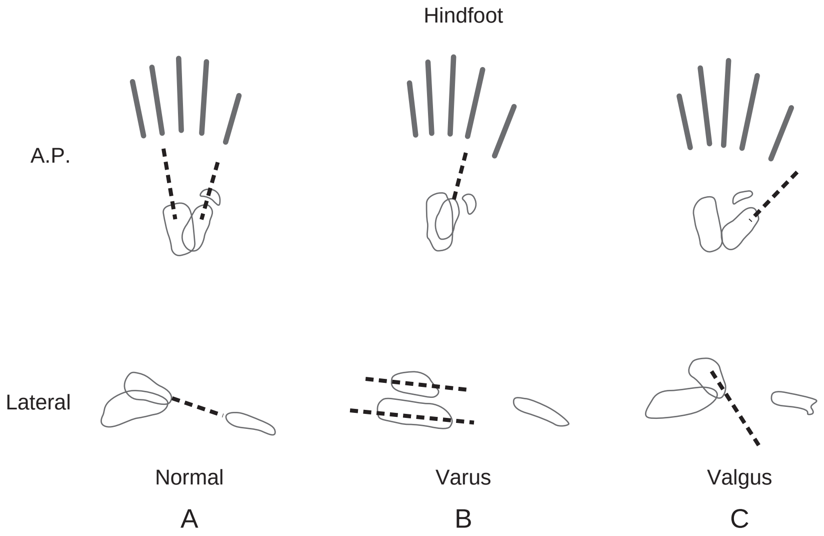


**Figure 133.25. Hindfoot and forefoot relationships in the anteroposterior and lateral projections.** (A) Normal hindfoot. The talar axial line intersects or points slightly medial to the first metatarsal base. The navicular is situated directly distal to the head of the talus. The calcaneus points toward the fourth metatarsal base, forming a definable angle with the talus. On the lateral projection, the anterior portion of the talus is slightly plantarflexed, and the calcaneus is slightly dorsiflexed. The talar axial line points down the shaft of the first metatarsal. (B) Hindfoot varus. The talocalcaneal angle is decreased, with these two bones more parallel to each other and actually superimposed. The navicular is medially displaced, and the axial talar line points lateral to the first metatarsal base. On lateral projection, the calcaneus and the talus are more horizontal and parallel to each other. (C) Hindfoot valgus. The talocalcaneal angle is increased, with the navicular and other midfoot bones displaced lateral to the talus. The talar axial line passes medial to the first metatarsal base. On lateral projection, the talus is more vertical than normal. *(From Ozonoff MB.* Pediatric orthopedic radiology, *2nd ed, Philadelphia: WB Saunders; 1992.)*

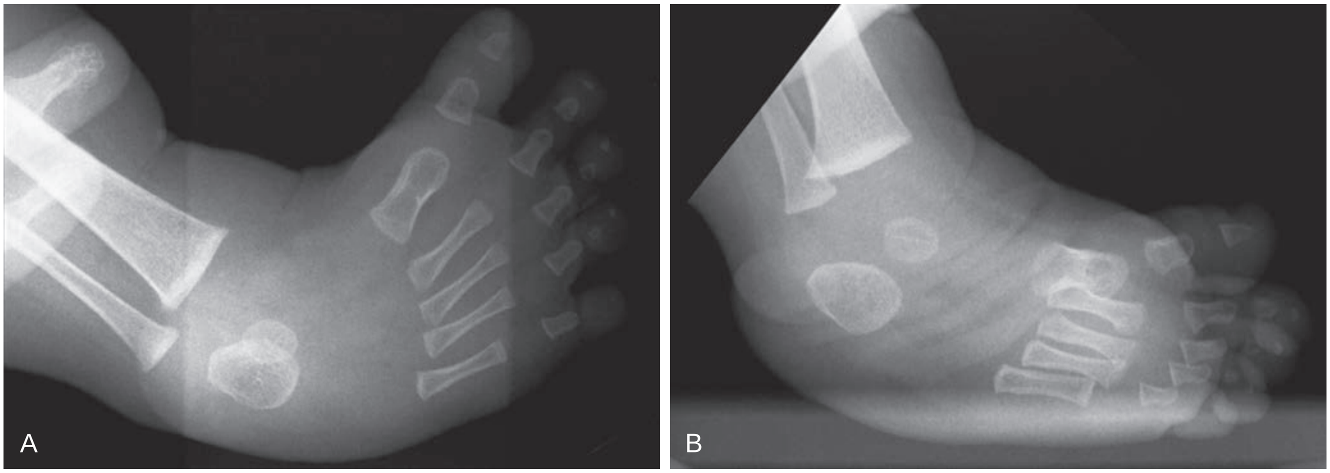

**Figure 133.26. Congenital clubfoot.** Simulated weight-bearing radiographs were obtained for evaluation. (A) Note the ankle inversion and forefoot adduction in the anteroposterior view. (B) Inversion on the lateral view shows “laddering” of the metatarsals. Equinus of the hindfoot and parallelism of the talus and calcaneus are evident.

## Congenital Vertical Talus

***Etiologies, Pathophysiology, and Clinical Presentation.*** Congenital vertical talus (congenital rigid flatfoot) may be an isolated condition or may be seen in association with various syndromes (e.g., trisomies) or other systemic abnormalities (i.e., central nervous system defects, arthrogryposis, and neurofibromatosis).[89,90] The term *oblique talus* refers to a similar abnormality except that it is flexible (reducible) and does not require operative management.

***Imaging.*** The talus is almost completely vertical in this condition (parallel with the longitudinal axis of the tibia), and the calcaneus is fixed in plantar flexion (equinus) (Fig. 133.28). In the anteroposterior projection, the talar axis is medial to the base of the first metatarsal (valgus). The navicular dislocates dorsally, and clinically, a pronated rocker-bottom foot is present. After the navicular ossifies, its abnormal position helps to distinguish congenital vertical talus from severe planovalgus or flatfoot deformity. Prior to ossification, the position of the navicular can

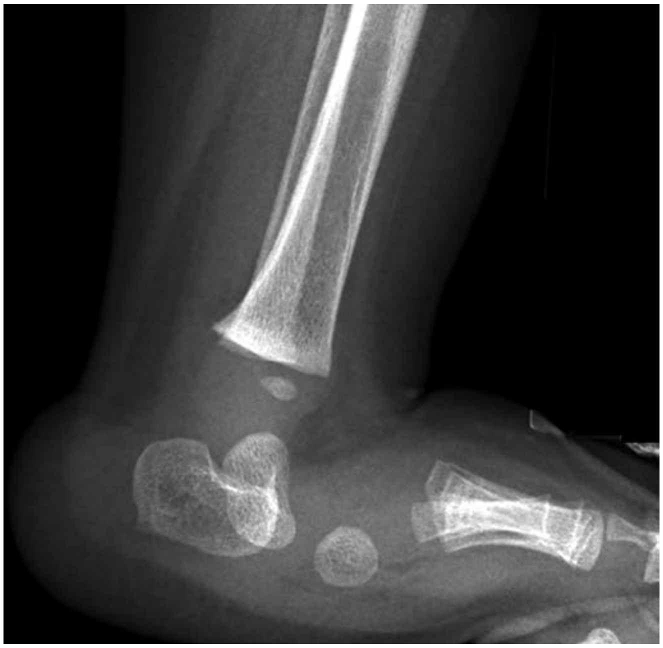

**Figure 133.28. Congenital vertical talus in 5-month-old boy.** Lateral foot radiograph shows hindfoot valgus with the talus nearly vertical in orientation and with the calcaneus plantarflexed.

be determined by US, which can distinguish vertical from oblique talus if this is not evident clinically.[91,92]

***Treatment.*** Congenital vertical talus is initially managed with conservative measures and casting, followed by surgical correction for recalcitrant cases.[90]

## Rocker-Bottom Foot

***Etiologies, Pathophysiology, and Clinical Presentation.*** Rocker-bottom foot is a clinical descriptive term seen with congenital vertical talus, severe cerebral palsy with hindfoot valgus, and as a complication of overcorrected clubfoot.

***Imaging.*** In rocker-bottom foot, the calcaneus is in equinus position and the metatarsals are dorsiflexed, producing a convex surface on the bottom of the foot.

## Metatarsus Adductus (Varus)

***Etiologies, Pathophysiology, and Clinical Presentation.*** Metatarsus adductus, the most common pediatric foot deformity, is a cause of in-toeing that is usually seen in children younger than 5 years of age. Forefoot adduction differs from clubfoot in that midfoot and hindfoot alignment is normal. The foot has a C-shaped contour on examination. Forefoot adduction simulating metatarsus adductus may occur as a result of excessive internal tibial torsion or femoral anteversion.

***Imaging.*** The metatarsals are adducted and hindfoot alignment is normal. There is no stepladder appearance of the metatarsals on the lateral view (e-Fig. 133.29).

***Treatment.*** Metatarsus adductus without other deformity commonly resolves with normal maturation.[93]

## Skewfoot

***Etiologies, Pathophysiology, and Clinical Presentation.*** Skewfoot (Z-foot; serpentine metatarsus adductus) is a rare entity distinct from metatarsus adductus. It develops idiopathically in young children. It can also be seen after treatment of clubfoot or vertical talus, in children with cerebral palsy, and with some dysplasias.[94]

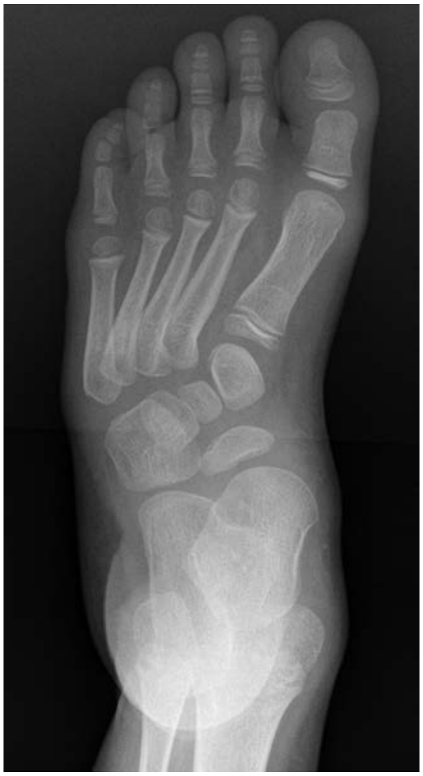

**Figure 133.30. Skewfoot in a 6-year-old girl.** AP radiograph shows the forefoot is adducted, midfoot is abducted with lateral deviation of the navicular, and the hindfoot is in valgus, resulting in a Z-shaped appearance of the feet.

***Imaging.*** In skewfoot, the forefoot is adducted, the midfoot is abducted (navicular shifted lateral to the talar head), and the hindfoot is in valgus, resulting in a “Z”-like distortion of the bones of the foot (Fig. 133.30).[94]

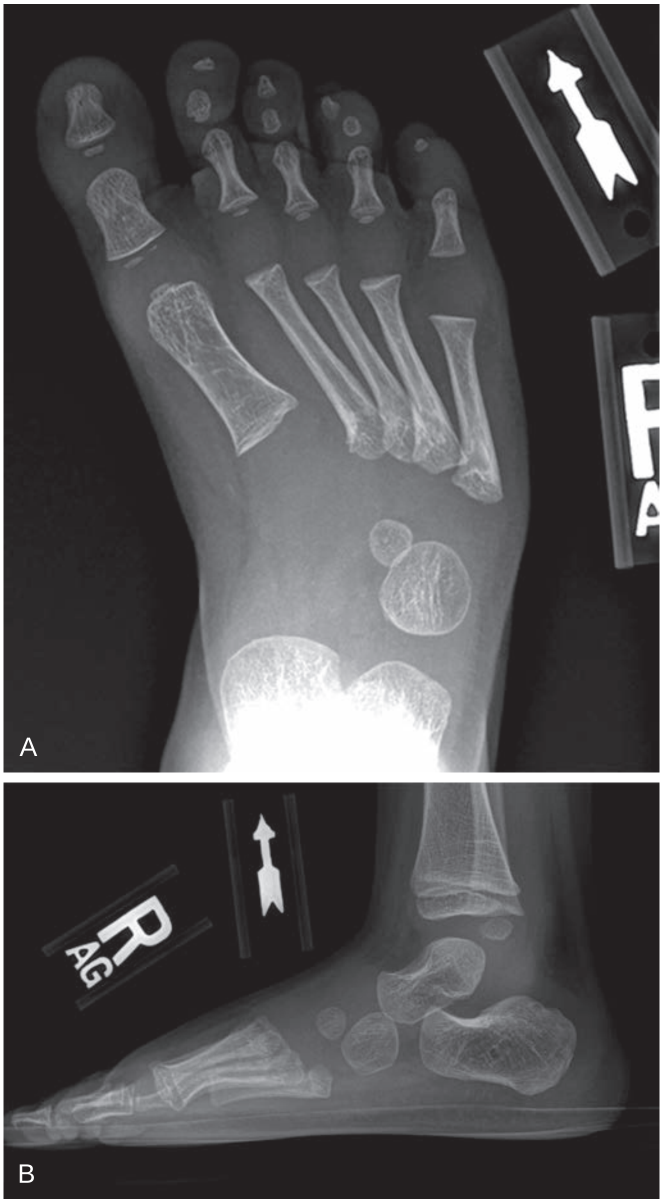
***Treatment.*** Conservative management is applied to most idiopathic cases. A variety of surgical techniques have been applied to reduce deformity in children with fixed or progressive deformity.[93,94]

## Flatfoot (Pes Planus)

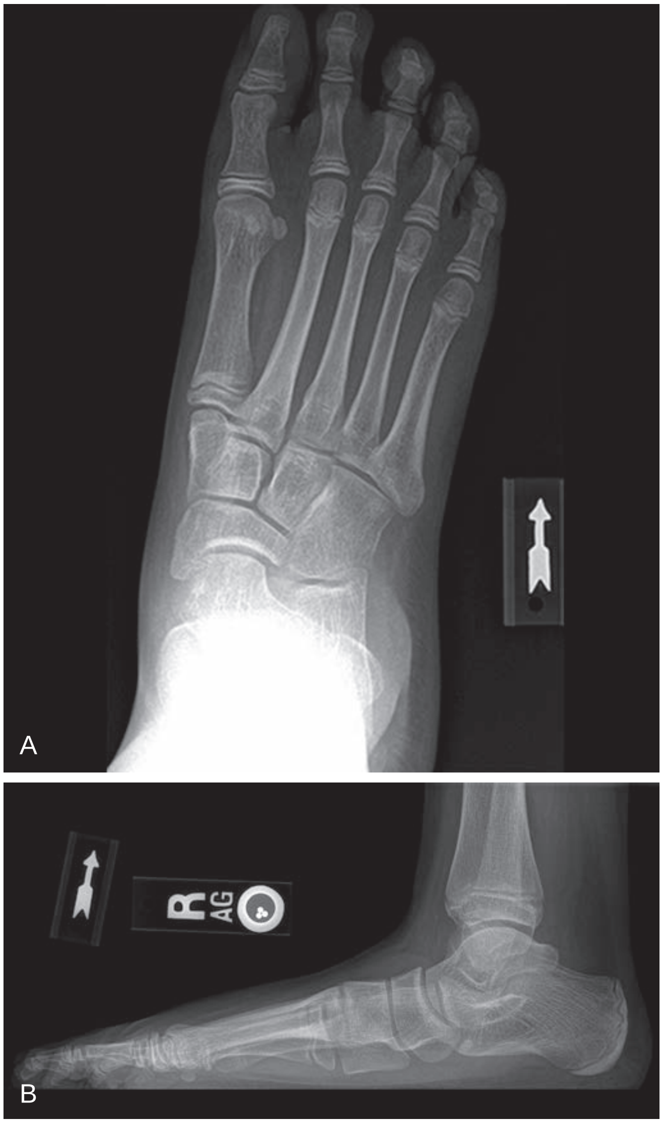
***Etiologies, Pathophysiology, and Clinical Presentation.*** Flatfoot (pes planus) is a descriptive term. The differential diagnosis of pes planus includes flexible planovalgus (common flatfoot), peroneal spastic (rigid) flatfoot related to tarsal coalition, congenital vertical talus (rigid flatfoot), and congenital calcaneovalgus (flexible flatfoot, discussed in the next section).[89,95–97] Tarsal coalition is discussed in Chapter 131.

The common flatfoot is a painless, flexible planovalgus foot.[89] Variable degrees of hindfoot valgus, plantar arch flattening, and forefoot pronation occur. Pathology is thought to involve excess ligamentous laxity, which allows the calcaneus to shift into a valgus position under the talus. Abduction and eversion result from loss of calcaneal support. Patients may develop peroneal muscle spasm and pain caused by irritation.

***Imaging.*** With flexible planovalgus foot, the anteroposterior projection shows hindfoot valgus with an increased talocalcaneal angle and the midtalar line passing medial to the first metatarsal. On the lateral projection, hindfoot valgus causes the talus to be more vertical than normal (e-Fig. 133.31). The navicular subluxes dorsally and laterally with respect to the talar head. The calcaneus



**e-Figure 133.29. Metatarsus Adductus in a 2-year-old boy with pain.** (A) AP weight-bearing radiograph shows adduction of the forefoot and metatarsals. (B) Lateral weight-bearing view shows normal hindfoot alignment and no "laddering" of the metatarsals.



**e-Figure 133.31. Flat foot (planovalgus) in a 10-year-old boy with pain.** (A) Weight-bearing frontal radiograph shows deviation of the talar axis medial to the first metatarsal suggesting hindfoot valgus. (B) Lateral standing view shows flattening of the plantar arch and increased talo-calcaneal angle.

and metatarsals are horizontal longitudinally, and loss of the plantar arch is noted.[89] Similar deformity may occur in children with cerebral palsy (e-Fig. 133.32). With a rigid or painful flatfoot (peroneal spastic flatfoot), CT or MRI may be performed to detect underlying subtalar coalition.

***Treatment.*** Therapy for pes planus depends on the etiology and type of deformity.[95] Flexible planovalgus deformity is managed conservatively.[96] Rigid (spastic) flat foot with tarsal coalition requires surgery.[97]

### Calcaneovalgus

***Etiologies, Pathophysiology, and Clinical Presentation.*** Calcaneovalgus feet are reflective of intrauterine positioning. A total of 30% to 50% of newborns have mild calcaneovalgus deformity.[89] In severe congenital calcaneovalgus, the foot is dorsiflexed with respect to the talus. The defect is flexible and correctable.

***Imaging/Treatment.*** Radiographs are rarely performed but will show a calcaneus deformity and hindfoot valgus. Calcanovalgus foot is treated conservatively with physical therapy.

### Cavus Foot

***Etiologies, Pathophysiology, and Clinical Presentation.*** An idiopathic congenital form of cavus foot exists, but more commonly, the finding is related to neuromuscular abnormalities, including peroneal muscular atrophy (Charcot–Marie–Tooth disease), Friedreich ataxia, myelomeningocele, poliomyelitis, and other paralytic conditions.[98,99] A cavus foot may also result from treated clubfoot deformity.

***Imaging/Treatment.*** In pes cavus, the longitudinal plantar arch is increased. The anterior calcaneus is abnormally dorsiflexed and the metatarsals are plantarflexed (Fig. 133.33). Treatment may involve conservative measures and surgery (soft tissue and plantar fascia release, osteotomy, tendon transfers).[98]

### Hallux Valgus

***Etiologies, Pathophysiology, and Clinical Presentation.*** Hallux valgus deformity begins to develop and may present in childhood.[100] Juvenile hallux valgus affects girls 10 times as frequently as boys and is often bilateral. Patients present with pain and deformity, which may interfere with proper shoe fitting.

***Imaging/Treatment.*** The hallux angle, which is the angle between the long axes of the first metatarsal and first proximal phalanx, is increased in hallux valgus. A hallux angle less than 10 to 15 degrees is normal; in hallux valgus this angle is typically greater than 15 degrees (e-Fig. 133.34). US or MRI can evaluate for inflamed bursa at the metatarsal head in the setting of pain. First metatarsal osteotomy may be performed to correct alignment.[100]

## GENERALIZED DISORDERS

### Cerebral Palsy

***Overview.*** Children with cerebral palsy are afflicted with multiple orthopedic disorders requiring radiographic investigation and surveillance.[35,101,102] Variable manifestations of cerebral palsy are caused by differences in severity and location of the original insult, which can occur during the prenatal or perinatal period as well as a result of injury during early childhood.[101]

***Etiologies, Pathophysiology, and Clinical Presentation.*** The orthopedic disorders of cerebral palsy are caused by imbalanced muscular forces. Although cerebral palsy is a static encephalopathy, the resultant musculoskeletal disease may be progressive, even after skeletal maturity.

***Imaging.*** About 25% of cerebral palsy patients have scoliosis.[35,103] Scoliosis is more prevalent and severe with greater neurologic deficit. As opposed to the S-shaped curves of idiopathic scoliosis, curves in cerebral palsy often have a broad C-shaped contour, and the curves may progress after skeletal maturation.[35,103] Associated findings may include accentuated thoracic kyphosis or lumbar lordosis, spondylolysis or spondylolisthesis, and pelvic obliquity. Nonambulatory patients also show caninization of the vertebral bodies (narrow anteroposterior diameter) caused by lack of weight-bearing forces during development.

Upper extremity defects include radial head dislocation (Fig. 133.35) and contractures at the elbow, wrist, and fingers.[104,105] Kienböck disease and negative ulnar variance are of increased incidence in cerebral palsy.[106] Accelerated degenerative changes in the elbow and wrist are common in older patients.[104]

Abnormalities at the hip include coxa valga caused by lack of weight bearing, increased femoral anteversion, prominence of the lesser trochanter caused by external rotation forces by the iliopsoas tendon, femoral head subluxation or dislocation, acetabular dysplasia, and flattening of the femoral head (see Fig. 133.10).[35,107] Older patients with cerebral palsy show evidence of early degenerative disease at the hips.

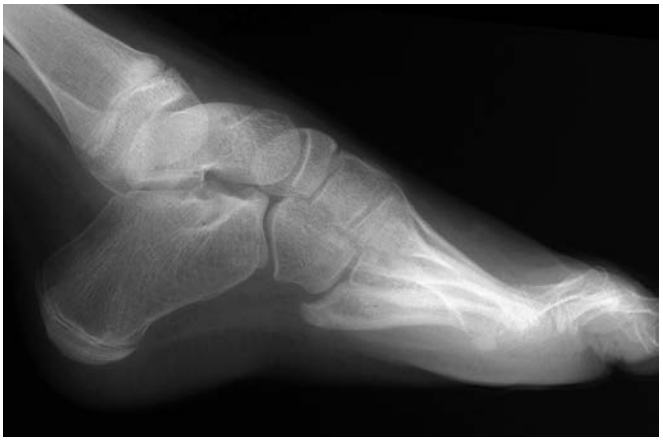


**Figure 133.33. Pes cavus in an 11-year-old girl with Charcot–Marie–Tooth (peroneal muscular atrophy).** Lateral radiograph shows that the talocalcaneal angle is increased, and the longitudinal arch is elevated. The metatarsophalangeal joints are extended, and the interphalangeal joints are flexed (hammertoe deformity).

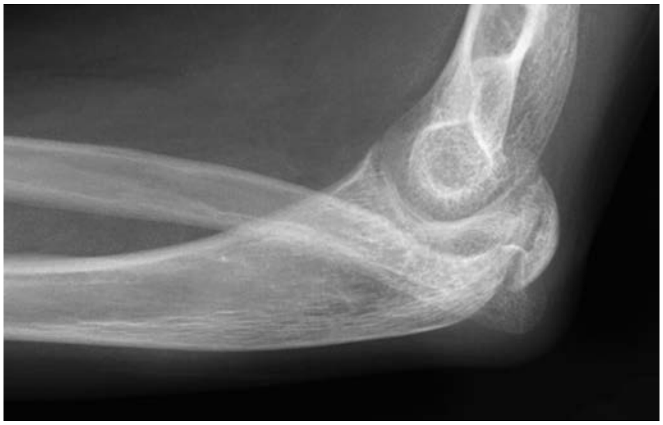

**Figure 133.35. Chronic radial head dislocation in a 14-year-old boy with cerebral palsy.** The radial head is displaced posteriorly and has a rounded contour. The radius is bowed anteriorly. Similar findings were present on the opposite side.

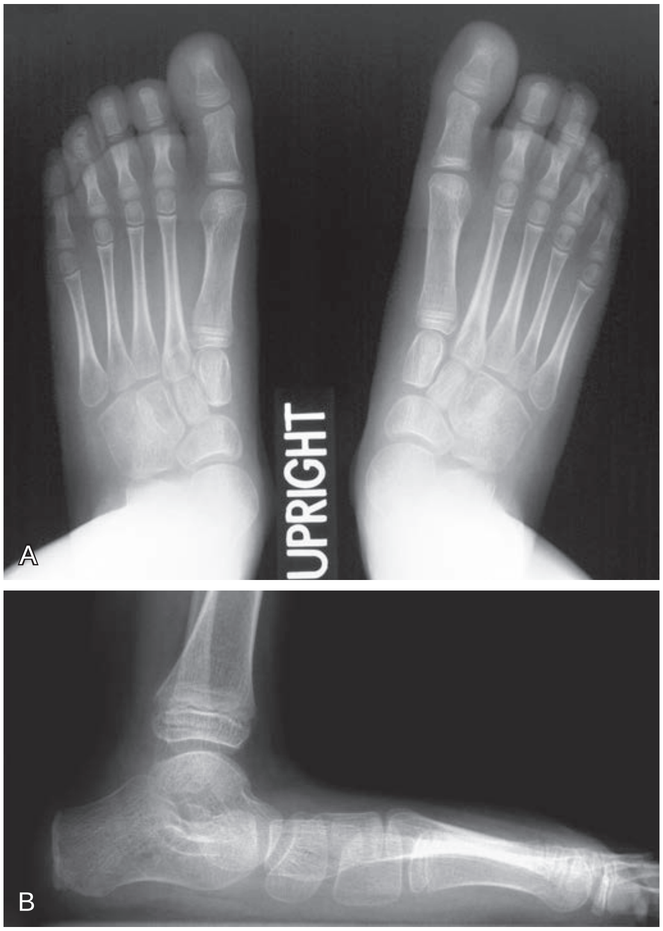
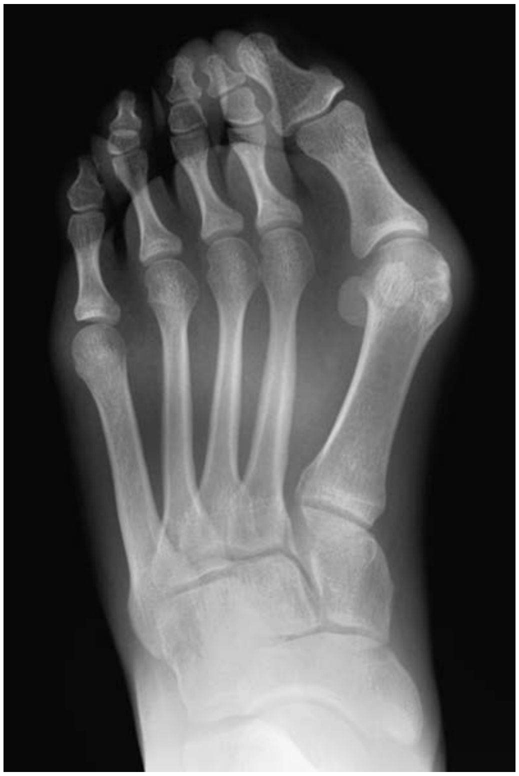


**e-Figure 133.32. Bilateral planovalgus feet in a 9-year-old with cerebral palsy.** (A) In the anteroposterior radiograph, hindfoot valgus is symmetric. (B) Lateral view of the right foot shows pes planus with a mild increase in the lateral talocalcaneal angle, also consistent with hindfoot valgus. The calcaneus is horizontal in orientation.



**e-Figure 133.34. Hallux valgus in a 14-year-old girl.** Slight sclerosis is present in the medial aspect of the first metatarsal head.

At the knee, flexion contractures may be present. The patella is often high (patella alta) and elongated.[33,108] Tug lesions are common at the lower pole of the patella, producing a fragmented appearance.[35,109] The tibial tuberosity may appear elevated and irregular. Genu recurvatum may be seen with rectus femoris contracture. Valgus is seen at the ankle, and equinus and hindfoot valgus are common in the foot (see e-Fig. 133.32).[35,110] Osteopenia predisposes patients with cerebral palsy to fracture.[111]

***Treatment.*** Treatment of orthopedic conditions in cerebral palsy is aimed at maximizing function and limiting the progression of deformity.

## Myelomeningocele

***Overview.*** Children with myelomeningocele and related spinal disorders may be afflicted with multiple orthopedic disorders of the spine and lower extremity requiring radiographic investigation and surveillance.[112,113] Variable manifestations of the disease relate to the level of the defect. Children with other spinal pathologies, including those suffering injury to the spinal cord at a young age, may develop orthopedic disorders similar to those with myelomeningocele.

***Etiologies, Pathophysiology, and Clinical Presentation.*** Orthopedic disorders in myelomeningocele patients are caused by lack of normal muscle development and function. This leads to scoliosis and joint malalignments.

***Imaging.*** Scoliosis in patients with myelomeningocele may be congenital or developmental.[113] In 20% of patients, congenital scoliosis is caused by vertebral segmentation anomalies. Congenital kyphosis is most common at L1–L2. Kyphosis may also be acquired.[113] Lumbar lordosis is commonly accentuated.

Up to one-half of patients with myelomeningocele have hip dysplasia. The hips are occasionally dislocated at birth; however, more often, dysplasia develops over time as the result of paralysis of the hip extensors and abductors with unopposed hip flexors and adductors (e-Fig. 133.36).[113] Coxa valga and increased femoral anteversion are common. Excessive tibial torsion may be seen. In all, 80% to 95% of patients have foot deformities. Equinovarus (clubfoot), congenital vertical talus, and other foot deformities are seen.[113]

Infants with myelomeningocele have an increased incidence of fracture of a lower extremity during birth.[114] A higher incidence of fracture is seen with contractures and higher levels of spinal defect. Patients with myelomeningocele may develop neuropathic injuries as the result of osteoporosis and lack of sensation.[113,115,116] Fractures are most commonly metaphyseal or diaphyseal. Periosteal new bone and callous may be exuberant because of delayed diagnosis without immobilization and abundant subperiosteal hemorrhage.[113,115] Such injuries may be mistaken for tumor or infection.

***Treatment.*** Treatment of orthopedic conditions in patients with myelomeningocele is aimed at maximizing function and limiting the progression of deformity.

### KEY POINTS

- Radiography plays a key role in the diagnosis and surveillance of disorders of alignment. Proper positioning of the patient facilitates evaluation.
- Radiography may show findings of an underlying disorder or complications of treatment, either of which might be clinically unsuspected.
- Bowleg and knock-knee may be physiologic, depending on the age of the patient and the degree of abnormality.
- Radiographic assessment of the foot requires a clear understanding of normal anatomic relationships.
- Orthopedic disorders are common in cerebral palsy. Deformity may continue to progress after skeletal maturity because of imbalanced muscular forces.

# 134 Scoliosis

Eric P. Eutsler, Arthur B. Meyers, and Sumit Pruthi

*Scoliosis* is defined as a lateral spinal curvature greater than 10 degrees, as measured by the Cobb method.[1] Curves less than 10 degrees are termed *spinal asymmetry*. The lateral curvature is often accompanied by abnormalities in the axial and sagittal planes rendering it a three-dimensional abnormality. Scoliosis is classified into various categories, according to etiology, curve location, age at onset, and curve type. The Scoliosis Research Society has classified scoliosis into the following broad subcategories[2]:

1. Idiopathic (infantile, juvenile, and adolescent)
2. Congenital
3. Neuromuscular (neuropathic and myopathic)
4. Syndromic scoliosis (genetic and nongenetic syndromes)

## BIOMECHANICS AND PATHOGENESIS

Scoliosis is a three-dimensional deformity. The initiation and progression of the scoliotic curve is commonly thought to result from the effect of the Hueter-Volkmann law, which states that, during skeletal immaturity, the ring apophyses in the vertebrae are inhibited by compressive forces and stimulated by tensile forces.[1,3] Due to its physiologic curvature, there are normally increased compressive forces on the ventral aspect and distractive forces on the dorsal aspect of the thoracic spine. Initiation of a scoliotic curvature is believed to start with an abnormal axial rotation of vertebrae leading to abnormal distribution of these forces to the lateral margins of the vertebral bodies. The ventral portion of the spine, which is subjected to compressive forces, undergoes decreased growth and becomes the concave portion of the scoliotic curve. The dorsal portion of the spine, which is subjected to tensile forces, undergoes accelerated growth and becomes the convex portion of the curve.[3] This asymmetric growth is not only the genesis of the curve but may also have significant surgical implications, as the pedicles on the concave side become asymmetrically smaller, complicating pedicle screw placement for spinal fixation.[4]

## TERMINOLOGY

An understanding of the nomenclature and methods of measurement used to describe scoliosis on radiographs is essential for radiologists (Fig. 134.1). Identification of the curve apex, significant vertebrae, and central sacral vertical line (CSVL) is crucial for denoting the curve type, which guides treatment decisions.[5,6]

- *CSVL:* A vertical line (parallel to the edge of the radiograph) drawn on frontal radiographs through the center of the sacrum.[5–7] Also referred to as the *central sacral line (CSL).*
- *Apex:* The vertebra (apical vertebra) or the disk (apical disk) most laterally deviated in the scoliosis curve.
- *End vertebrae:* The vertebrae (cephalad end and caudal end) with the maximum tilt toward the apex of the curve.
- *Stable vertebra:* The most cephalad vertebra below the caudal end vertebra most closely bisected by the CSVL.
- *Neutral vertebrae:* Vertebrae with no axial rotation on a frontal standing radiograph.
- *Cobb method:* Used to measure degree of spinal curvature. The *Cobb angle* is formed between lines drawn along the superior endplate of the cephalad end vertebra and the inferior endplate of the caudal end vertebra. If the endplates cannot be visualized, the lines can be drawn along the borders of the pedicles.
- *Plumb line:* A vertical line drawn on standing frontal and lateral radiographs at the center of the C7 vertebral body. Used to determine coronal and sagittal balance.
- *Coronal balance:* Assessed by measuring the distance between the plumb line and the CSVL on a frontal radiograph. Positive coronal balance is present when the plumb line is greater than 2 cm to the right of the CSVL, and negative coronal balance is present when the plumb line is 2 cm to the left of the CSVL.[5–8]
- *Sagittal balance:* Assessed by measuring the distance between the plumb line and the posterosuperior corner of the S1 vertebral body. Positive sagittal balance is present when the plumb line is greater than 2 cm anterior to this corner, and negative sagittal balance is present when the plumb line is 2 cm posterior to this corner.[5–8]
- *Kyphosis:* Posterior convex angulation of the spine. The primary sagittal curves, which are present since birth, include the thoracic and sacral kyphoses. Thoracic kyphosis is measured on lateral radiographs as the angle between lines drawn along the superior endplate of the superior most thoracic vertebral body identified (usually T2 or T3) and the inferior endplate of T12. Normal thoracic kyphosis measures 20 to 45 degrees.[9–13] Most thoracic idiopathic scoliosis is associated with a decrease in normal thoracic kyphosis. A true kyphotic component may indicate a congenital or neuromuscular origin; however, some idiopathic cases may have a true kyphotic component.[1,6,13]
- *Lordosis:* Anterior convex angulation of the spine. Secondary sagittal curves, which are acquired to assume bipedal stance, include the cervical and lumbar lordoses typically established by age 6 years.[9,10] Lumbar lordosis ranges from 30 to 80 degrees when measured from L1 to L5.[1,11,12,14]
- *Curve location:* This is defined on the basis of the location of the apical vertebra and is classified as *cervical* (apex between C2 and C6), *cervicothoracic* (C7–T1), *thoracic* (T2–T11), *thoracolumbar* (T12–L1), *lumbar* (L2–L4), or *lumbosacral* (L5 and below).[1,6,13]
- *Curve types:* The curve is classified broadly as *primary* (major) or *secondary* (minor) *curves*, or *structural* or *nonstructural curves*.
- *Major (primary) curve:* Curve with the largest Cobb angle on the frontal radiograph.
- *Minor (secondary) curve:* Any curve that does not have the largest Cobb angle on the frontal radiograph. Usually develop after the major curve to stabilize the position of the head and pelvis.[6,13,15,16]
- *Structural curve:* A curve that is >25 degrees and does not correct to <25 degrees on an ipsilateral frontal bending view.[17] Additionally, a minor curve may be considered structural if it has a regional kyphosis of >20 degrees on a lateral radiograph, even if it does not meet the aforementioned criteria.[17]
- *Nonstructural curve:* Curves that do not meet the criteria for *structural curves*. These may be secondary curves or *functional curves* (curves related to posture, secondary to leg length discrepancy, muscle spasm, etc.).[13]
- *Classification of curves:* Various different classification systems exist describing the curve types preoperatively. The importance of classification systems is that they help guide the surgical approach and compare the efficacy of different treatment methods.[6,13] The most widely used classification system is

## Abstract:

Scoliosis is defined as a lateral spinal curvature greater than 10 degrees, as measured by the Cobb method. Curves less than 10 degrees are termed spinal asymmetry. The lateral curvature is often accompanied by abnormalities in the axial and sagittal planes rendering it a three-dimensional abnormality. Scoliosis is classified into various categories, according to etiology, curve location, age at onset, and curve type. This chapter reviews the various measurements and auxiliary findings in patients with scoliosis in order to aid pediatric radiologists in creating value-added reports.

## Keywords:

Scoliosis
Cobb
Idiopathic
Congenital
Neuromuscular
Adolescent

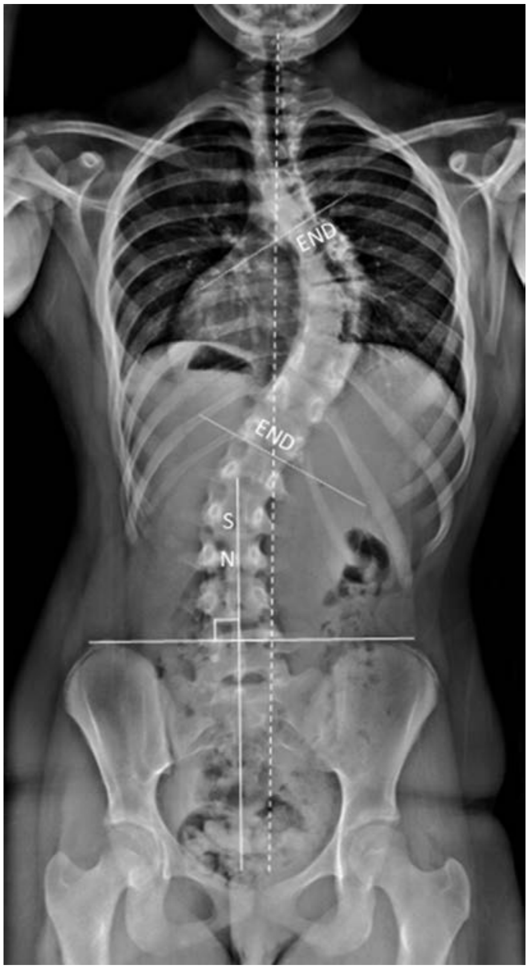

**Figure 134.1. Nomenclature.** Frontal image from a biplanar digital slot-scanning radiologic device (EOS Imaging, Paris, France) from a patient with scoliosis. Note that the image is presented with the patient's left side on the left side of the image, which is the way orthopedic providers typically view these images (similar to how they evaluate scoliosis on physical exam looking at the patient's back from behind). The end vertebrae *(END)* are the vertebra that are most tilted along the curve. The Cobb angle for the thoracic dextrocurvature is the angle between tangents *(thin oblique solid lines)* drawn along the cephalad end plate of superior end vertebra and the inferior end plate of caudal end vertebra. The central sacral vertebral line (CSVL) *(solid vertical line)* is a line that bisects the sacrum and is perpendicular to a tangent across the iliac crests *(solid horizontal line)*. The stable vertebra *(S)* is the most cephalad vertebra below the caudal end vertebra that is most closely bisected by the CSVL. A neutral vertebra *(N)* is one with no axial rotation on a frontal standing radiograph. The plumb line *(vertical thick dashed line)* is a line that is drawn from the center of the C7 vertebral body and is parallel to the edge of the image. If the distance between the CSVL and the plumb line is 2 cm or greater, it indicates coronal imbalance.

the Lenke system.[6,13,17,18] The Lenke system divides curves on the basis of location and type, differentiates structural from nonstructural curves, and includes lumbar and sagittal modifiers.[17,18]

## IDIOPATHIC SCOLIOSIS

Idiopathic scoliosis constitutes 80% of the patients with spinal deformity and is a diagnosis of exclusion.[1]

***Etiologies, Pathophysiology, and Clinical Presentation.*** The reported prevalence of idiopathic scoliosis in children and adolescents ranges from 0.5 to 3 per 100.[1,19,20] In the mild curves (<20 degrees), the female-to-male ratio is 1 : 1, but, when greater and progressive curves are evaluated (>30 degrees), females predominate with a 5 : 1 to 7 : 1 ratio. Only 0.2% of children have severe curves (>30 degrees).[1,20,21]

Idiopathic scoliosis is further divided into the following types based on age at diagnosis: *infantile* (0–3 years); *juvenile* (4–10 years); *adolescent* (11–18 years); and *adult* (≥18 years). Age at onset has significance both in terms of the prevalence of an associated underlying neuraxis abnormality as a cause and the natural history of the curve. The general term *early onset scoliosis* is increasingly being used to classify scoliosis beginning before the ages of 5 to 10 years.[2,22] The rationale behind this distinction is the increased risk of cardiopulmonary compromise in younger children with larger curves.[2,23]

***Imaging.*** The role of imaging is to characterize the curve type and severity, evaluate progression, determine the need for and planning of surgery, monitor treatment-related changes, and identify associated structural and underlying neuraxis abnormalities.[24] Radiography is principally utilized in idiopathic scoliosis to monitor curve progression, with cross-sectional imaging reserved for particular situations, discussed later.[2]

***Screening.*** Upright, standing, posteroanterior radiograph of the entire spine is the standard initial screening examination once the deformity is suspected clinically. The radiograph should include the cervicothoracic junction and pelvis. Standing radiography is preferred because treatment methods are based on standing views, and the magnitude of the curve is greatest in the standing position. However, sitting or supine positioning can be used in nonambulatory children. It is important to be aware of patient position because it is easy to mistake change in curvature as curve progression if an upright radiograph is compared with a prior supine radiograph.[1] The patient should stand with the feet shoulder-width apart, looking straight ahead with the elbows bent and knuckles in the supraclavicular fossa bilaterally, allowing visualization of the upper thoracic region on the lateral radiographs.[25] A lateral radiograph is not required at the time of screening but should be obtained in patients with documented scoliosis to assess sagittal balance. Radiographic techniques should minimize radiation exposure, especially to sensitive organs (e.g., breast, thyroid, and lens of eyes). A posteroanterior technique involves less radiation to the breast compared with an anteroposterior technique. Recently developed, the biplanar digital slot-scanning radiologic device (EOS Imaging, Paris, France) uses two narrow fan beam sources to acquire concurrent, high-quality, orthogonal radiographic images of the spine without the need for a grid, thus reducing radiation exposure.[26] Stereotactic three-dimensional reconstructions can also be created from the images, which is useful for both patient education and surgical planning.[26]

*Curve Magnitude:* The Cobb angle is the accepted standard for assessing the magnitude of the scoliotic curve. Although the Cobb angle provides limited assessment of the deformity and does not take rotation into account, it is still the foundation for diagnosis, follow-up, and treatment.[1] It is important to note that multiple factors, including patient positioning, radiographic techniques, known diurnal variation of 5 degrees, and interobserver and intraobserver variability may all affect the reproducibility of the angle.[27–31] Despite multiple caveats, measurements of the Cobb angle are generally considered reproducible when techniques are kept constant. A progressive curve is usually defined by a Cobb angle increase of 5 degrees or more between consecutive examinations.[1,2,6]

*Assessing Curve Patterns and Progression:* Prognosis and management in scoliosis is highly variable but is usually governed by three important factors: (1) etiology, (2) magnitude and the type of the curve(s) at presentation, and (3) speed of curve progression. The risk of progression is directly related to the spinal growth

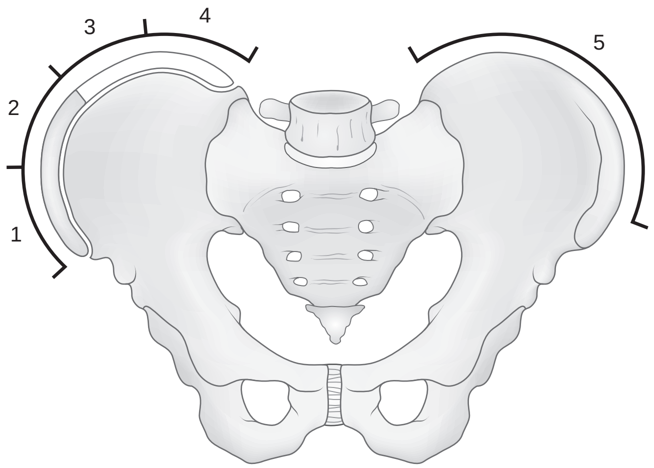

**Figure 134.2. Risser grade.** The Risser grade proceeds from grade 0 (no ossification) to grade 4 (all four quadrants show ossification of the iliac apophysis). When the ossified apophysis fuses completely to the ilium (Risser grade 5), the patient is skeletally mature. *(From Herring JA, ed. Scoliosis. In: Herring JA, ed.* Tachdjian's pediatric orthopedics. *vol 1. 3rd ed. Philadelphia: WB Saunders; 2002:213–321.)*

remaining, the severity of the curve at presentation, and the gender of the patient.[1,10,20,32,33] Various clinical tools to assess residual growth potential include chronologic age, menarche in girls, serial height measurements, and Tanner staging.[10,20,34–38] In general, the onset of the adolescent growth spurt occurs at 13 years in boys and 11 years in girls. In girls, menarche indicates the declining phase of the growing peak and a low risk of progression for idiopathic curves under 30 degrees.[1,10,34,36] Development of the iliac bone apophysis, quantified by Risser, has become a universally accepted sign (Fig. 134.2). Despite the wide use of the Risser grade as a measure of maturity, the appearance of the iliac apophysis generally occurs after the most important period of rapid growth.[1,34,35] As a result, other radiographic parameters are also used to assess bone maturation. Bone age may be assessed from a hand and wrist radiograph; however, use of bone age becomes less accurate in the juvenile age group secondary to the larger standard deviation and interobserver variability.[1,39] Assessment of pelvic triradiate cartilage is considered more accurate than the Risser grade. The triradiate cartilage closes around age 11 years in girls at the time of peak growth velocity.[1,24] More than one imaging parameter is often taken into consideration for accurately assessing skeletal maturation.

With regard to *curve patterns*, curves with an apex above T12 are more likely to progress compared with isolated lumbar curves.[1] With regard to *curve magnitude*, Risser stage 0 or 1 patients with an initial curve of 5 to 19 degrees progressed in 22% of cases, compared with curve progression in 68% of cases with initial curve magnitude of 20 to 29 degrees.[33] The rate of curve progression increased to 90% when the initial curve was 30 to 59 degrees.[1]

Most idiopathic scoliosis cases do not require imaging beyond radiography. Given that the prevalence of central nervous system abnormalities in patients with presumed adolescent idiopathic scoliosis is very low, ranging from 2% to 4%, magnetic resonance imaging (MRI) is typically reserved for patients with an unusual curve pattern or clinical findings that increase the likelihood of an underlying abnormality.[40–42] There is not yet a clear consensus on when to perform MRI in idiopathic scoliosis, but indications include the following: age 10 years or younger; abnormal neurologic examination; painful scoliosis; a left thoracic curve; hyperkyphotic sagittal alignment; rapidly progressing curves; and other radiographic abnormalities (Fig. 134.3).[1,2,6,40,41,43]

***Treatment and Follow-up.*** Treatment of idiopathic scoliosis varies on a case-by-case basis and is surgeon specific. The majority of patients with idiopathic scoliosis present with curves less than 20 degrees with very minimal risk of progression even without treatment. These patients are often monitored with clinical and radiographic follow-up only.[1,6]

*Bracing:* Bracing (e-Fig. 134.4) is generally indicated when a scoliotic curve progresses from 25 to 30 degrees with a documented annual curve progression of at least 5 degrees, with the upper limit of curve magnitude being 45 degrees.[1,44] Bracing modifies spinal growth by applying an external force and is usually effective in patients with substantial spinal growth remaining (Risser 2–3 or less).[1,2,6] Bracing typically limits progression, but it usually does not stop or improve the curve.

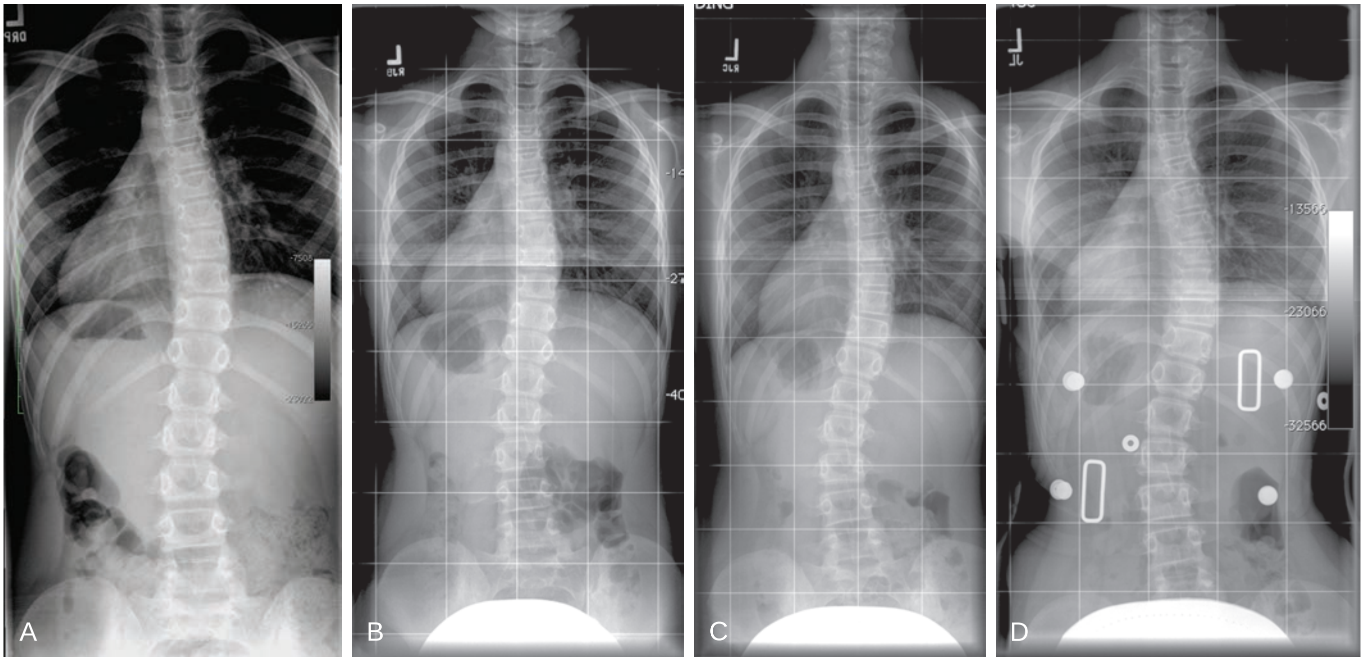
*Risser Casting:* In some cases, a molded (Risser) cast is applied as an alternative to bracing to provide increased corrective force (e-Fig. 134.5). The primary indication is in patients who have progressive scoliosis and are too small for rigid instrumentation or in those patients who have severe deformities and are too young to undergo fusion. The idea behind casting is to avoid the repeated surgeries necessary after application of a growing rod instrumentation system.[1] Similar to bracing, Risser casting only limits curve progression.

*Surgery:* The primary goal of surgical treatment is stabilization of curve progression, with secondary goals of improvement in spinal alignment and balance of the body.[1,6] The indications for surgical correction include the degree of curvature, risk for progression, skeletal maturity, and curve pattern. Moreover, the cosmetic perception of the deformity by the patient or the patient's family may also influence the decision for surgery.[1]

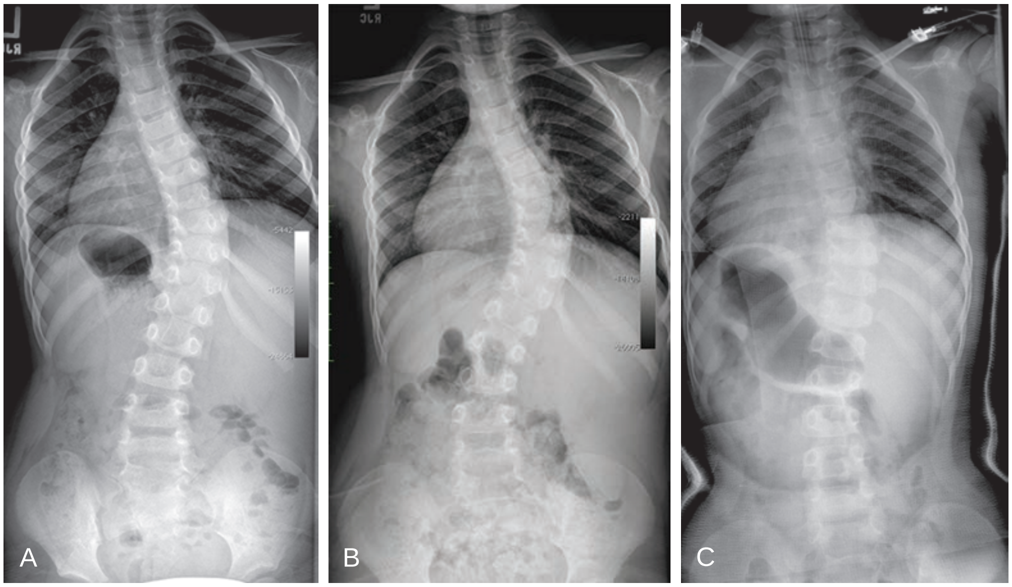
Thoracic curves of greater than 40 to 50 degrees in skeletally immature patients are usually surgically corrected; in skeletally mature patients, surgical correction is reserved for curves of 50 degrees or more.[1] Surgical treatment includes corrective instrumentation plus anterior or posterior fusion of the spine, with the aim of correcting both the coronal and sagittal deformities. The surgical goal is to achieve a stable bony fusion mass to maintain the correction over time, with the hardware serving as internal struts while fusion proceeds. Harrington rods were previously used for surgical correction; however, they failed to address the hypokyphotic component occurring in most patients with idiopathic scoliosis, and often resulted in a "flat back deformity."[1] Therefore Harrington rods have been replaced by various hook-and-rod or screw-and-rod systems, which correct the coronal imbalance while maintaining sagittal balance (e-Fig. 134.6).[1,45] Instrumentation without fusion (as with growing rods) is sometimes used in young children with rapidly progressing curves. The vertical expandable prosthetic titanium rib (VEPTR) is one such system, which is more commonly used in the treatment of infantile and juvenile types of idiopathic scoliosis. Traditionally, growing rods required multiple surgeries to lengthen the rods. To eliminate the risks from repeated operations, magnetically controlled growing rods (MCGR) have been developed. These rods can be distracted in small increments in an exam room under ultrasound guidance, eliminating the need for surgery and reducing radiation exposure (Fig. 134.7).

In broad perspective, to improve surgical outcomes, the segment to be fused should be as short as possible but long enough to minimize residual disease. Usually, the stable vertebra defines the lower limit of fusion.[13] Efforts are made to avoid nonstructural curves and to spare as many mobile segments of the lower lumbar spine as possible.[6]

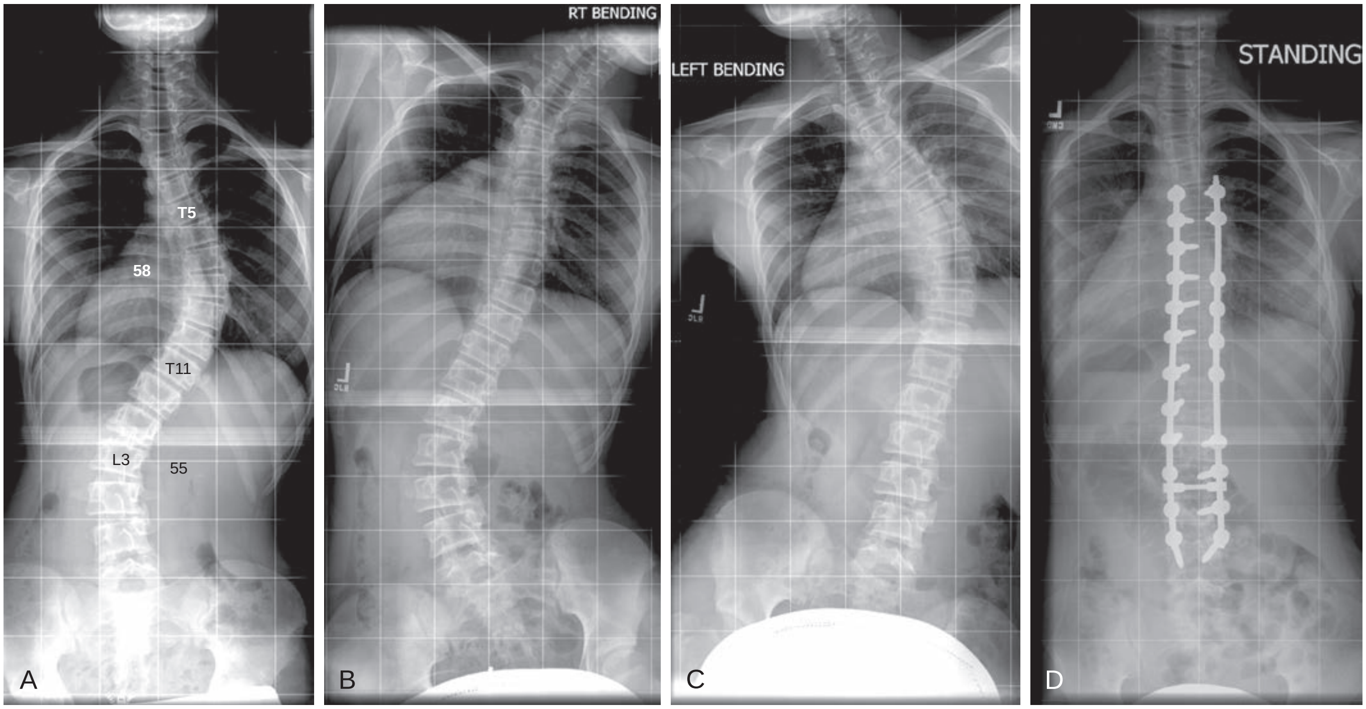
***Follow-up Imaging.*** No standard guidelines are available to monitor patients with idiopathic scoliosis. It is generally recommended that patients with idiopathic scoliosis be monitored every 4 to 12 months, depending on age and growth rate. Those in the rapid phase of growth are seen at more frequent intervals (every 4–6 months).[1,6] After cessation of spinal growth, only curves with



**e-Figure 134.4. Juvenile idiopathic scoliosis.** (A–C) Multiple posteroanterior standing spine radiographs (A, age 9; B, age 10; C, age 11) demonstrates progression of the right thoracic and left lumbar curve in a patient with idiopathic scoliosis (juvenile) with remaining skeletal growth. (D) A brace was finally applied, and it shows reduction of both the curves. In general, bracing is indicated in patients with remaining skeletal growth and curves between 25 degrees and 45 degrees. Usually, a definite progression of 5 degrees is used as a threshold to use a brace in patients with a curve of less than 30 degrees.



**e-Figure 134.5. Infantile scoliosis.** Posteroanterior spine radiographs at 2 years of age (A) and 4 years of age (B) demonstrate progressive infantile scoliosis. A Risser body cast was finally placed, and it shows decreased thoracic and lumbar curves (C).



**e-Figure 134.6. Idiopathic scoliosis.** A posteroanterior radiograph (A) shows a right main thoracic curve with the largest Cobb angle of 58 degrees with its apex at the level of the T8-T9 disk and its end vertebrae at T5 and T11. Rightward-bending anteroposterior (AP) radiograph (B) shows some improvement of the main thoracic curve; however, the Cobb angle remains more than 25 degrees, a finding consistent with structural curve based on the Lenke classification. Leftward-bending AP radiograph (C) shows that the Cobb angles of the proximal thoracic and lumbar curves do not exceed 25 degrees, indicating nonstructural curves. A postoperative radiograph (D) shows posterior spinal fusion extending from T5 through L3 level.

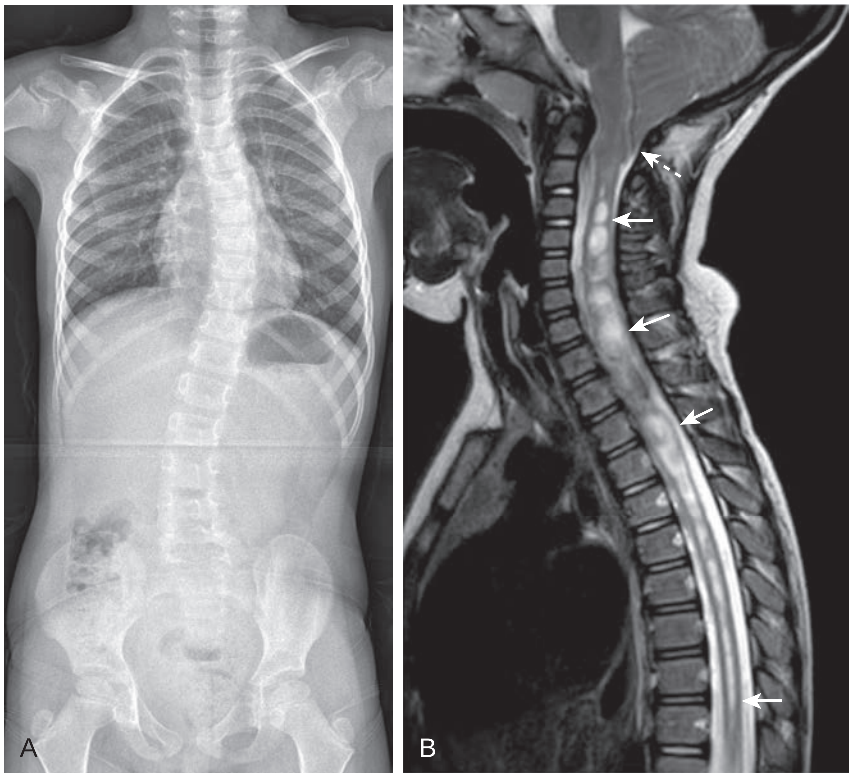


**Figure 134.3. Neuraxis abnormality in juvenile idiopathic scoliosis.** A 6-year-old girl with an atypical levocurvature of the thoracic spine. (A) Frontal radiograph shows levocurvature of the thoracic spine. Idiopathic juvenile scoliosis is typically associated with a thoracic dextrocurvature. (B) Sagittal T2-weighted MRI shows pointed and inferiorly displaced cerebellar tonsils *(dashed arrow)* and hydrosyringomelia expanding the cervical to upper thoracic spinal cord *(solid arrows)*.

Cobb angles greater than 30 degrees should be monitored for progression. Follow-up imaging usually is performed every 5 years, although the follow-up interval depends on the patient's symptoms and the severity of the curvature.[1]

Follow-up usually involves not only monitoring curve progression but also the efficacy of nonsurgical treatment such as bracing. Effective bracing should achieve about 30% correction of the Cobb angle.[46] Subsequent to fixation, patients are usually followed until the fusion has matured to exclude the development of pseudoarthrosis and to exclude recurrence of the deformity.[46]

## CONGENITAL SCOLIOSIS

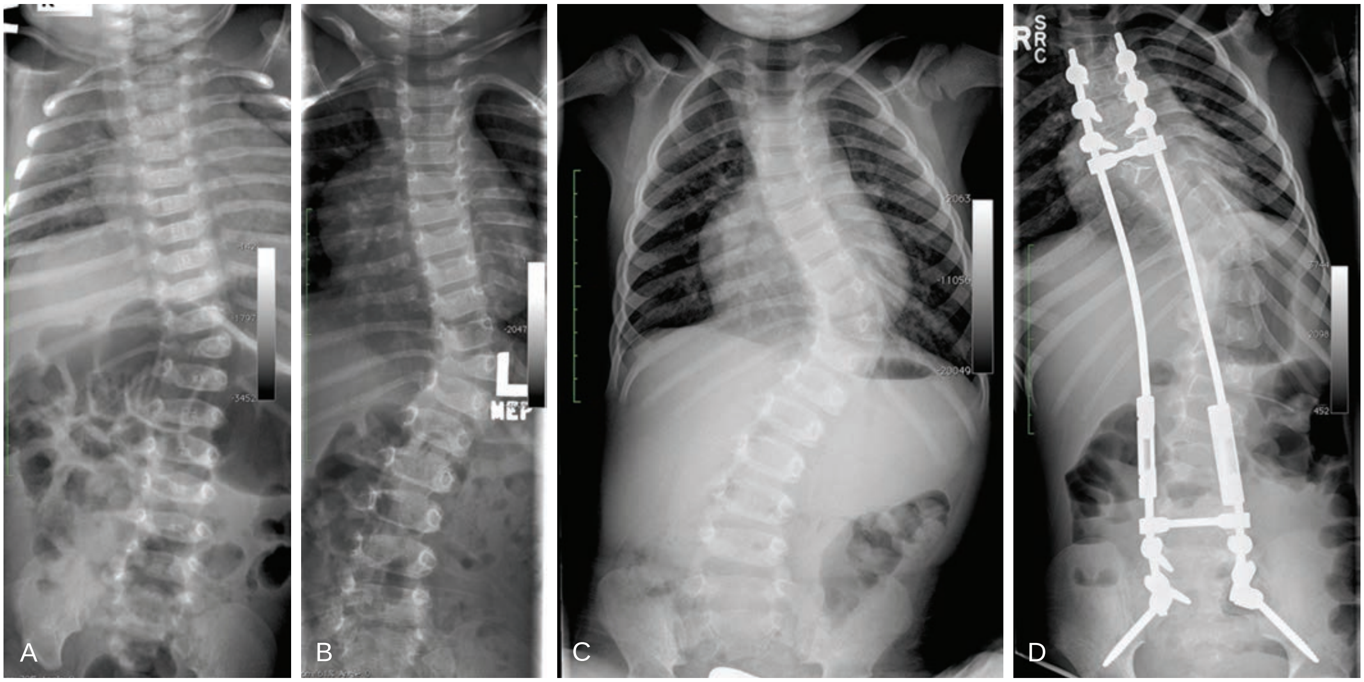
Congenital scoliosis results from disordered embryologic or intrauterine spine development, presumably during somitogenesis between weeks 5 and 8 of gestation.[47] Vertebral malformations are often associated with coexistent nonspinal malformations. Multiple recognized syndromes are associated with congenital scoliosis. The two most common coexisting conditions are VACTERL (*v*ertebral anomalies, *a*norectal malformation, *c*ardiac lesion, *t*racheo*e*sophageal fistula, *r*enal anomalies, *l*imb anomalies) association and Klippel-Feil syndrome.[47] Scoliosis associated with a skeletal dysplasia is considered separate from congenital scoliosis. Although labeled as congenital, it is important to note that the clinical deformity may not be apparent at birth and usually develops with spinal growth, presenting later in childhood.[47,48]

***Etiologies, Pathophysiology, and Clinical Presentation.*** Congenital scoliosis is caused by failures of vertebral segmentation, formation, or a combination of the two. Classifications by Winter et al. and McMaster (Fig. 134.8) are helpful in describing anomalies and predicting which will be progressive.[48–51] If the failure of formation or of segmentation occurs on the right or left side of the vertebral body, scoliosis results. If the segmentation anomaly occurs along the anterior or posterior vertebral body, then congenital kyphosis or lordosis results, respectively.[47] Most cases involve both coronal and sagittal plane deformities.

The most common underlying spinal abnormality is a hemivertebra, seen in about 40% of cases, usually resulting from unilateral complete failure of formation.[47,52] Hemivertebrae may be further classified as fully segmented, semisegmented, or nonsegmented on the basis of the relationship to the cranial and caudal vertebrae. Wedged vertebrae result from a unilateral partial failure of formation with presence of two pedicles. "Butterfly vertebrae" are presumed to originate from failure of anterior midline fusion between somite pairs. Complete anterior and posterior failure of segmentation creates a block vertebra, whereas unilateral anterior and posterior failure of segmentation causes a unilateral bar.[47]

Natural history and the risk of progression in congenital scoliosis are related to multiple elements: (1) type of anomaly, (2) site, (3) age at presentation, (4) single versus multiple curves, and (5) associated nonspinal abnormalities.[53] Curve progression has been strongly related to the type of vertebral abnormality (Table 134.1), with unilateral unsegmented bars with contralateral hemivertebrae having the poorest prognosis, a less severe progression with hemivertebrae, and the least severe progression with block and wedge vertebrae (e-Fig. 134.9).

***Imaging.*** Fetal imaging, including ultrasonography and MRI, allows for early and more comprehensive detection of fetal spinal anomalies, but the significance of earlier detection and prognosis is debated.[47] The postnatal diagnosis of congenital scoliosis is usually made with radiography. Suggestive findings include absence



**e-Figure 134.9. Congenital scoliosis.** Rapid progression of curve in a patient with fully segmented hemivertebra from 32 months (A) to 3 years of age (B) to 4 years of age (C). A postoperative radiograph (D) shows placement of expandable posterior spinal fusion hardware, which still allows some continued growth of the abnormal spine with maintaining or controlling the deformity. Curve progression in congenital scoliosis is strongly related to the type of underlying vertebral abnormality, with a poor prognosis associated with unilateral unsegmented bars with contralateral hemivertebrae and fully segmented hemivertebrae, as in this case.

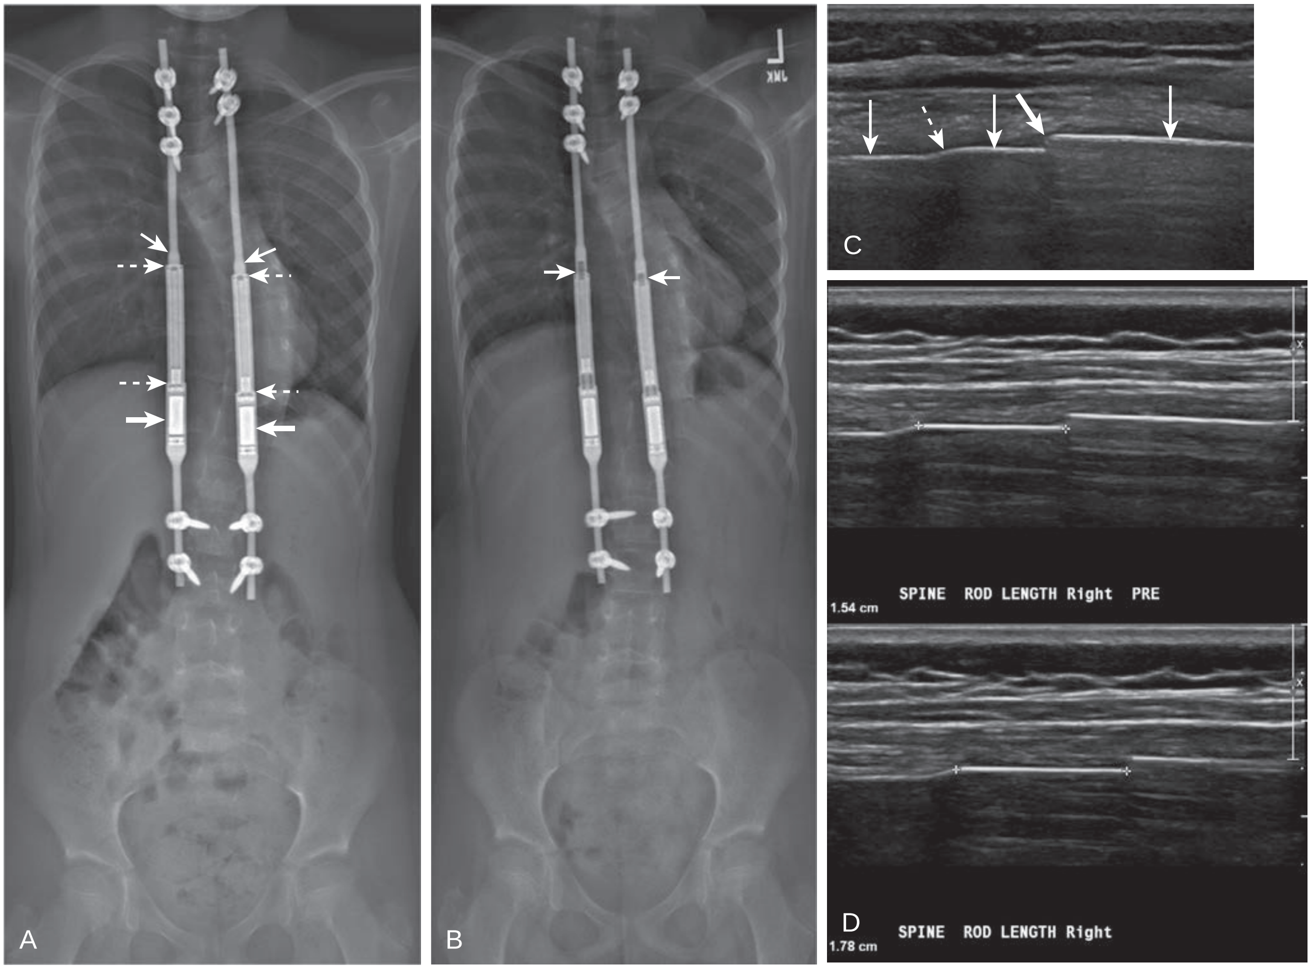


**Figure 134.7. Magnetically controlled growing rods (MCGR).** (A) Bilateral MCGR stabilizing a thoracic curve. *Thick solid arrows* show the motors of the rods. The portions of the rods between the dashed arrows are the housings that contain the expandable portions of the rods. *Thin solid arrows* point to the necks of the rods, where the rods taper. (B) Follow-up radiograph 6-months later after multiple distractions show that the portions of the rods between the necks and the housings *(arrows)* have expanded. (C) Ultrasound evaluation of MCGR rod. Linear bright echogenicity *(solid thin arrows)* along the surface of the MCGR rod is seen deep to the subcutaneous soft tissues. A small step off between the housing and the expandable portion of the rod *(thick solid arrow)* is a normal finding. The neck of the rod *(dashed arrow)* is also noted. (D) Pre- and postspinal rod lengthening ultrasounds show the procedure for measuring MCGRs before and after distraction. Note the calipers are placed at the base of the neck and at the top of the housing to measure the length of the expandable portion of the rod before and after the procedure; this rod was lengthened by 0.24 cm.

**TABLE 134.1** Median Yearly Rate of Deterioration (in Degrees) Without Treatment for Type of Single Congenital Scoliosis in Each Region of the Spine

| | | | **Hemivertebra** | | | |

DEFECTS OF SEGMENTATION
Block vertebra
Bilateral failure of segmentation
Unilateral bar
Unilateral failure of segmentation
Unilateral bar and hemivertebra
DEFECTS OF FORMATION
Hemivertebra
Unilateral complete failure of formation
Fully segmented
Semisegmented
Incarcerated
Nonsegmented
Wedge vertebra
Unilateral partial failure of formation

**Figure 134.8. Forms of congenital scoliosis.** Various types of congenital scoliosis based on defects of segmentation versus defects of formation. *(From McMaster MJ. Congenital scoliosis. In: Weinstein SL, ed.* The pediatric spine. *Philadelphia: Lippincott Williams & Wilkins; 2001:161–177.)*

of spinous processes, rib fusions, joined pedicles, or absent or narrowed disk spaces.[47] In the majority of cases, identification of the type of anomaly is possible with radiography. Absolute Cobb angle magnitude is of much less significance than the overall deformity and the change in that deformity over time with growth. Documentation of radiographic change with growth is the mainstay of observation and surgical decision making.[47]

Radiography is very useful if both anterior and posterior structures of anomalous vertebrae correspond to each other. However, it is not uncommon to have differences between the anterior and posterior structures often leading to a complex unclassified pattern of abnormality.[47,52] These characteristics make independent evaluation of the malformation in each vertebra extremely difficult with radiography, which may require three-dimensional computed tomography (CT) in the evaluation of complex malformations, particularly the posterior elements. Radiography has difficulty in accurately identifying the deformities that will be progressive, which has called for a newer three-dimensional classification of congenital scoliosis.[52] CT is currently used as a preoperative evaluation tool to evaluate osseous anomalies not clearly depicted on radiography. Preoperative CT angiography may also be useful for determining coexistent vascular anomalies and to assess the relationship of the aorta and important branches to the spine.

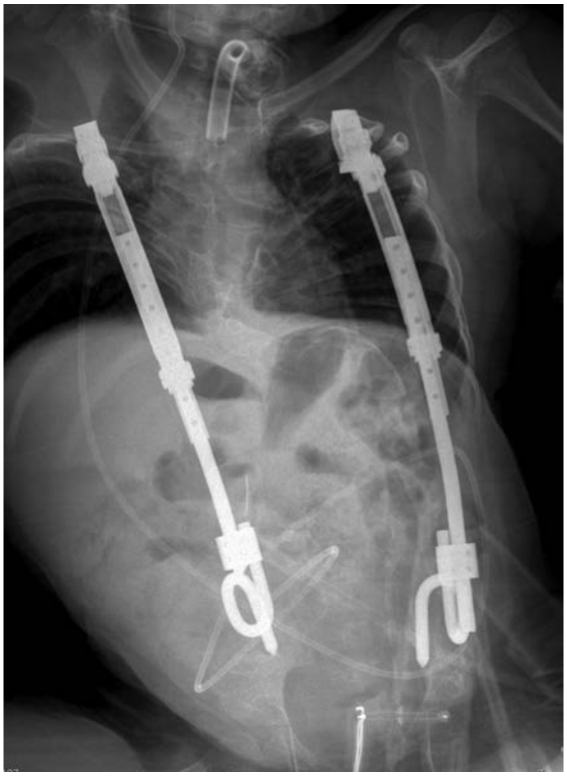
Imaging in congenital scoliosis demands not only detailed evaluation of the spine but also exclusion of extraspinal anomalies, mainly cardiovascular and genitourinary anomalies.[47] Associated intraspinal or neural axis abnormalities with congenital scoliosis may occur in 20% to 37% of patients, mandating screening.[47,54,55] The most common associated abnormalities include syrinx, Chiari I malformation, cord or spinal canal tumors, diastematomyelia, and low conus medullaris.[47] Spinal ultrasonography may be effective for initial screening. The role of MRI as a screening tool in all congenital scoliosis cases is controversial, with some experts believing that MRI should be restricted to presurgical evaluation. If not addressed preoperatively, major associated intraspinal abnormalities, including cord tethering, may lead to progressive deformity and progressive or acute neurologic loss (Fig. 134.10).[47,55]

***Treatment.*** Surgery is the mainstay in the treatment of congenital scoliosis, as nonoperative measures provide no definite efficacy. If an underlying spinal cord abnormality is found, it should be corrected before scoliosis surgery. The various surgical options are complex and beyond the scope of this discussion; however, the traditional approach still includes early fusion to avoid the development of more severe deformities.[47] In some patients, such as those with shortened spines or chest wall anomalies, expansion thoracoplasty with the use of the VEPTR device (e-Fig. 134.11) is performed instead of early fusion.[56] The VEPTR technique allows some continued growth of the abnormal spinal elements while still controlling the deformity. A major disadvantage of this treatment is the need for repetitive lengthening procedures, but it may be an appropriate temporary choice in certain children.[47]

## NEUROMUSCULAR SCOLIOSIS

Neuromuscular scoliosis is caused by a defect in the neural pathways through which the central nervous system controls and coordinates muscle activity.

***Etiologies, Pathophysiology, and Clinical Presentation.*** The Scoliosis Research Society further classifies neuromuscular scoliosis



**e-Figure 134.11. Severe thoracolumbar scoliosis due to multiple thoracolumbar segmental fusion anomalies in a 7-year-old girl.** A vertical expandable prosthetic titanium rib (VEPTR), extending from the upper ribs and anchored along the iliac crests, was placed.

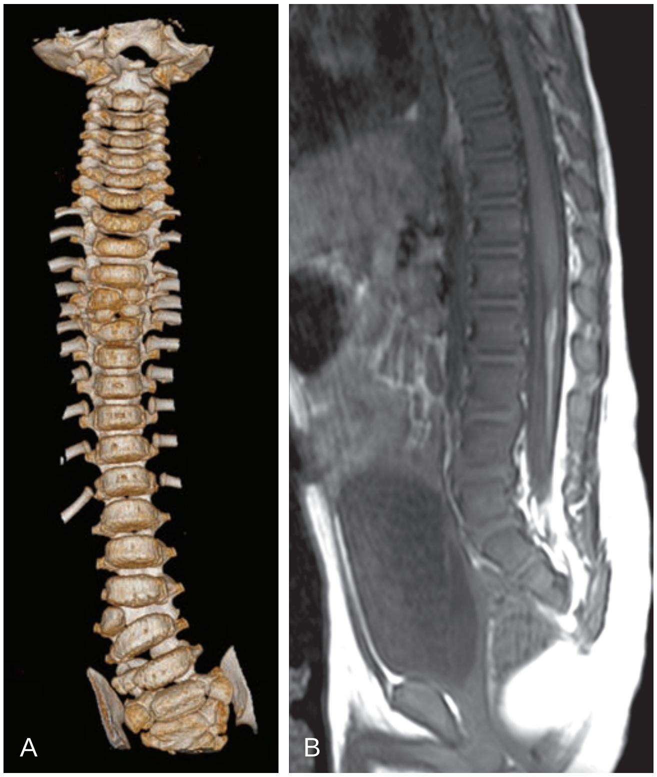


**Figure 134.10. Neural axis abnormality in congenial scoliosis.** A coronal three-dimensional, surface-shaded reformatted image of the spine (A) clearly demonstrates a lumbar hemivertebra with butterfly vertebrae involving the midthoracic spine. A sagittal T1 MRI of the lumbar spine (B) in the same patient shows a low-lying cord with an associated filum lipoma. Intraspinal abnormalities in congenital scoliosis are not uncommon, and magnetic resonance imaging of the neural axis is a routine prerequisite before any treatment is contemplated.

into neuropathic and myopathic scoliosis.[10] The first group includes neurologic disorders such as cerebral palsy or spinomuscular dystrophies, and the second group includes muscular disorders such as the muscular dystrophies.

***Imaging.*** The characteristic curve pattern in neuromuscular scoliosis is an early onset long C-shaped curve (e-Fig. 134.12) with rapid progression, which continues beyond skeletal maturity. Curve patterns similar to adolescent idiopathic scoliosis may also be seen. Affected children also often present with severe kyphosis or lordosis in the sagittal plane, with multiple additional comorbidities related to their primary disease.[10] Because of nonweight-bearing status, the vertebral bodies are often tall and slender. Additional findings include diminished lumbar lordosis with a single, broad-based thoracic kyphosis.

***Treatment.*** Bracing is usually reserved for nonsevere flexible curves, immature children, and ambulatory patients, and usually does not prevent curve progression.[57] Surgical fusion is the mainstay of treatment. The objectives of curve correction in neuromuscular scoliosis are to restore seating balance, to facilitate wheelchair use, to control pain, and to support the trunk so as to reinforce respiratory function.[10] Postoperative complications occur more frequently in patients with neuromuscular scoliosis than in those with idiopathic scoliosis, ranging from 44% to 62%, likely related to the presence of multiple comorbidities.[58]

## SCOLIOSIS AND RADIATION

The radiographic examination of children with scoliosis has historically involved a relatively high radiation dose, particularly to the breast, and may increase the risk of subsequent breast cancer.[59–62] The issues are twofold: (1) Initially, scoliosis radiographs were done in the anteroposterior projection, exposing the adolescent breast to maximum dose; and (2) many patients with scoliosis are adolescent girls with pubertal growth spurt and rapid breast development. Radiography for scoliosis must entail optimization to minimize radiation risk. This includes the use of posteroanterior positioning, high tube voltage, high-speed screen film combinations, contoured filtration, shielding of breasts (if anteroposterior positioning is used), and replacement of antiscatter grids with air gap techniques. The radiation dose may be further reduced by using CT and digital imaging systems.[63,64] As mentioned earlier, utilization of newer biplanar digital slot-scanning devices can dramatically reduce dose, however, the cost of these devices has limited their availability.[26] Finally, early studies have shown that ultrasound can be used to monitor lengthening of MCGRs to limit radiation (see Fig. 134.7).[65,66]

### KEY POINTS

- Curve measurement is usually performed by using the Cobb method. Wide interobserver and intraobserver variations exist with this technique, but measurements are reproducible if the levels measured and patient positioning are kept constant.
- CT imaging with three-dimensional reconstructions is mainly utilized for visualization of and preoperative planning for complex scoliotic deformities and preoperative planning.
- MRI is often utilized in the setting of congenital, infantile, and juvenile idiopathic scoliosis because of higher incidence of associated neural axis abnormality. It is also used in the setting of painful scoliosis, atypical curves, or scoliosis associated with specific neurologic or clinical abnormalities.
- Surgical treatment is usually resorted to in curves greater than 45 degrees in patients with remaining spinal growth.
- Sagittal balance is an important concept in normal spinal stability. All efforts are made to maintain normal thoracic kyphosis and lumbosacral lordosis while treating patients with scoliosis.

# 135 Developmental Dysplasia of the Hip

Sabah Servaes

## ETIOLOGY

Developmental dysplasia of the hip (DDH), formerly referred to as *congenital dislocation of the hip*, was first described thousands of years ago. DDH is a spectrum that may vary from a normal congruent hip with normal appearing acetabula with ligamentous laxity, to a structurally abnormal hip with joint incongruity related to primary acetabular dysplasia. Usually, DDH is a result of a combination of both structural and ligamentous laxity leading to an abnormal incongruent hip. Ultimately, the precise underlying etiology of DDH is not known. Purported in utero developmental factors and fetal crowding may result in DDH. Hippocrates is credited with ascribing intrauterine pressure as a possible etiology.[1] During week 7 of gestation, hip joint cleavage occurs.[2] The lower extremity rotates medially during week 12 of gestation and hip muscles develop during week 18. However, it has been suggested that only 2% of cases result from intrauterine factors at this early phase of development and that the remaining 98% of cases are caused by changes to a normal hip during the last 4 weeks of pregnancy or in the immediate postnatal period.[2] Hypothesized postnatal factors include tight swaddling or the use of cradle boards that force the legs into extension and adduction.

Structural causes leading to DDH are related to a primary acetabular dysplasia with secondary changes that may affect the femoral head leading to joint incongruity. Ligamentous laxity is often related to exposure to maternal hormones, particularly in female infants, leading to capsular, ligamentum teres, and transverse ligament laxity and subsequent hip joint incongruity. Proper development of the acetabulum and femoral head requires close approximation of the articular surfaces. Therefore untreated DDH with hip joint incongruity may result in further progression of acetabular dysplasia and secondary femoral head dysplasia, with DDH changes becoming more severe over time.

## EPIDEMIOLOGY

Being the first-born, a breech birth, large for gestational age, and female or having oligohydramnios, skull-molding deformities, and a positive family history is associated with DDH. DDH is more common on the left.[2] The underlying theory of many of these factors relates to constricted in utero space. The uterus of a primiparous woman has less give. The hips are subjected to increased pressure and hyperflexion in breech presentations. With frank breech presentations, the risk is even greater. Decreased amniotic fluid or a large gestation also results in increased constriction. The most common fetal presentation is cephalic, with the fetal spine aligned to the mother's left. This causes the left hip to be wedged against the maternal spine, which limits abduction and leads to a higher incidence of DDH on the left. Females are thought to be more affected because they are more sensitive to the circulating maternal hormone relaxin, resulting in ligamentous laxity.[2]

DDH is associated with myelodysplasia, arthrogryposis, multiple syndromes (e.g., Moebius and Poland syndromes), and chromosomal abnormalities. Other associations include talipes equinovarus or clubfoot, torticollis (fibromatosis colli, with a reported incidence of 5.5%), and congenital knee dislocation.[3,4]

The prevalence of DDH is reported in up to 28.5 per 1000, depending on the population studied.[5] Variation in rates may result from expertise of the examiners and inclusion of children with isolated ligamentous laxity. The incidence of DDH increases with family history: 6% chance with an affected sibling, 12% chance with one affected parent, and 36% chance with both parents affected.[2] During the first 2 weeks of life, physiologic instability exists but resolves with increasing muscle tone and resolving ligamentous laxity as maternal hormones decrease.

## NATURAL HISTORY

If undiagnosed or left untreated, DDH may result in permanent acetabular dysplasia in children of walking age, typically having a shallow acetabular roof with undercoverage of the lateral and/or anterior femoral head. Similarly, the femoral head may become secondarily dysplastic and lose its normal sphericity related to eccentric loads because of an incongruent hip, with resultant spherical growth plate disturbance and remodeling changes.[6] The femoral head must be seated within the acetabulum for normal development to occur. If the femoral head is dislocated, the transverse acetabular ligament and inferior capsular fibers may become interpositioned within the joint, further inhibiting hip congruity. Proliferation of fibrofatty tissue within the joint, termed *pulvinar*, and/or hypertrophy of the ligamentum teres, due to abnormal traction, may interpose between the femoral head and acetabulum, interfering with hip congruity. Compensatory fibrocartilaginous hypertrophy of the labrum, referred to as a *limbus*, can occur and may hinder attempts to reduce a dysplastic hip.[2] Long-term sequelae include incomplete coverage of the femoral head, excessive femoral anteversion, coxa valga, and coxa magna with muscle tightness (with the greatest impact on the adductors) (Fig. 135.1).[7] As a result of these morphologic features, individuals with untreated DDH may develop premature degenerative changes of the hip joint and a permanent limp. Excessive femoral anteversion will lead to in-toeing. Hip degenerative changes are caused by loss of cartilage and labral tears secondary to abnormal eccentric joint contact pressure from chronic incongruent acetabular and femoral head articulation.[8] Degenerative changes caused by hip subluxation typically appear before women reach the age of 40 years and before men reach the age of 55 years; however, symptoms may become apparent during adolescence.[2] Even with completely dislocated hips, many patients may function well even into late adolescence with development of a neoacetabulum that forms along the iliac wing.[2]

## PHYSICAL EXAMINATION

The most commonly used diagnostic physical examination techniques consist of maneuvers described by Ortolani, a pediatrician, and by Barlow, an orthopedic surgeon. In 1937 Ortolani highlighted the importance of clinical testing for the assessment of hip instability.[5] In 1961 Barlow described his technique to demonstrate laxity of the infant hip.[5]

In the Ortolani maneuver, forward pressure is applied to each femoral head with the infant in the supine position and the hips flexed to abduct the hip and to reduce a subluxated or dislocated femoral head. If subluxation or dislocation exists, a "clunk" may occur, which is more often felt than heard, as the femoral head is reduced into the acetabulum. In the Barlow maneuver, the infant is placed in a supine position and the hips are flexed at 90 degrees

## Abstract:

Developmental dysplasia of the hip (DDH) is a spectrum of abnormalities, that may vary from a normal congruent hip with normal appearing acetabula with ligamentous laxity, to a structurally abnormal hip with joint incongruity related to primary acetabular dysplasia. This chapter reviews the etiology, epidemiology, and natural history of DDH. Then primarily focuses on the multimodality diagnostic imaging of DDH and its implications for treatment.

## Keywords:

Developmental dysplasia of the hip
Acetabular dysplasia
MRI

screening

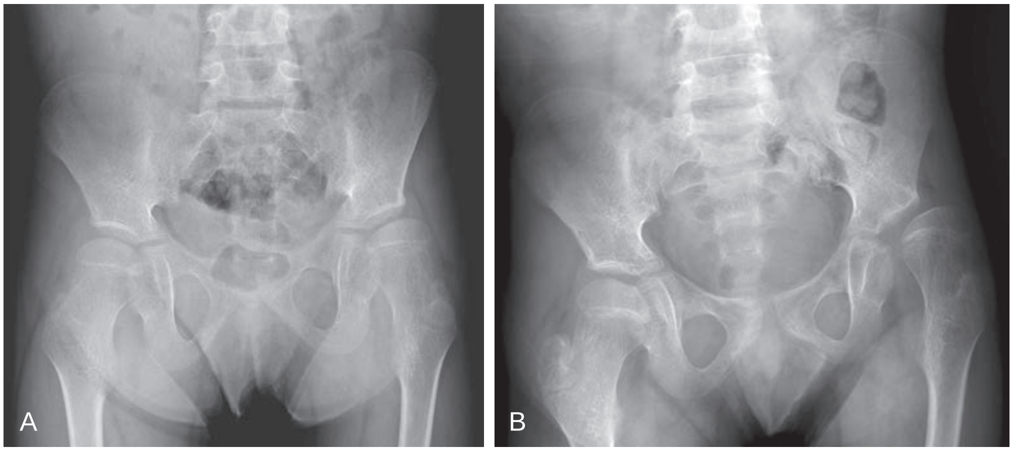

**Figure 135.1. Late presentation and progression of developmental dysplasia of the left hip in an 11-year-old boy.** (A) Frontal radiography at presentation shows a dysplastic left hip with a shallow acetabulum and mild undercoverage of the femoral head. Also the left femoral head is aspherically shaped. (B) Three years later, there is progressive lateral uncovering of the left femoral head, which also shows progressive secondary dysplastic changes.

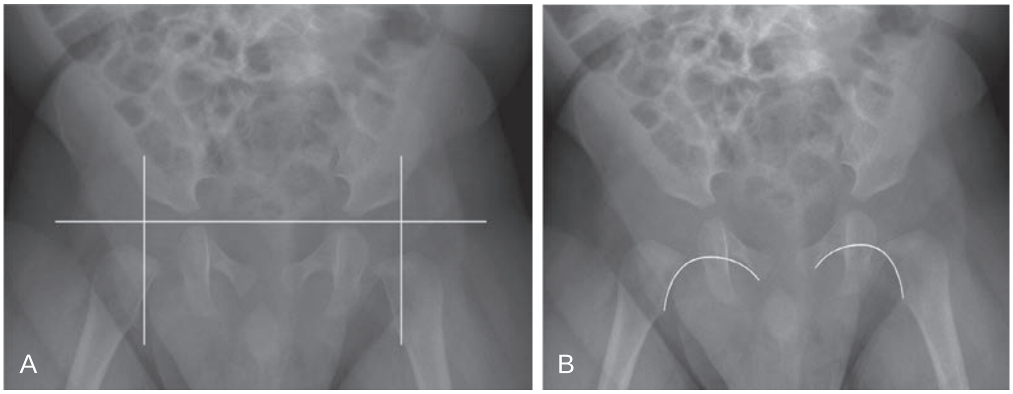

**Figure 135.2.** (A) Frontal radiograph of the pelvis with the horizontal Hilgenreiner and vertical Perkin lines. The expected location of the femoral head is in the medial, inferior quadrant of the intersection of the Hilgenreiner and Perkin lines. (B) The Shenton lines are drawn on this same pelvic radiograph. Disruption of this line will occur if the hip is dysplastic with either a subluxation or a dislocation.

with the knees fully flexed. Then pressure in a posterior/outward direction is applied to the femoral heads; if the hips dislocate, the test is considered positive.[9–11] Both of these maneuvers may fail to diagnose bilateral irreducible hip dislocations.

Asymmetric thigh skin creases, limited abduction, leg length discrepancies, and isolated hip clicks have also been suggested as signs of DDH but are less reliable. The Galeazzi sign may help diagnose DDH in older children. Unequal height of the knees in a supine child with flexed hips and knees is a positive result; however, the result is negative if both hips are abnormal. Older children may have a limp as the only symptom of DDH.

## IMAGING

### Radiography

The infant's lower extremities should be positioned in neutral extension with longitudinal symmetry. For symmetric imaging, the central ray should be directed above the pubic symphysis in the midline. In the presence of abnormality, a frog-leg view may be useful to evaluate reduction of the femoral head and may provide an opportunity for a second look at acetabular morphology.[12] Positioning the thigh in abduction and internal rotation (the von Rosen view) may provide additional information when evaluating DDH.

Several lines may be drawn to assist in the assessment of hips, but attention should be made to the overall configuration rather than to the measured angles, which could have varying rates of interobserver and intraobserver variability. The Hilgenreiner line passes horizontally through the superior aspect of the triradiate cartilages. The Perkin line is the vertical line extending from the lateral margin of the acetabulum. The expected location of the femoral head is in the medial, inferior quadrant of the intersection of the Hilgenreiner and Perkin lines (Fig. 135.2A). The Shenton line curves along the lesser trochanter, femoral neck, and superior margin of the obturator foramen and should be smooth (Fig. 135.2B).

The acetabular index is the angle between a line drawn along the acetabular roof and the Hilgenreiner line on a frontal radiograph. The acetabular index changes with age and normal values are different between girls and boys. Approximate measurements are 28 degrees in newborns, 23.5 degrees at age 6 months, 22 degrees at age 1 year, and 20 degrees at age 2 years. The maximal normal measurement for the acetabular index is 30 degrees up to age 4 months and 25 degrees up to age 2 years. The orientation of the pelvis on the radiograph affects this measurement.[13,14]

Hips should be in slight flexion during radiographic evaluation. Concavity of the acetabulum, which occurs as a result of pressure from the femoral head, should be noted. Typically, in this region of pressure at the acetabular roof normal sclerosis develops, which is called the *sourcil*, and is most prominent in the middle third of the acetabulum. The sourcil should normally have a rounded or arched configuration.

In preschool children and older children, the lateral center edge angle can assess the relative lateral acetabular coverage of the femoral head. The lateral center edge angle is the angle between a vertical line drawn through the center of the femoral head and a line connecting the center of the femoral head and the lateral acetabulum. This measurement is used in children over age 5 years. DDH should be suspected when the center edge angle is less than 19 degrees in children aged 6 to 13 years and less than 25 degrees in those over age 13 years.[13,15]

Radiographs are utilized to screen for DDH after age 4 to 6 months, when ultrasonography becomes more challenging and less reliable because of ossification of the femoral heads. Radiographic findings of DDH include shallow acetabula, with upward slanting sourcils, small capital femoral epiphysis, and superolateral subluxation of the femoral head (Figs. 135.3 and 135.4). Anteroposterior views are sufficient for screening. When abnormal, a frog-leg lateral view or a von Rosen view may be obtained to assess whether the femoral head reduces with hip abduction. When chronic, untreated DDH exists, the ossified portion of the ipsilateral capital femoral epiphysis may be disproportionately smaller (see Fig. 135.4) than a normal contralateral femoral head.

## Ultrasonography

Reinhard Graf, an orthopedist, described the use of ultrasonography in the assessment of the anatomy of the infant hip in 1980.[16] Four years later, Ted Harcke and colleagues, a group of radiologists, described the dynamic technique to assessing infant hips.[17] Advantages of sonography include its lack of ionizing radiation, direct visualization of cartilaginous structures, widespread availability, and the ability to perform a dynamic examination.

The examination is performed with a linear array transducer using the highest frequency that provides adequate penetration (often 12 megahertz [MHz]); however, a lower frequency transducer may be needed in children older than 6 months. The transducer is placed over the lateral aspect of the hip in either the coronal plane, with the hip in neutral or flexed positions, or in the transverse or axial plane, with the hip in adduction or abduction (e-Fig. 135.5). The infant should be placed in the lateral decubitus or supine position. In the coronal plane, the ilium should appear as a horizontal echogenic line, the midportion of the acetabulum visualized to its maximal depth, and the middle of the fibrocartilaginous labrum seen. Without technical accuracy, a normal hip may appear abnormal; the converse is not true. The femoral head should be in close apposition with the acetabulum with at least 50% of the femoral head covered by the acetabulum. Subluxation is present if the femoral head is less than 50% covered but in contact with the acetabulum. In the absence of contact between the femoral head and acetabulum, the hip is dislocated. The hip may reduce with changes in position, typically in abduction and flexion.

The alpha-angle, which is assessed on a coronal ultrasound image, is the angle between a line drawn along the straight edge of the iliac bone and a line along the roof of the bony acetabulum. An alpha-angle greater than or equal to 60 degrees is normal (Fig. 135.6). In infants less than 3 months of age, an alpha-angle between 50 to 60 degrees may represent physiologic immaturity of the hip. The majority of these hips develop normally without treatment, but maturation should be confirmed with a follow-up study. The beta-angle is the angle between a line drawn along the iliac bone and a line drawn along the axis of the fibrocartilaginous labrum on a coronal ultrasound image. This angle, which should be less than 55 degrees, is less commonly used than the alpha-angle.

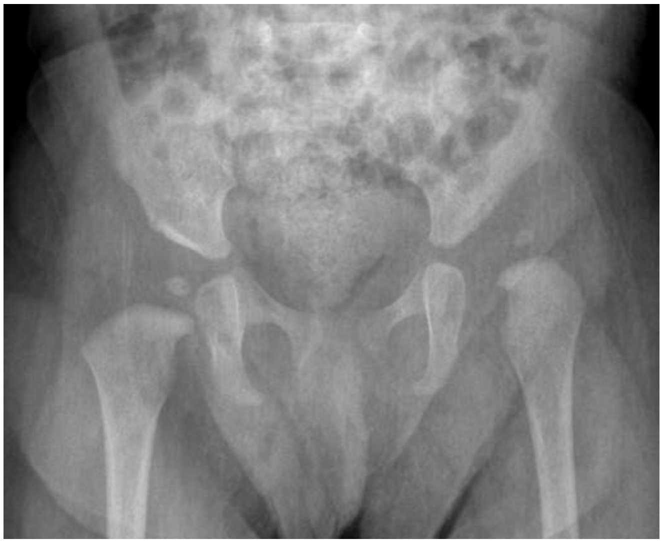

**Figure 135.3. Bilateral developmental dysplasia of the hip, left hip worse than the right hip, in an 8-month-old girl.** Anteroposterior radiograph shows that both acetabula are shallow. The right femoral head is concentrically located within its dysplastic acetabulum. The left femoral head is superolaterally dislocated.

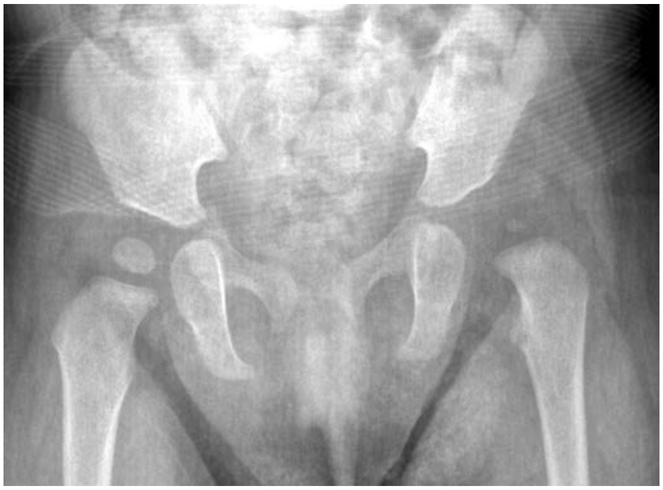

**Figure 135.4. Left-sided developmental dysplasia of the hip in a 1-year-old girl.** Anteroposterior radiograph shows a shallow left acetabulum with an upward slanting sourcil, a superolaterally subluxated femoral head, and delayed ossification of the left capital femoral epiphysis.

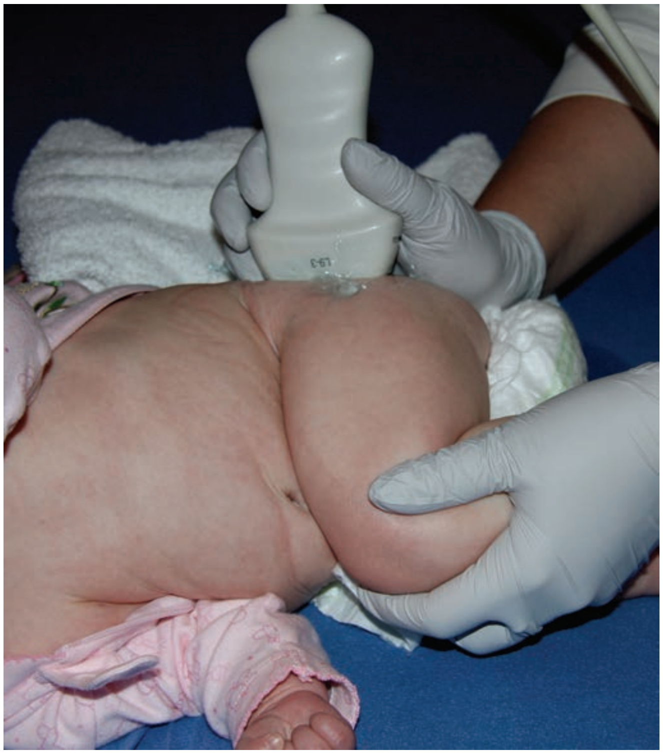
In addition to the abnormally lateral and superior positioning of the femoral head and the abnormal angle of the acetabulum seen with DDH, the labrum may become thick and echogenic. The acetabular rim in normal hips has a sharply defined corner at the intersection of the anterior iliac line and lateral acetabulum (see Fig. 135.6). With progressive acetabular dysplasia, this corner becomes rounded and dysplastic (Fig. 135.7A). A deformed labrum that is interposed between the femoral head and acetabulum, pulvinar, and a thickened ligamentum teres may be obstacles to hip joint reduction (see Fig. 135.7).

Dynamic examination includes the use of stress maneuvers, which correspond to the physical tests of Ortolani and Barlow.



**e-Figure 135.5.** Positioning of the ultrasound transducer on an infant for examination of the left hip in the coronal plane with flexion.

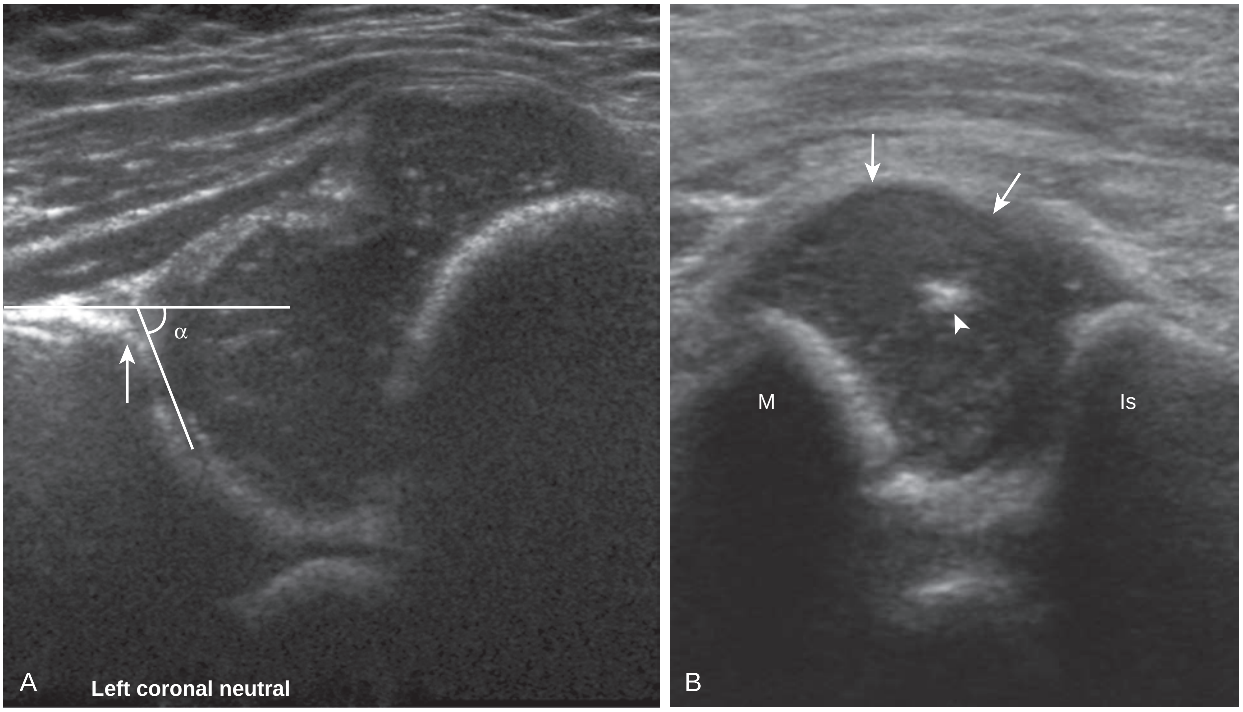


**Figure 135.6. Normal hip.** (A) Coronal sonogram with the hip in neutral position. The alpha-angle is the angle between a line along the straight edge of the iliac bone and the acetabular roof. The alpha-angle is normal, measuring 64 degrees in this example. The acetabular roof is mature, with a sharply angulated acetabular margin *(arrow)*. (B) Transverse sonogram with the hip in a flexed position shows the normal relationship between the femoral head *(arrows)* and ischium *(Is)*. The majority of the femoral head is unossified cartilage but an early ossification center is present *(arrowhead)*. *M*, Proximal femoral metaphysis.

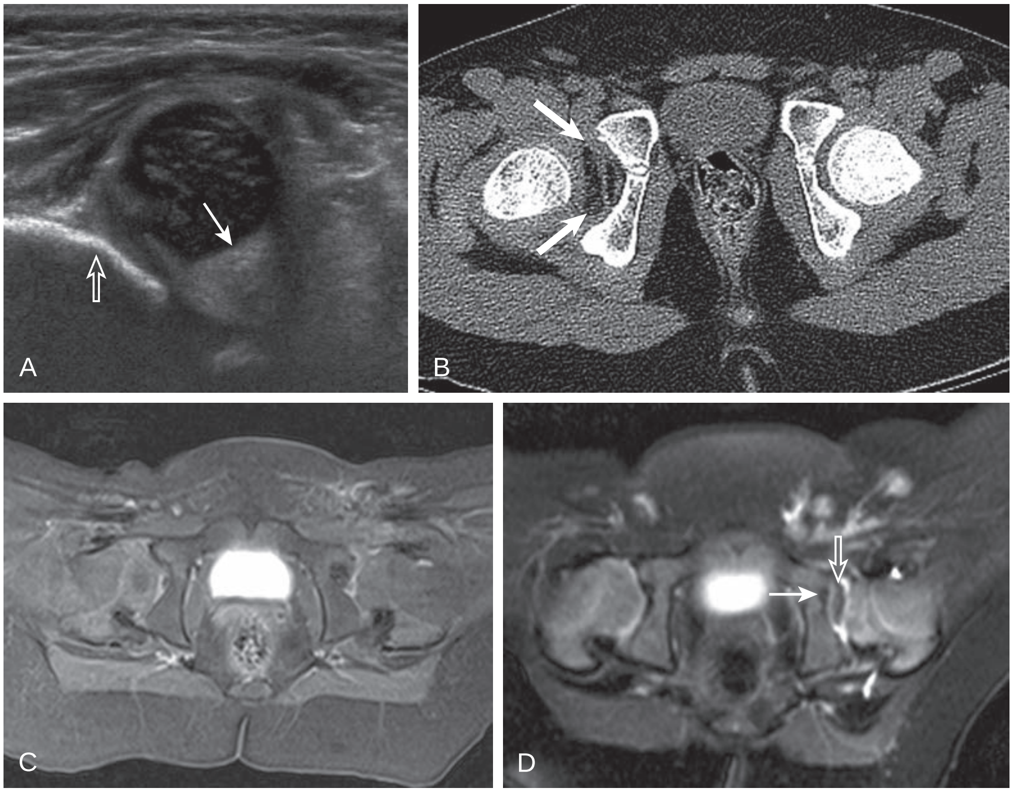

**Figure 135.7. Obstacles to hip reduction.** (A) Coronal sonogram of a dysplastic hip with echogenic pulvinar *(solid arrow)*. Note the dysplastic shallow acetabulum with blunted obtuse margin *(open arrow)*. (B) Low-dose axial CT demonstrating fatty pulvinar *(arrows)* within the right hip joint. (C) An axial T1-weighted MR image in an infant with left hip dysplasia, which was successfully reduced, demonstrates a thickened posterior labrum. (D) An axial T2-weighted MR image shows a thickened ligamentum teres *(open arrow)* between the femoral head and acetabulum *(solid arrow)*.

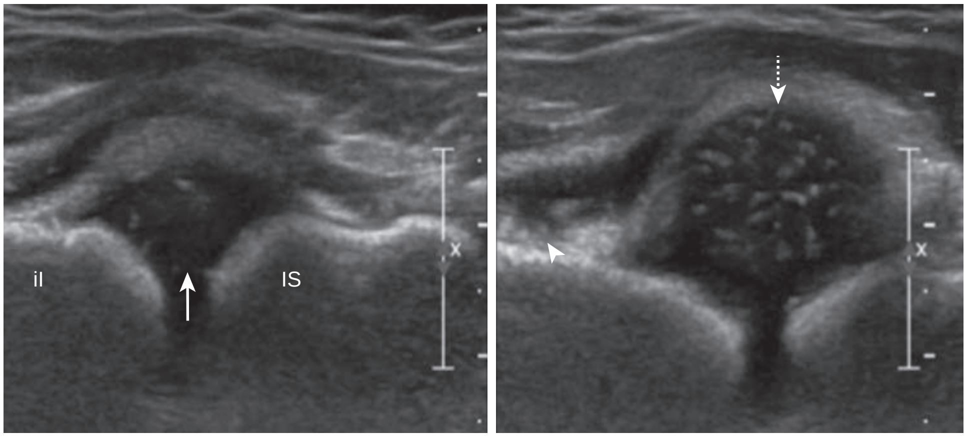

**Figure 135.8. Coronal posterior lip view showing femoral head subluxation with stress.** The left sonogram shows the coronal posterior lip view without stress. The posterior aspect (posterior lip) of the unossified triradiate cartilage *(arrow)* is seen between the iliac bone *(il)* and ischium *(IS)*. The right sonogram shows the coronal posterior lip view with stress. The unossifed femoral head *(dashed arrow)* has subluxed posteriorly over the posterior lip of the acetabulum.

Normally, the femoral head is well seated within the acetabulum at rest and while stress maneuvers are applied. If laxity exists or if the hip is dislocatable, the femoral head moves lateral and posterior when stress is applied. The transverse view and the coronal posterior lip view can be used to evaluate for subluxation or dislocation during stress maneuvers (Fig. 135.8). These maneuvers are typically not performed if the patient is undergoing therapy with a harness.[18]

Because of the physiologic laxity in newborns, hip ultrasound is typically not performed on infants younger than 3 weeks of age unless there are clinical findings of dislocation. Femoral head ossification usually limits hip ultrasound evaluation after 6 months of age unless there is delayed ossification. Therefore, after 6 months of age, pelvic radiographs become the preferred imaging modality.

### Ultrasound Screening

Some advocate for screening of all newborns for DDH, while others recommend screening only those with risk factors or a positive or equivocal clinical examination. Many studies have been published describing the merits of each approach.[19–34] General screening may help prevent delayed diagnosis and the need for surgical intervention but also increases costs and leads to unnecessary treatment. The benefits of screening all newborns are not yet clear, and the current practice in the United Sates is to sonographically screen only patients with an abnormal physical examination or those who have positive risk factors for DDH.[34–36]

## Computed Tomography

Computed tomography (CT) is primarily used for patients who have undergone treatment or will undergo open surgical repair with orthopedic hardware for DDH, rather than as a means of obtaining a diagnosis.[37] CT may be performed immediately after surgical reduction of DDH and is ideally performed using low-dose techniques and a small scan extent (Fig. 135.9). Displacement and subluxation should be described in both the coronal and axial planes. Reconstructions of CT data may assist in demonstrating anatomic relationships.[18,37] CT can also be performed postoperatively to evaluate periacetabular and/or proximal femoral osteotomies and to determine bone graft quality and position.[18,38–40]

CT is particularly useful in children with hardware placement near the joint, which may limit visualization on magnetic resonance imaging (MRI). Identification of any orthopedic hardware failures such as pin extrusion into the joint line, migrated interposition bone grafts, and identification of any intrinsic or extrinsic causes of failed reduction should be made.

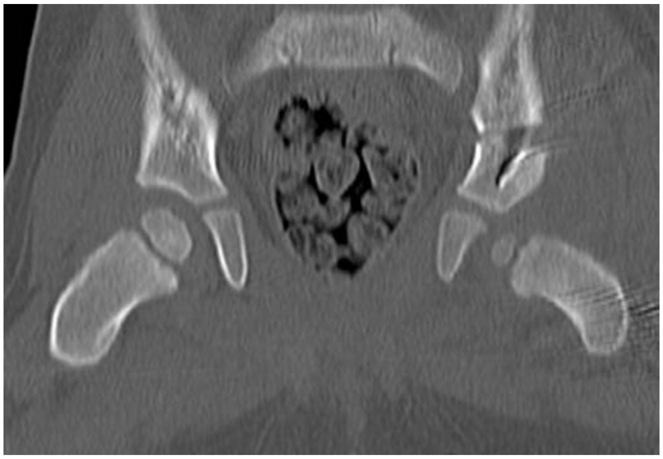

**Figure 135.9. Salter osteotomy for treatment of left-sided developmental dysplasia of the hip in a 2-year-old boy.** On this coronal reformatted CT, note that both femoral heads are concentrically located. The left femoral head is small, an expected finding in the setting of developmental dysplasia of the hip.

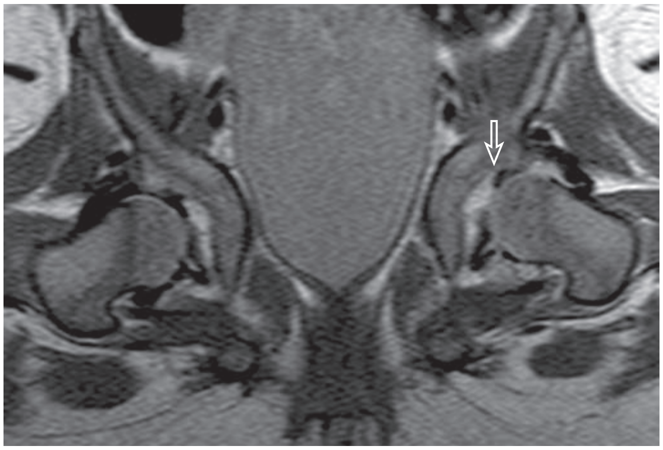
As part of surgical planning for older patients (usually in their second decade or older) with DDH, measurement of femoral and acetabular version can be made on a low-dose CT scan of the hips and distal femurs. In addition, preoperative CT is also used to provide additional details of bone quality and joint morphology, which are helpful in planning pelvic and femoral osteotomies.

## Magnetic Resonance Imaging

MRI is increasingly utilized to evaluate hip positioning after reduction and placement of a spica cast. The better visualization of unossifed cartilage and soft tissues and the lack of ionizing radiation are advantages over CT (Fig. 135.10).[41–46] The study can typically be performed without sedation. In addition to providing anatomic information regarding the relationship between the femoral head and the acetabulum, obstacles to reduction are visualized better than with CT (e-Fig. 135.11). Fatty pulvinar,



**e-Figure 135.11. Inverted labrum.** Coronal proton density MR image in an 8-month-old girl demonstrates an inverted labrum on the left *(arrow)*. There is susceptibility artifact noted in right hip joint space related to iodinated contrast from intraoperative arthrography performed before MR imaging.

transverse acetabular ligaments, and hypertrophied ligamentum teres (see Fig. 135.7) may be present in the hip joint preventing successful reduction. MRI can also detect hypertrophy and increased signal intensity within the labrum, and if the labrum is inverted, hindering reduction. An abnormal shape of the acetabulum and/or the capital femoral epiphysis may also be contributing factors when reduction is difficult. Extrinsic obstacles to reduction include shortened external rotator and adductor muscles, interpositioning of the iliopsoas muscle, and capsular adhesion to the ilium.[47] The most useful sequences include T1-weighted and proton density–weighted sequences in the axial and coronal planes.[48–50]

Postcontrast magnetic resonance (MR) images can evaluate perfusion of the femoral head. Some studies have shown that globally decreased enhancement of the femoral head on postcontrast MRI is predictive of an increased risk of future avascular necrosis (AVN). Epiphyseal osteonecrosis is the most common serious complication of hip reduction and may occur to some degree in more than 70% of cases. The risk of epiphyseal osteonecrosis is increased with greater hip abduction, which has led to the concept of the "safe zone," which is the amount of abduction that is large enough to prevent redislocation and small enough to prevent avascular necrosis, usually at 55 degrees maximal hip abduction.[46] Abduction greater than this may compromise the blood supply to the femoral head, which arises primarily from the deep medial femoral circumflex vessels. On postcontrast T1-weighted MR images, this is seen as globally decreased enhancement of the vascular channels within the unossifed epiphyseal cartilage and decreased enhancement within the ossification center of the femoral head (Fig. 135.12).[45,46,51] Hips that show decreased global enhancement may be considered for recasting in a less abducted position.[46]

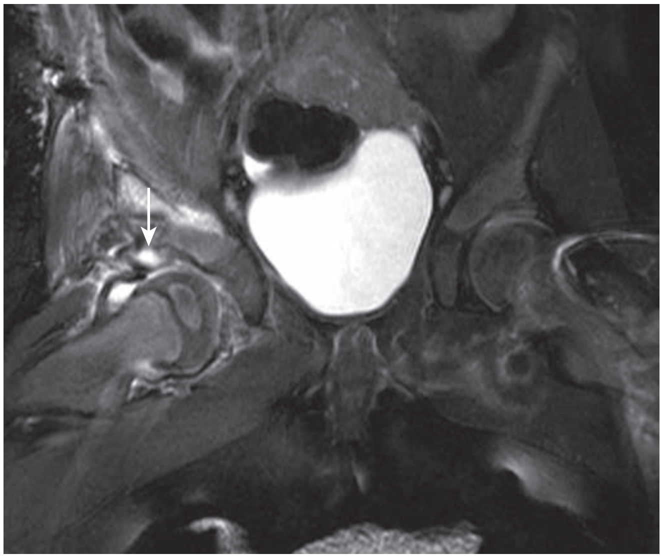


**Figure 135.10. MRI after hip reduction, iliac osteotomy, and spica cast placement.** T2-weighted fat-saturated coronal MR image shows that the femoral heads are concentrically located. Also note the hypertrophy and increased signal within the right superior labrum *(arrow)*. No sedation was used for this study.

## TREATMENT

The objective of DDH treatment is concentric reduction of the femoral head into the acetabulum. The method of achieving this outcome depends on the age of the patient as well as the severity of the presentation. Up to age 6 months, orthoses, often a Pavlik harness, are used to place the hip in flexion and abduction. This treatment aids in developing the acetabulum along the lateral edge. The risk of epiphyseal osteonecrosis increases with greater hip abduction, as discussed above. The harness is often worn for 3 to 6 weeks after successful reduction; both clinical examination and ultrasonography are performed to evaluate the effectiveness of therapy.

Children over 6 months but less than 2 years of age are often treated with a spica cast after closed or open reduction. Intraoperative arthrography is often performed to assess for structures that my impede reduction and to assess the anatomy (e-Fig. 135.13). Positioning of the femoral heads after placement of the cast may be ascertained with CT or MRI, with MRI having the advantages previously discussed. Follow-up radiographs can detect more advanced features of avascular necrosis. Recurrent dislocation may occur in up to 8% of patients and is more common in those with bilateral or right-sided DDH, decreased abduction in the spica cast, and large pelvic width.[52]

DDH that is diagnosed late or that persists despite treatment may require surgical osteotomy. For patients with persistent subluxation and mild to moderate acetabular dysplasia, an innominate or Salter osteotomy, which attempts to better align the acetabulum to cover the femoral head, may be indicated. A horizontal osteotomy is placed in the ilium superior to the acetabulum allowing the acetabulum to be rotated and placement of an iliac bone graft at the osteotomy site (e-Fig. 135.14). There are a number of other surgical procedures that may be used depending upon the clinical scenario and surgeon. These include incomplete iliac osteotomies (e.g., Dega and Pemberton), double and triple innominate osteotomies (e.g., Sutherland and Tonnis), periacetabular osteotomies (e.g., Ganz), as well as salvage procedures (e.g., Chiari and shelf osteotomies) (e-Fig. 135.15). Femoral shortening and derotational osteotomies and adductor tenotomies may also be performed.

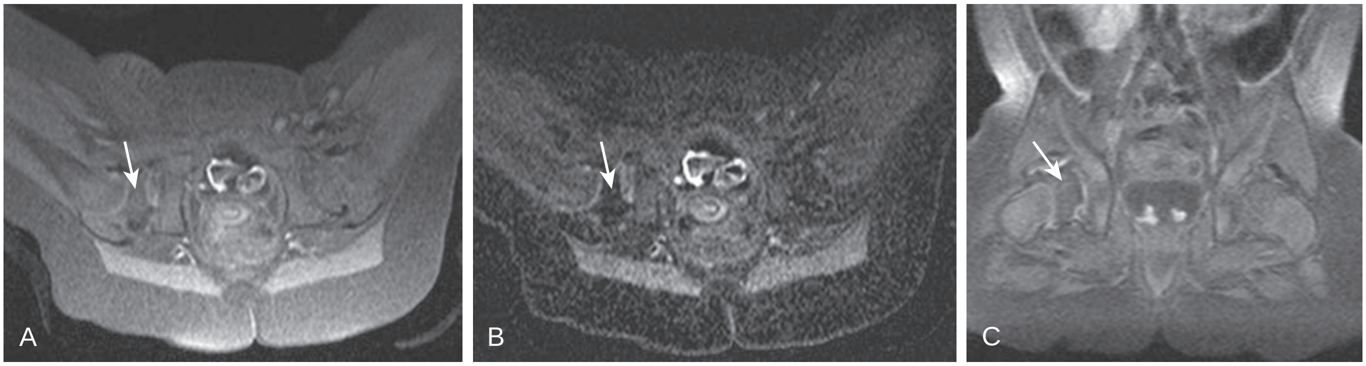

**Figure 135.12. Decreased perfusion of the right femoral head.** (A) Axial T1-weighted, (B) axial subtraction T1-weighted, and (C) coronal T1-weighted fat-suppressed post contrast MR images demonstrate globally decreased perfusion of the right femoral head *(arrows)* best seen on the subtraction images (B).

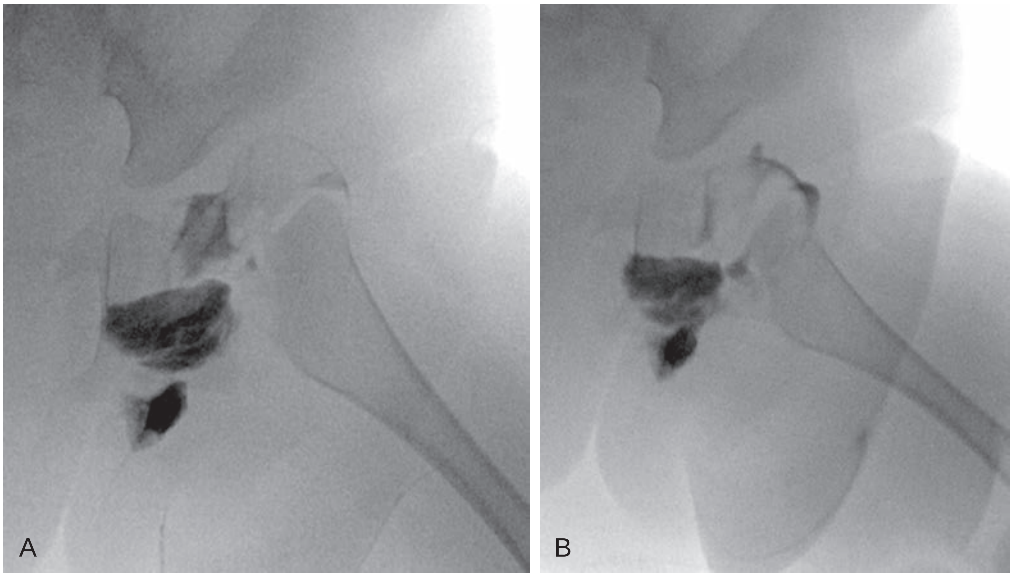
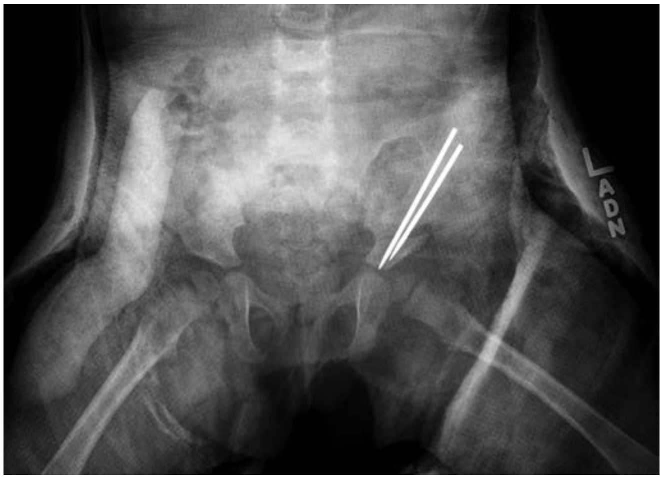
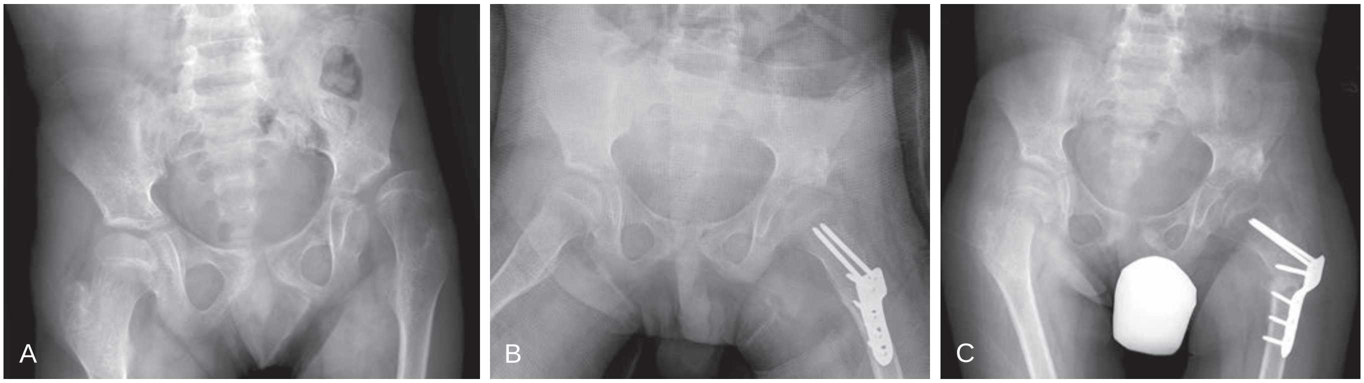


**e-Figure 135.13.** Intraoperative arthrogram obtained before (A) and after (B) reduction of the left hip in this child with Larsen syndrome.



**e-Figure 135.14. Salter osteotomy treatment for left developmental dysplasia of the hip.** A frontal radiograph of patient after left Salter osteotomy while in spica cast shows fixation pins securing the left supraacetabular osteotmy.



**e-Figure 135.15. Radiographs of a 14-year-old patient who underwent left-sided Dega osteotomy.** (A) Preoperative image demonstrating subluxation of the left hip. (B) After 7 days following surgery. (C) After 1 month following surgery. Note the femoral osteotomy and hardware in place.

## KEY POINTS

- In the United States, screening for DDH is done on the basis of clinical examination findings and patient risk factors.
- Ultrasonography provides a dynamic examination to evaluate the location of the femoral head and the shape of the acetabulum, as well as to identify obstacles to reduction.
- CT may be used for presurgical planning or postoperative evaluation.
- MRI is used to evaluate the success of closed reduction and spica cast placement and may identify obstacles to reduction and, if contrast is administered, decreased femoral head perfusion.

# 136 Arthritis and Differential Inflammatory Joint Disorders

Arthur B. Meyers, Andrea Schwarz Doria, and Paul Babyn

Rheumatologic conditions in children are myriad in presentation, with overlapping imaging features that may sometimes superficially mimic infection. Rheumatologic conditions in children do not follow the typical course and presentation compared with their counterparts in adults. As a consequence, the International League of Associations for Rheumatology (ILAR) formulated a revised nomenclature to describe the various pediatric rheumatologic conditions (Box 136.1).[1] In this chapter, we discuss imaging of pediatric arthritis from the point of view of noninfectious synovial proliferation using the ILAR classification, including juvenile idiopathic arthritis (JIA) and its differentials: hemophilic arthropathy, lipoma arborescens, synovial chondromatosis, pigmented villonodular synovitis (PVNS), and reactive synovitis (Box 136.2). Subtypes of JIA, enthesitis-related arthritis and psoriatic arthritis, will be discussed in their own subsections because of their unique presentation and imaging findings. Infectious arthritis is discussed in Chapter 137.

## JUVENILE IDIOPATHIC ARTHRITIS

### Clinical Overview

JIA, which occurs worldwide, is the most frequent cause of chronic musculoskeletal pain in youths and the most common chronic musculoskeletal disease of childhood.[2–4] It is a chronic, monoarticular or polyarticular arthropathy of childhood.[2]

The diagnostic criteria for JIA include arthritis in one or more joints for at least 6 weeks before the age of 16 years. The onset type is defined by pattern of disease in the first 6 months of diagnosis (see Box 136.1) and exclusion of other forms of juvenile arthritis.[1] JIA may be associated with systemic manifestations that include fever, erythematous rashes, nodules, leukocytosis, and, less commonly, iridocyclitis, pleuritis, pericarditis, anemia, fatigue, and growth failure.[5] At the time of presentation, other causes of inflammation should be excluded. JIA differs from the adult type of rheumatoid arthritis because of the age of presentation, its preference for large joints, its tendency to generate joint contractures and muscle wasting, and its association with extraarticular clinical manifestations.[6]

A new internationally accepted classification system was established in 1995[1,7] and revised in 2001[1] (see Box 136.1). The previously used terms *juvenile chronic arthritis* and *juvenile rheumatoid arthritis* were incorporated under the term *JIA*.

The early diagnosis of JIA is essential to interrupt or delay the course of the disease, which results in joint deformity, severe functional impairment, and chronic pain if the disease is not treated at its early stage.

The currently available clinical and laboratory tests for assessment of JIA are poor for characterization of early inflammatory, hypoxic, and vascular changes, which are the primary physiologic events involved in the disease.[8–10] Therefore imaging is vitally important for early diagnosis and assessing treatment response during follow-up in persons with this disease.

### Epidemiology

The incidence and prevalence of JIA in Europe varies greatly in published reports, with the incidence and prevalence, respectively, of 1.6 to 42.5 and 3.8 to 400 per 100,000.[11] Twice as many girls as boys have JIA.[12] Although few data are available on geographic or racial groups, studies suggest that, in the United States, proportionately fewer African American than white children have JIA.[13] The onset of JIA before the age of 6 months is distinctly unusual; nevertheless, the age at onset is often quite young, with the highest frequency occurring between 1 and 3 years.[14]

Radiographic changes are seen most frequently in children with JIA who have a polyarticular course.[15,16] Large joints are most commonly affected in persons with this disease. The knee is the most frequently affected joint, followed by the ankle. Changes may also develop in the cervical spine or temporomandibular joint.[17] It has been suggested that patients with JIA who have polyarthritis and wrist disease are at high risk of experiencing radiographic progression.[18] The wrist is the most vulnerable site for early radiographic changes in patients with JIA.[16,19]

### Pathophysiology

Although the etiology of JIA is unknown, some investigators believe that it is multifactorial given the heterogeneity of presentations and course of the disease.[20] JIA is characterized by an acute synovitis that leads to synovial proliferation and formation of a highly cellular pannus.[21] The pannus erodes the adjacent articular cartilage and subchondral bone, leading to centripetal articular destruction; that is, the articular damage starts at the periphery of the joint and progresses toward its center. Inflammatory changes also can involve tendon sheaths and bursa and can give rise to periostitis. With prolonged inflammation, more extensive joint changes, including cartilage destruction, bone erosions, and joint malalignment, often are present.

Despite the fact that JIA is usually transient and self-limited, without active synovitis in adulthood, up to 10% of children become severely disabled in adulthood. Despite therapy, 28% to 54% of children have progressive disease and experience cartilage or bone erosions, with a median onset of radiographic findings between 2.2 to 5.4 years after initial presentation.[22] The disease process may lead to joint instability, subluxation, and ankylosis.[23,24] Disturbance of joint growth can be consequent to the disease itself and/or to the treatment.[17]

### Imaging

Imaging plays a key role in establishing the presence, severity, and extent of joint disease and monitors disease complications, excludes other diagnoses, and assesses treatment response. Advanced imaging allows detailed evaluation of synovitis and osteochondral damage.[25–27]

## Abstract:

Rheumatologic conditions in children have a variety of presentations and imaging is useful in establishing a diagnosis and in the evaluation of treatment response. In this chapter, we discuss the imaging of noninfectious arthritis in children using the International League of Associations for Rheumatology classification of these conditions. Specifically we review juvenile idiopathic arthritis and its differentials: hemophilic arthropathy, lipoma arborescens, synovial chondromatosis, pigmented villonodular synovitis, and reactive synovitis. Subtypes of JIA, enthesitis-related arthritis and psoriatic arthritis, are discussed in their own subsections because of their unique presentation and imaging findings.

## Keywords:

Juvenile idiopathic arthritis
enthesitis-related arthritis
psoriatic arthritis
reactive synovitis
hemophilic arthropathy
synovial chondromatosis
pigmented villonodular synovitis

### BOX 136.1 Classification of Juvenile Idiopathic Arthritis

Onset <16 years
Duration: at least 6 weeks
Other known conditions are excluded

**SUBTYPES**

1. Systemic arthritis
2. Oligoarthritis
    a. Persistent—affecting ≤4 joints throughout the disease course
    b. Extended—affecting a total of >4 joints after the first 6 months of disease
3. Polyarthritis (rheumatoid factor negative)
4. Polyarthritis (rheumatoid factor positive)
5. Psoriatic arthritis
6. Enthesitis-related arthritis
7. Other undifferentiated arthritis
    a. Does not meet any criteria for categories 1–6
    b. Meets criteria for more than one of the categories 1–6

*From Petty RE, Southwood TR, Manners P, et al. International League of Associations for Rheumatology classification of juvenile idiopathic arthritis: second revision, Edmonton, 2001.* J Rheumatol. *2004;31:390–392.*

Radiographs are typically the initial imaging study for the diagnosis of JIA; however, they have low sensitivity (50%) and moderate specificity (85%) for detection of cartilage destruction.[8]

Both magnetic resonance imaging (MRI) and ultrasound can detect synovial hypertrophy, cartilage erosion, and joint effusion in peripheral joints, and clinically meaningful response to treatment in children with JIA. Ultrasound is less sensitive than MRI for assessment of both soft tissue findings (sensitivity, 62%) and superficial cartilage loss (sensitivity, 60%).[8] Overall, MRI is the imaging modality of choice for evaluation of joints in children with JIA. However, ultrasound can be an excellent initial imaging tool for evaluation of young children who otherwise would require sedation for MRI.[8] As expertise and standardization continues to develop, ultrasound will likely prove to be a complementary imaging method along with MRI.[28]

## Radiography

Conventional radiography is not effective in the evaluation of soft tissue abnormalities, which are precursors of cartilage degeneration in persons with JIA.[26] Moreover, available radiographic scoring systems have poor internal consistency and poor criterion and construct validity because they do not take into consideration patients' sex and age.[29] As mentioned earlier, there is low sensitivity (50%) and moderate specificity (85%) in the detection of cartilage

### BOX 136.2 Differential Diagnosis of Juvenile Idiopathic Arthritis

**NONINFECTIOUS DISORDERS**

**Synovial Disorders**

***Pauciarticular***

Acute
- Early rheumatic disease
- Arthritis associated with chromosomal abnormalities—Down, Turner syndromes
- Seronegative spondyloarthropathy
- Acute transient synovitis

Chronic
- Rheumatic diseases
- Arthritis associated with chromosomal abnormalities—Down, Turner syndromes
- Tenosynovial giant cell tumors (pigmented villonodular synovitis)
- Intraarticular venous malformation
- Lipoma arborescens
- Synovial osteochondromatosis

Other
- Foreign body arthritis
- Hemophilic arthropathy
- Sarcoidosis
- Intraarticular osteoid osteoma

***Polyarticular***

Seronegative spondyloarthropathy
Connective tissue disorders
  - Systemic lupus erythematosus
  - Sarcoidosis

Inherited disorders
Familial hypertrophic synovitis
Hemophilic arthropathy
Immunodeficiency

**Nonsynovial Disorders**

***Pauciarticular***

Acute
- Malignancy
- Leukemia
- Neuroblastoma

Chronic
- Noninflammatory disorders
- Avascular necrosis
- Slipped capital femoral epiphysis and dysplasias

Other
- Juvenile osteoporosis
- Multifocal osteolysis

***Polyarticular***

- Metabolic or inherited disorders
- Diabetic arthropathy
- Turner syndrome
- Lysosomal storage disease
- Kniest syndrome
- Winchester syndrome
- Chondrodysplasias
- Frostbite
- Goldbloom disease

**INFECTIOUS DISORDERS**

***Pauciarticular***

Infectious arthritis
Septic arthritis
Reactive arthritis
Tuberculous arthritis
Postinfectious arthritis

***Polyarticular***

Infectious arthritis
Lyme disease
Reactive arthritis

## **BOX 136.3** Radiographic Features of Juvenile Idiopathic Arthritis

### ALIGNMENT ABNORMALITIES

- Atlantoaxial subluxation
- Coxa valga or varus
- Finger deformities including boutonniere or swan neck deformity
- Knee valgus
- Hallux valgus

### BONE DENSITY

- Juxtaarticular osteoporosis
- Diffuse osteoporosis (late)
- Metaphyseal lucent band (rarely)
- Periosteal reaction adjacent to affected small joints

### CARTILAGE AND JOINT SPACES

- Erosions (late), may appear corticated
- Cartilage space narrowing (late)
- Ankylosis (especially spine, wrists)

### DISTRIBUTION

- Monoarticular, oligoarticular, or polyarticular

### GROWTH ABNORMALITIES

- Affected small bones are shorter than normal
- Overgrowth (lengthening) of affected long bones
- Advanced maturation of affected epiphyses
- Large epiphyses
- Micrognathia (may have mandibular notching)
- Protrusio acetabuli
- Small fused cervical vertebrae
- Angular carpal bones
- Square patella
- Intercondylar notch widening (also a feature of hemophilia)

### SOFT TISSUES

- Effusions and joint distension
- Nodules
- Periarticular calcification (probably due to corticosteroid injections)

*From Johnson K, Gardner-Medwin J. Childhood arthritis: classification and radiology.* Clin Radiol. *2002;57:47–58.*

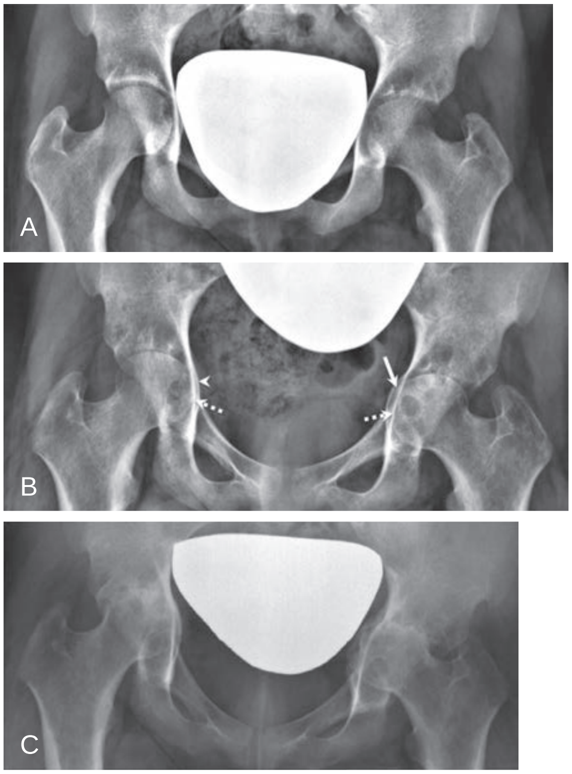

**Figure 136.1. Juvenile idiopathic arthritis in a girl with progressive bilateral hip arthritis.** Frontal radiograph of the pelvis at 16 years of age (A) shows diffuse left hip joint space narrowing and subchondral cystic changes in the left acetabulum. (B) At 18 years of age, despite aggressive treatment, there has been interval progression of disease with marked bilateral joint space loss and progression of subchondral cystic changes in the left acetabulum and left femoral head. Protrusio acetabuli, defined as the femoral head *(solid arrow)* projecting medial to the ilioischial line *(dashed arrow)*, is present on the left. Coxa profunda, defined as the acetabular fossa *(arrowhead)* projecting medial to the ilioischial line *(dashed arrow)*, is present on the right. These findings indicate medial migration of the femoral heads. (C) At 19 years of age, there has been further progression of disease in both hips. At 20 years of age, this patient underwent bilateral hip replacements.

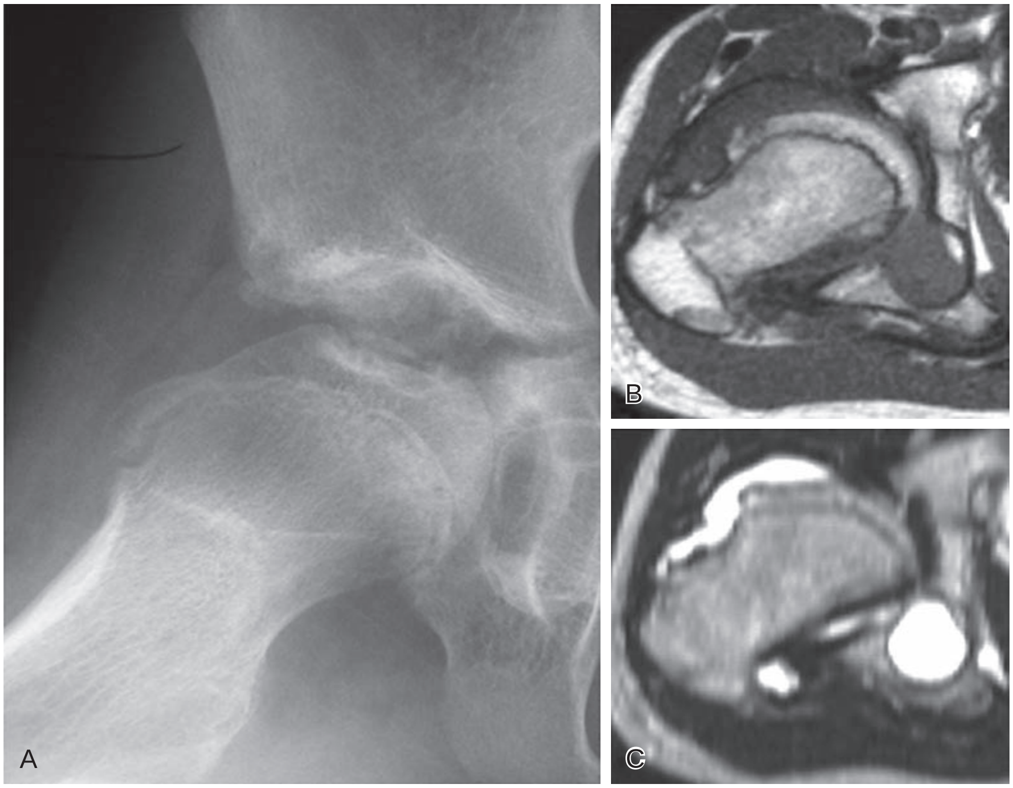
destruction with radiography,[8,29] hence the expanding role for ultrasound and MRI in the evaluation of JIA.[30]

A variety of radiographic features can be encountered with joint disease. Specific joint findings will depend on the underlying abnormality, the chronicity of the disease, and the response to therapy. A systematic approach to the imaging interpretation of any joint is highly recommended. One popular approach is the "ABCDS" of joint disease, featuring assessment of joint *A*lignment, *B*one density and other bone changes, *C*artilage loss, *D*istribution of joint disease (whether monoarticular, oligoarticular, or polyarticular), and *S*oft tissue abnormalities (Box 136.3).

The earliest abnormalities include soft tissue swelling, osteopenia, and effusion. Periosteal reaction occasionally may be seen. Typically, the osteopenia is initially periarticular (Fig. 136.1), becoming more diffuse with time. Osteopenia may be subtle and better recognized by comparison with the contralateral extremity (if it is unaffected). With long-standing disease, uniform bone loss may occur with a thin cortex. Uncommonly, a linear subphyseal demineralization can be observed, but this finding is nonspecific and can also be seen in persons with other conditions such as leukemia.[31]

Joint effusions are encountered commonly and can be seen in inflammatory or noninflammatory joint disease. A sign of knee effusions is fullness in the suprapatellar region, which is best seen on the lateral view. In the elbow, knee, and ankle, adjacent fat lines and fat pads are displaced. Periosteal reaction, when present, is commonly seen in the phalanges, metacarpals, and metatarsals but also can occur in the long bones. Joint space narrowing may be caused by cartilage loss (see Fig. 136.1). In persons with JIA, the joint space narrowing is usually uniform. In some patients with rheumatoid factor positive polyarthritis or systemic arthritis, early erosive disease can occur (Fig. 136.2).

Bone erosions are typically located at joint margins in the bare areas but also may occur at tendinous insertions. Bone erosions also can be seen in persons with septic arthritis or hemophilic arthritis related to the inflammatory reaction caused by intraosseous hemorrhage. Large erosions can also be seen in the camptodactyly arthropathy coxa vara pericarditis syndrome[32] (e-Fig. 136.3). Deformity of the fingers, whether with boutonniere (proximal interphalangeal [PIP] flexion with distal interphalangeal [DIP] extension) or swan neck (PIP extension with DIP flexion) deformity, can be seen in a variety of disorders, including JIA (Fig. 136.4),



**e-Figure 136.3. Camptodactyly arthropathy coxa vara pericarditis syndrome.** Radiograph (A) axial T1-weighted (B) and axial T2-weighted (C) MR images of the right hip show coxa vara, short broad femoral necks, synovitis/joint effusion, and erosive changes in the right hip.

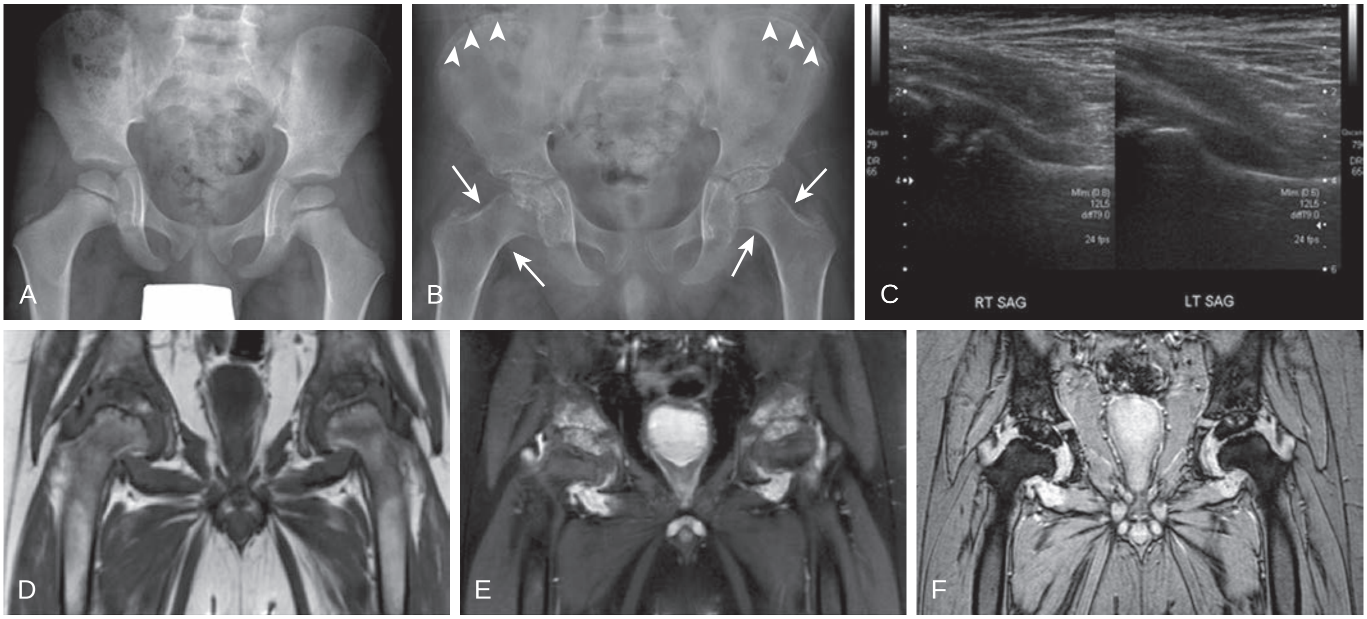


**Figure 136.2. Systemic juvenile idiopathic arthritis in a patient with multiple hip infections.** At the age of 4 years, only slight irregularity of the contour of the proximal femoral epiphyses is noted on a frontal radiograph (A) representing a variation of normal, with preserved joint spaces. At the age of 11 years, extensive erosive changes are seen in the femoral heads and acetabula with further bilateral hip joint space loss, as seen on radiographs (B). Interval increased sclerosis is noted along the acetabular roofs bilaterally. Nonspecific periosteal reaction is seen along the medial aspect of the femoral necks bilaterally *(arrows)*. Sclerotic lines are shown along the iliac wings *(arrowheads)* compatible with previous bisphosphonate therapy. Ultrasound images (C) obtained at 11 years demonstrates a moderate left and mild right hip joint effusion. Coronal noncontrast (D), contrast-enhanced T1-weighted fat-saturated (E), and gradient recalled echo (F) MR images, 1 month after the ultrasound, show markedly thickened, lobulated, heterogeneously enhancing synovium in both hip joints. Enhancing marrow signal abnormality, loss of articular cartilage, and articular surface irregularity is present in the femoral heads and acetabula. The findings are consistent with severe progression of inflammatory arthritis with diffuse pannus formation and secondary avascular necrosis of the femoral heads.

camptodactyly arthropathy coxa vara pericarditis syndrome, or systemic lupus erythematosus. Enlarged or irregular epiphyseal ossification centers can be seen in persons with hemophilia, JIA, and tuberculous arthritis. Atlantoaxial subluxation or cervical vertebrae pseudosubluxation and ankylosis (e-Fig. 136.5) may be noted in persons with JIA, the arthropathy of Down syndrome, dysostosis multiplex, and systemic lupus erythematosus.

In contrast to adult patients with inflammatory arthritis, bone erosions are less commonly seen in children because the epiphyseal ossification center is surrounded not only by articular cartilage but also by epiphyseal cartilage and the spherical growth plate. As a result, significant cartilage loss must occur before osseous erosions are visible with radiography. Therefore the role of MRI is relatively more important in children to detect articular or epiphyseal cartilage erosions before actual bony erosions are visible on radiography.

Changes in bone growth and maturation with changes in the normal size of ossification centers and alteration of normal bone modeling can be seen in persons with JIA, and with infections and hemophilia. Enlargement of ossification centers and epiphyses (see Fig. 136.4), contour irregularity, trabecular changes, and squaring (typically of the patella) can be seen. Tibiotalar slant (ankle valgus) can also be seen.[33]

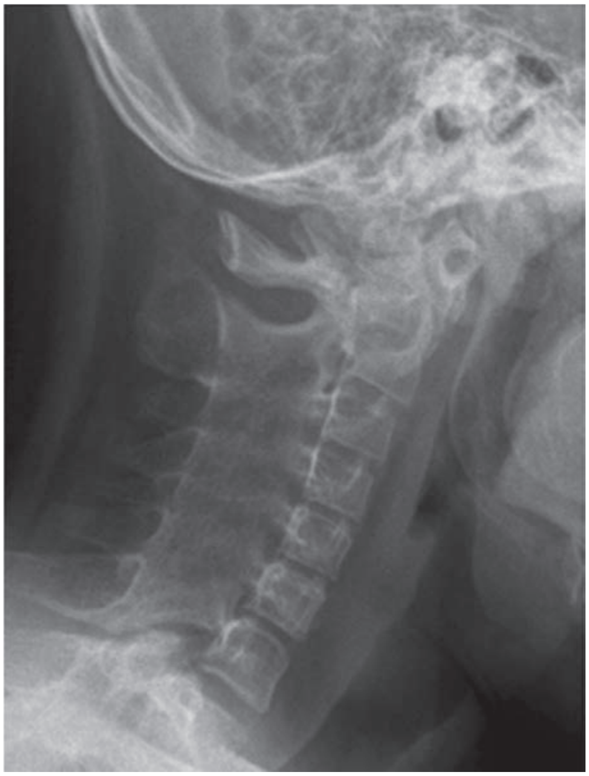
Late sequelae of JIA include epiphyseal deformity, abnormal angular carpal bones, widening of the intercondylar notch of knees (see Fig. 136.4), and premature fusion of the growth plates. Growth disturbances are more frequent if disease onset is early. Joint space narrowing and osseous erosions are usually late manifestations. At the hip, protrusio acetabuli (see Fig. 136.1), premature degenerative changes, coxa magna, and coxa valga can be seen. Joint space loss can progress to ankylosis, particularly in the apophyseal joints of the cervical spine (see e-Fig. 136.5) and wrist. Rarely, ankylosis also can be seen in larger joints, including the hips. Subluxation of the joints, especially at the wrist, may be evident. Growth disturbance of the temporomandibular joint may lead to micrognathia and temporomandibular disk abnormality.[33]

Although radiography should be used initially in evaluation of joints, cross-sectional imaging techniques have provided a significant improvement in anatomic delineation and diagnosis.

## Magnetic Resonance Imaging

MRI is an optimal tool for evaluation of both soft tissues and osteochondral abnormalities with superb tissue contrast.[34,35] Contrast-enhanced MRI is extremely sensitive for detecting active disease and for early detection of cartilage loss, bone erosions, and synovial hypertrophy in children and adolescents.[35,36] MRI provides multiplanar evaluation with a combination of available imaging sequences, including T1 and fast spin echo T2-weighted sequences, gradient echo sequences, and postcontrast studies all tailored to the specific clinical problem.[37–39] High cost, limited availability, and frequent need for sedation in very young patients are limitations.

Various forms of cartilage can be visualized on MRI, including articular, unossified epiphyseal, and the physeal cartilage.[40] Gadolinium-enhanced MRI can demonstrate normal vessels



**e-Figure 136.5. Polyarticular juvenile idiopathic arthritis.** Lateral cervical radiograph demonstrates diffuse ankylosis of the posterior elements of C3-T1.

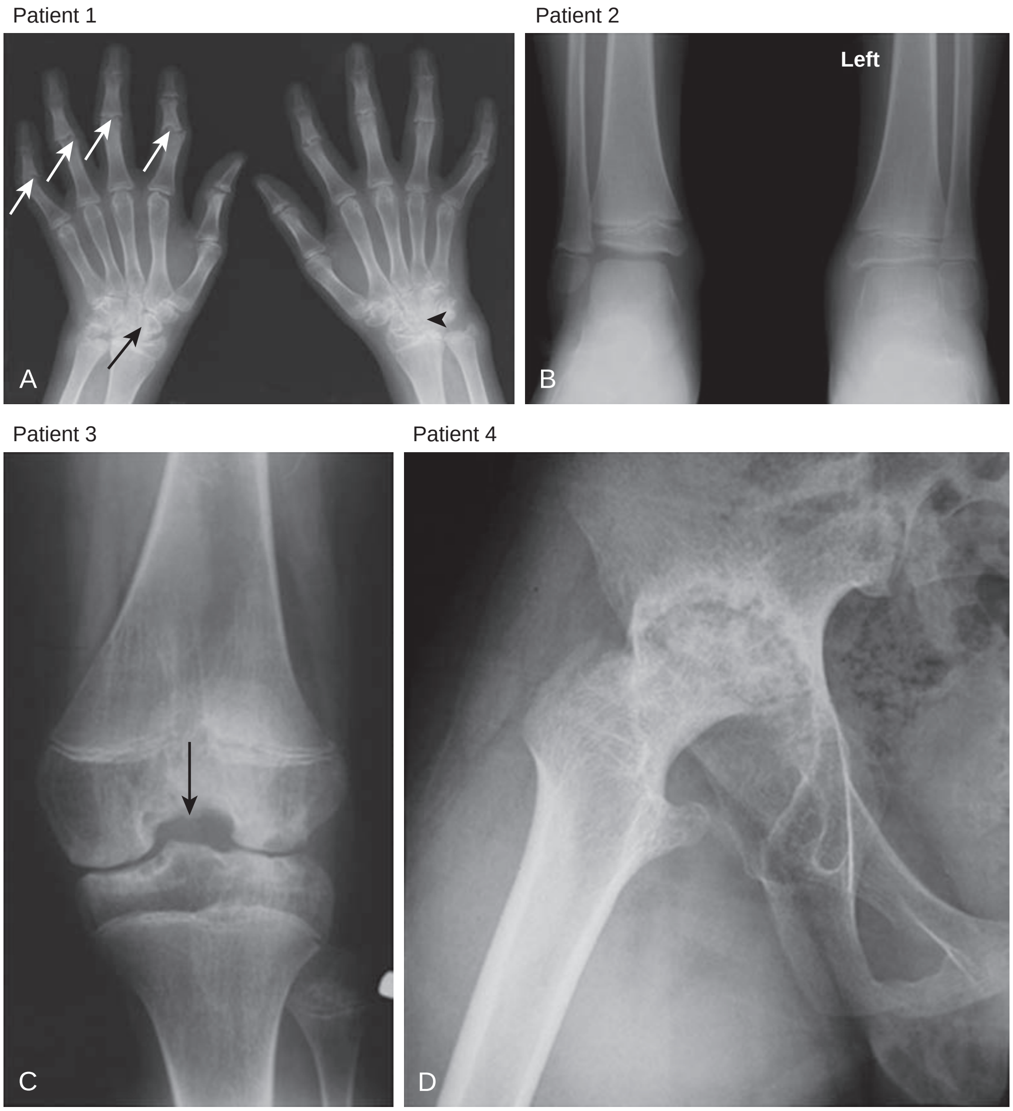


**Figure 136.4. Advanced juvenile idiopathic arthritis in the peripheral skeleton in different patients.** (A) Patient 1: Deformity of the digits as a result of erosive changes is seen at the phalangeal heads and bases *(white arrows)* and metacarpal and carpal bones *(black arrow)*, along with joint space narrowing, carpal ankylosis *(arrowhead)*, and ray subluxation. (B) Patient 2: A radiograph shows joint space narrowing, advanced maturation, and epiphyseal overgrowth (shown in the distal left tibia and fibula in comparison with normal-appearing right counterparts). (C) Patient 3: Widening of intercondylar notch *(arrow)* of the knee. (D) Patient 4: Extensive joint space narrowing of the right hip, articular irregularity, and subchondral cystic changes in the femoral head and acetabulum.

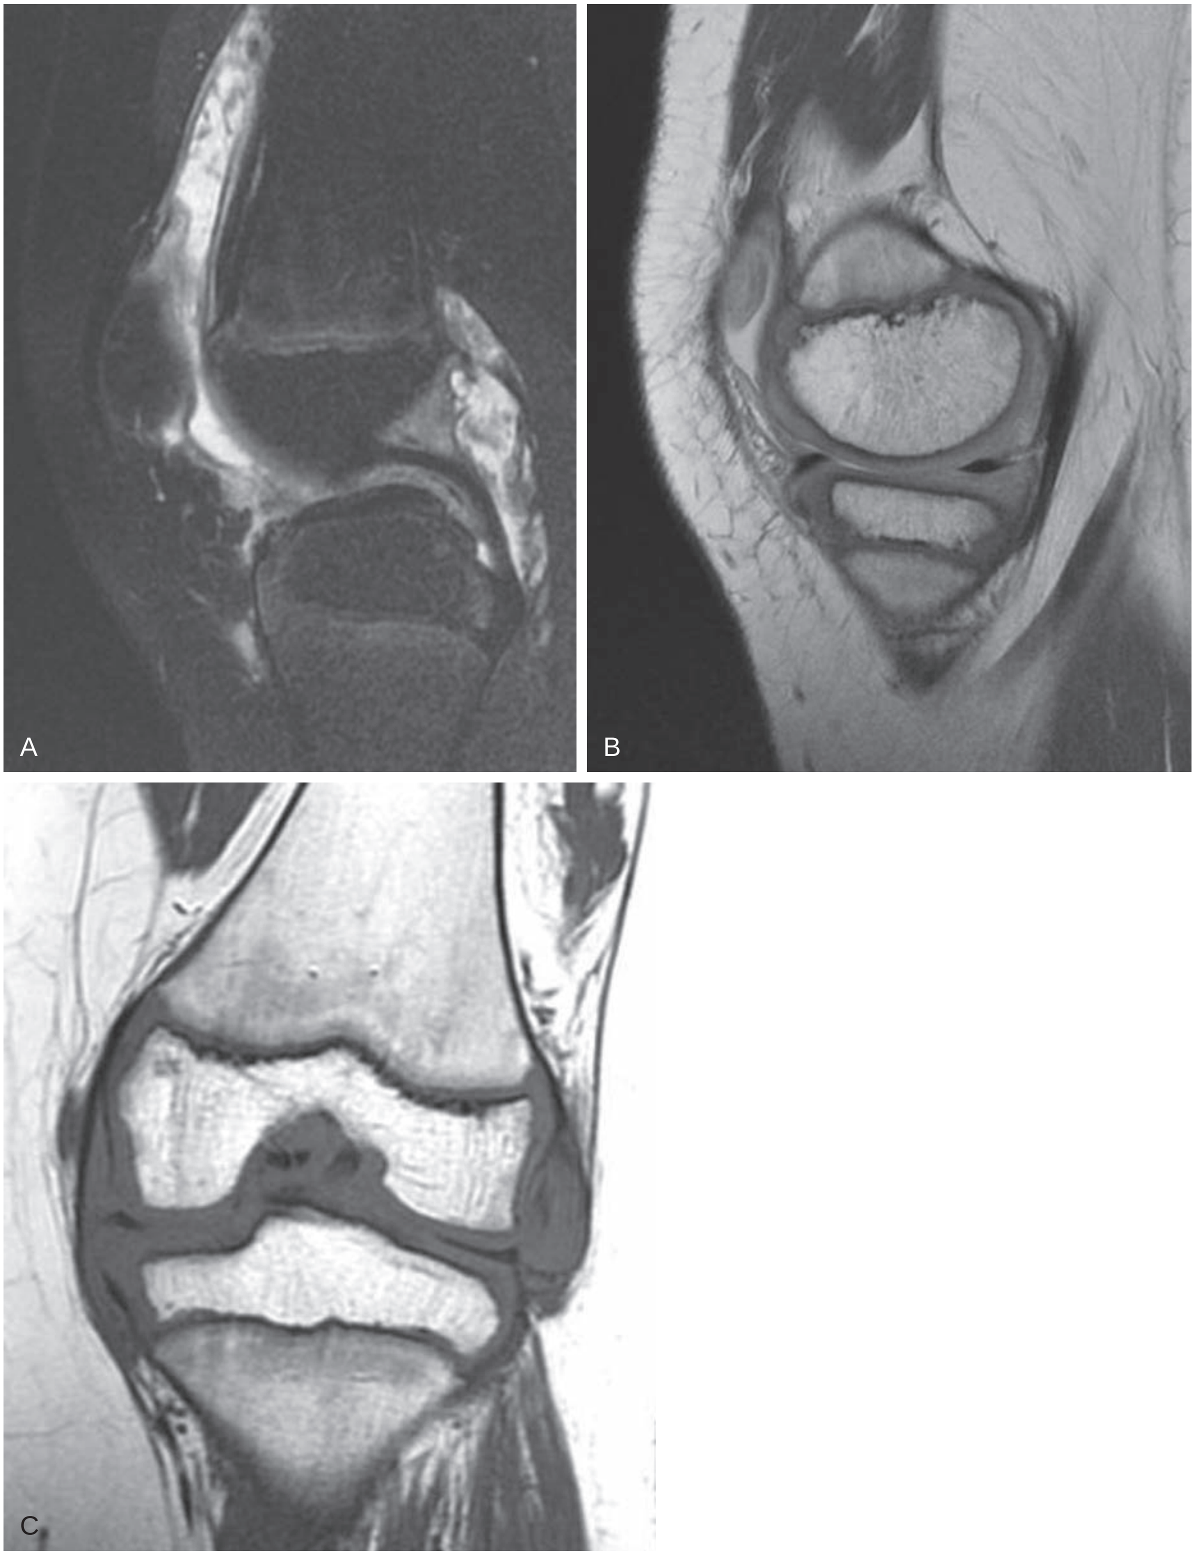
present within the cartilaginous epiphysis.[41] MRI also is helpful in detecting synovial abnormalities[42] and can be used to assess for changes with therapy.[43]

Without contrast material, proliferating synovium on MRI appears as soft tissue thickening, which is typically intermediate signal on T1-weighted and increased signal intensity on T2-weighted images (Fig. 136.6). It may have slightly higher signal intensity than adjacent fluid on unenhanced T1-weighted images. At times, pannus may appear as intermediate to dark signal intensity on T2-weighted images outlined by bright signal joint fluid. Its variable signal intensity reflects the relative amount of fibrous tissue and hemosiderin. Intravenous administration of gadolinium-based contrast agents improves visualization of thickened synovium, especially with use of fat-suppression techniques. Proliferating synovium appears as enhancing linear, villous, or nodular tissue. Images should be obtained immediately after contrast injection because diffusion of contrast material from the synovium into joint fluid occurs over time. Hypervascular inflamed pannus enhances significantly (see Fig. 136.2E), whereas fibrous inactive pannus shows much less enhancement. Subchondral cysts and bone erosions (see Fig. 136.2) appear as low signal areas on T1-weighted sequences,[37] with overlying articular and epiphyseal cartilage loss better delineated on fluid-sensitive sequences. Meniscal hypoplasia can be seen in some cases of JIA (e-Fig. 136.7).[35]

Quantitative techniques have been developed for synovial volume.[44,45] MRI is more sensitive than clinical evaluation in detecting some specific joint involvement, including the temporomandibular joint, which often demonstrates inflammatory change in the absence of clinical symptoms.[46]

With prolonged synovial inflammation, well-defined intraarticular nodules termed “rice bodies” (Fig. 136.8) may be present. Rice bodies likely arise from detached fragments of hypertrophied



**e-Figure 136.7. Juvenile idiopathic arthritis in a 13-year-old girl.** (A) Sagittal T2-weighted MR image shows diffuse synovitis and a joint effusion. (B) Sagittal proton-density MR image through the medial joint compartment shows hypoplastic anterior and posterior horns of the medial meniscus. (C) Coronal T1-weighted MR image shows hypoplasia of the medial and lateral menisci.

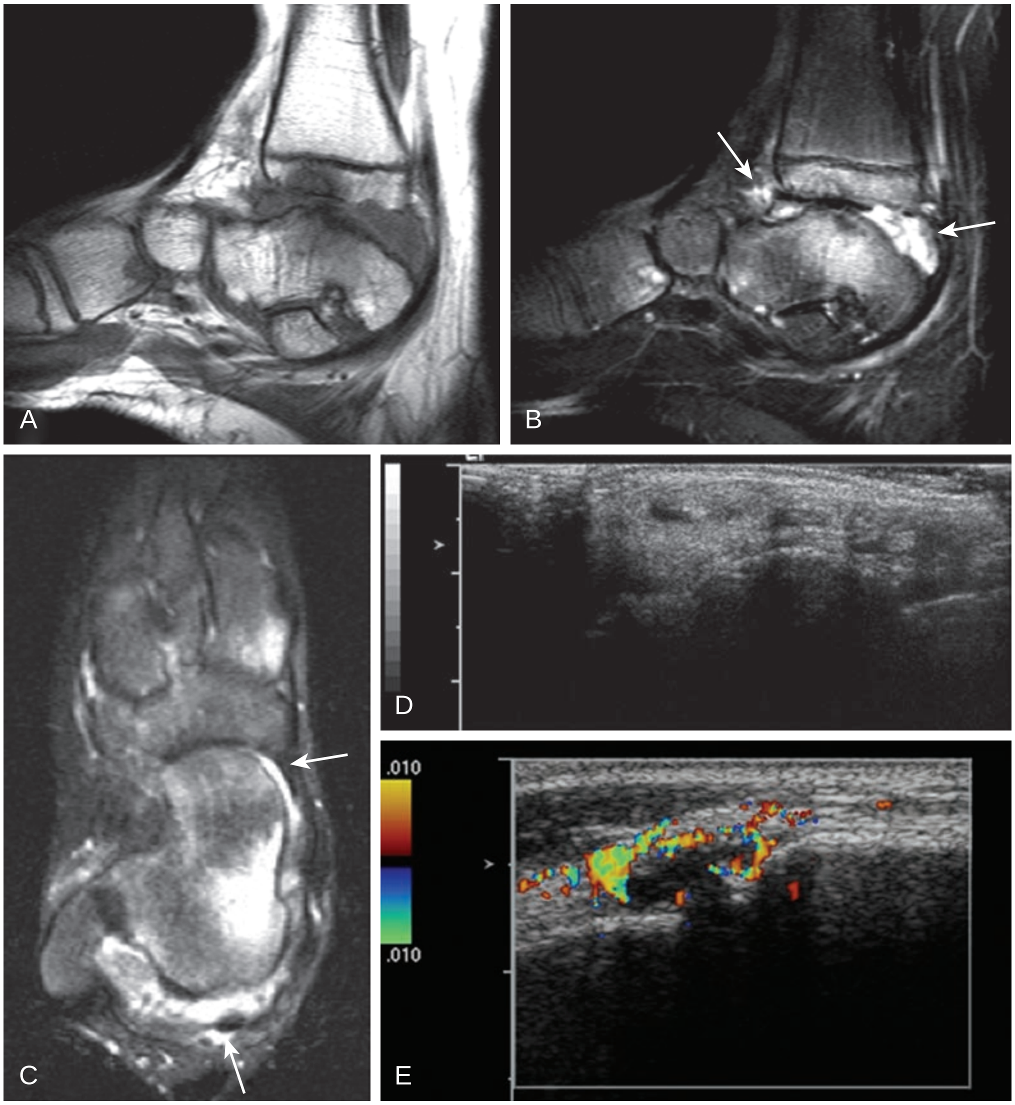


**Figure 136.6. Juvenile idiopathic arthritis and symptomatic tenosynovitis in a 14-year-old girl.** Sagittal T1-weighted (A) and fat-saturated T2-weighted (B) MR images of the right ankle show synovial overgrowth within the tibiotalar *(arrows)* and intertarsal joints. Extensive erosive changes and bone marrow edema are noted at the tibiotalar joint (A and B). Increased signal intensity is seen within the synovial sheaths of the tendons of the medial aspect of the right foot, including the tibialis posterior *(medial arrow)* and flexor hallucis longus *(posterior arrow)* on axial T2-weighted MR images, suggesting tenosynovitis (C). Longitudinal gray-scale (D) and color Doppler (E) ultrasound scans demonstrate a small amount of fluid within the tendon sheaths and synovial proliferation and hyperemia of the tendons of the medial right foot.

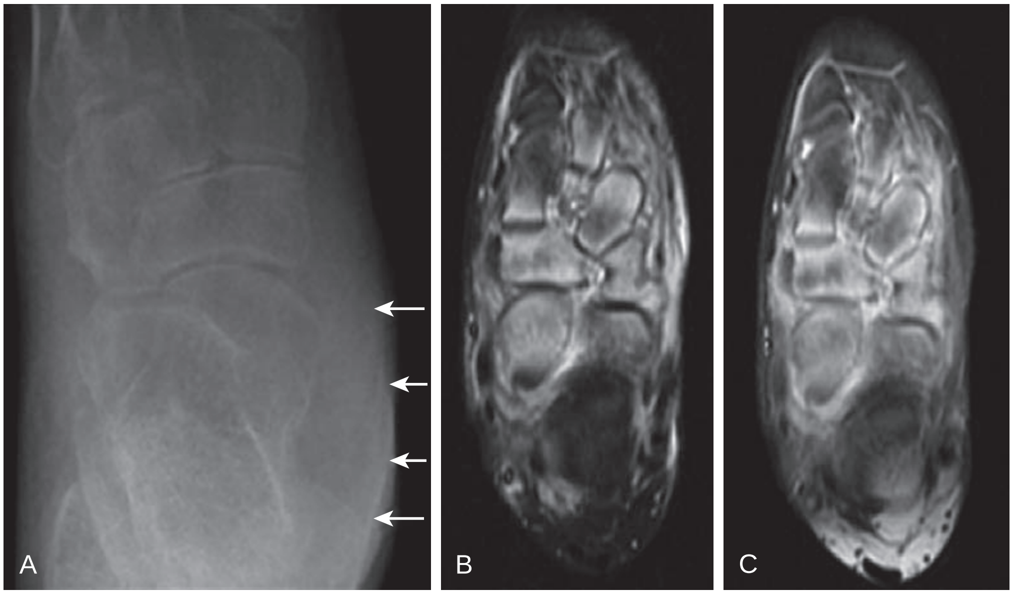
synovial villi. On MRI, rice bodies are low signal on T2-weighted images because of their fibrous tissue composition and are associated with joint effusion, synovial hypertrophy, and synovial enhancement after gadolinium administration.[47]

Bone marrow edema is represented by areas of low T1-weighted and high T2-weighted signal intensity (e-Fig. 136.9) and should be differentiated from normal marrow speckling seen on fluid-sensitive sequences, most frequently in the ankle and foot. Studies in adults[48–50] have shown an association between presence of subchondral bone marrow edema in persons with inflammatory arthritis and radiographic erosive progression.

Because cartilage is one of the earliest sites of damage in persons with JIA, it is an important area to be evaluated with MRI. Standard T2-weighted and proton density magnetic resonance (MR) sequences can assess articular cartilage injury, from increased signal intensity within cartilage to articular cartilage thinning, erosions, and areas of full-thickness cartilage loss. Fat-saturated fluid-sensitive sequences will also depict subchondral bone marrow edema. Advanced sequences for cartilage evaluation are discussed later.

Although MRI has been extensively investigated in JIA,[8,51] standardized measures for data acquisition and interpretation are not widely used[52]; hence this technique is underutilized both in clinical practice and in research. Few MRI scales have been designed to specifically assess morphologic changes with JIA.[53,54]

**Novel Magnetic Resonance Imaging Techniques.** A number of novel MRI techniques are under evaluation for improved assessment of synovial, cartilaginous, or osseous abnormalities. These MRI techniques include diffusion-weighted imaging (DWI)



**e-Figure 136.9. Juvenile idiopathic arthritis in an 11-year-old girl with a swollen left ankle and midfoot.** The radiograph (A) and MRI examination (B and C) were obtained 1 week apart. Unenhanced axial inversion-recovery (B) and postcontrast axial T1-weighted spin echo MR images (C) of the left foot obtained with fat saturation are shown. Soft tissue swelling is present along the left ankle (A) *(arrows)*. Marked osteopenia and navicular-cuneiform joint space narrowing (A) are also present. MR images show extensive bone marrow edema predominantly within the anterior aspect of the talus, navicular, and cuneiforms. Increased signal intensity on inversion recovery images (B) and contrast enhancement (C) are also noted in the soft tissues surrounding the involved bones.

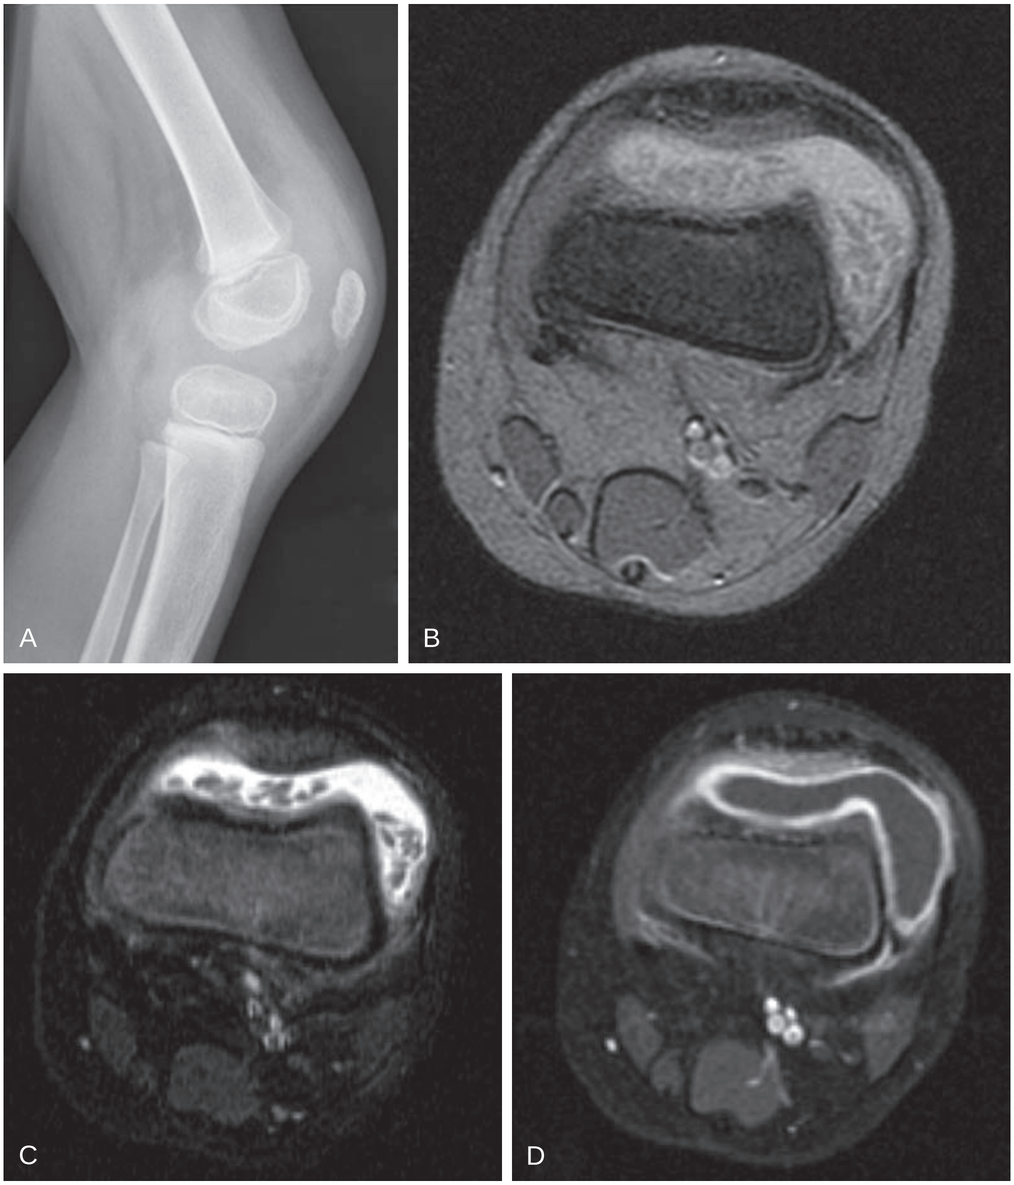


**Figure 136.8. Rice bodies.** A 3-year-old boy had persistent knee pain 1 month after sustaining a trauma. The lateral radiograph view (A) shows moderately large joint effusion distending the suprapatellar bursa. Intraarticular elongated bodies that extend into the recesses of the joint space and layer in dependent portions are seen on axial multiplanar gradient-recalled acquisition (B) and T2-weighted fat-saturated (C) and contrast-enhanced T1-weighted fat-saturated (D) MR images. Marked synovial enhancement also is noted.

and perfusion imaging, delayed gadolinium-enhanced cartilage imaging, T2 quantification, and ultra-short echo time (TE) pulse sequences. DWI evaluates the translational movement (Brownian motion) of water molecules that occurs in all tissues, including synovium and cartilage. Alteration of normal diffusion can occur in diseases including infection, inflammation, and infarction.[55] Diffusion tensor imaging (DTI) is a variant of DWI and has been used to study the structure of ordered biologic tissue, and holds potential to delineate synovial inflammation.[56–58]

Contrast-enhanced perfusion MRI assesses blood flow using intravenously administered paramagnetic contrast agents. Potential uses of this technique include recognition of epiphyseal ischemia and quantification and monitoring of synovial inflammation.[59] The rate of synovial enhancement depends in part on tissue vascularization and capillary permeability, both of which are highly correlated with synovial inflammation.[60,61] Rapid enhancement suggests active synovial inflammation, whereas gradual delayed enhancement suggests subacute/chronic synovial inflammation. Quantitative dynamic contrast-enhanced MRI based on pharmacokinetic modeling has been proposed as an objective measure of therapeutic efficacy in patients with JIA.[62,63]

Delayed gadolinium-enhanced MR cartilage imaging is a sensitive technique for assessing cartilage proteoglycan content using the negative charge of the intravenously administered paramagnetic MR contrast agent.[64] The contrast agent distributes into cartilage inversely to the fixed charge density of negatively charged glycosaminoglycan (GAG). Delayed gadolinium-enhanced MR cartilage imaging may be used to assess early cartilage injury with depletion of GAG before anatomic changes are visible by conventional cartilage sequences.

Cartilage assessment can also be provided by mapping T2 relaxation time measurements. These measurements may help characterize the structural integrity of the cartilaginous tissue and quantitatively assess the degree of cartilaginous hydration and collagen orientation.[65] Typically there is a decrease in T2 relaxation from the cartilage surface to the deeper layers.[66,67] In persons with JIA, increased cartilage T2 relaxation time is thought to be an early marker of disease progression in JIA, because it can identify microstructural changes before damage becomes visible.[68] In a longitudinal study evaluating patients with JIA from 3-month to 2-year follow-up, the clinical assessments improved, whereas T2 maps showed increased T2 values.[69] This increase likely represents progressive microstructural changes, even though clinical symptoms improved with treatment.

Other advanced MRI techniques for cartilage assessment include T1 rho, sodium imaging, and ultrashort TE sequences.[70–79]

## Ultrasonography

Recent advances in ultrasonography, including better transducers and more pediatric musculoskeletal experience, have stimulated increased use of ultrasound in the assessment of pediatric joint disease. Ultrasound is ideal for assessing the pediatric musculoskeletal system because of its ability to visualize intraarticular structures such as cartilage and thickened synovium without the need for radiation. Ultrasound is very sensitive in detecting joint effusion, even in areas where radiographs are insensitive, such as the hip (see Fig. 136.2C) and shoulder.[80] Intraarticular masses may be detected with ultrasound, although their appearance is often nonspecific. Tendons and ligaments also can be assessed with higher-frequency transducers.[81] Fluid within the synovial sheath appears as an anechoic halo surrounding the tendon (Fig. 136.10), whereas synovial thickening appears as a hypoechoic thickening around the tendon. Synovial hyperemia leads to increased signal on Doppler evaluation.[82] Power Doppler has been shown to detect residual disease activity more sensitively than clinical examination and/or MRI both in active disease and when JIA is in remission[83,84] and could be used to predict short-term relapse in patients with JIA who appear to be in remission clinically.[85]

Sonography can also be used to assess other periarticular soft tissue abnormalities, including popliteal cysts (e-Fig. 136.11) or other soft tissue masses, and to guide aspiration or injection of joints.[86]

Disadvantages of ultrasound include lack of standardization of ultrasound techniques for assessment of growing joints and normative data, lack of capability to visualize the central aspect of some joints, and difficulty in assessing some joints such as the temporomandibular joints (Fig. 136.12).[46,87]

Erosions and focal or diffuse thinning of the articular cartilage also can be detected but only peripherally in the joint. Color Doppler ultrasound enables the detection of perisynovial hyperemia. Studies in children[88,89] have demonstrated the ability of color and power Doppler sonography, with or without intravenous injection of contrast agents, to estimate synovial activity in JIA. Resistive indices and fraction of color pixels may be used as quantitative measurements of the blood flow.[90,91] Contrast-enhanced sonography holds potential for detecting active synovial inflammatory disease in persons with subclinical JIA and may help guide early treatment.[88]

Very limited information is available about the diagnostic performance and accuracy of ultrasound compared with MRI or clinical examination (in knees, sensitivity for joint effusion is 62%,[92] ranging between 60% and 90% for clinically active joints and approximately 70% for clinically inactive joints[93–95]; for superficial cartilage destruction, overall sensitivity is 60%).[92] Ultrasound-determined synovial thickness of the knee seems to correlate with clinical and laboratory (sedimentation rate and C-reactive protein levels) disease activity scores and with biomarkers of disease activity.[95] In ankles, however, very poor agreement was observed comparing clinical and ultrasound scores.[96]

## Treatment and Follow-up

A systematic review on evidence-based treatment of JIA[97] showed that nonsteroidal antiinflammatory drugs are effective only for a minority of patients, mainly those with oligoarthritis. Intraarticular corticosteroid injections are very effective for persons with oligoarthritis. Methotrexate is effective for the treatment of persons with extended oligoarthritis and polyarthritis and less effective for persons with systemic arthritis. Sulfasalazine and leflunomide may be alternatives to methotrexate. Antitumor necrosis factor medications are highly effective for polyarticular JIA that is not responsive to methotrexate but are less effective in persons with systemic arthritis. Therefore, despite many treatment advances, evidence is still lacking for treatment of several disease subtypes.

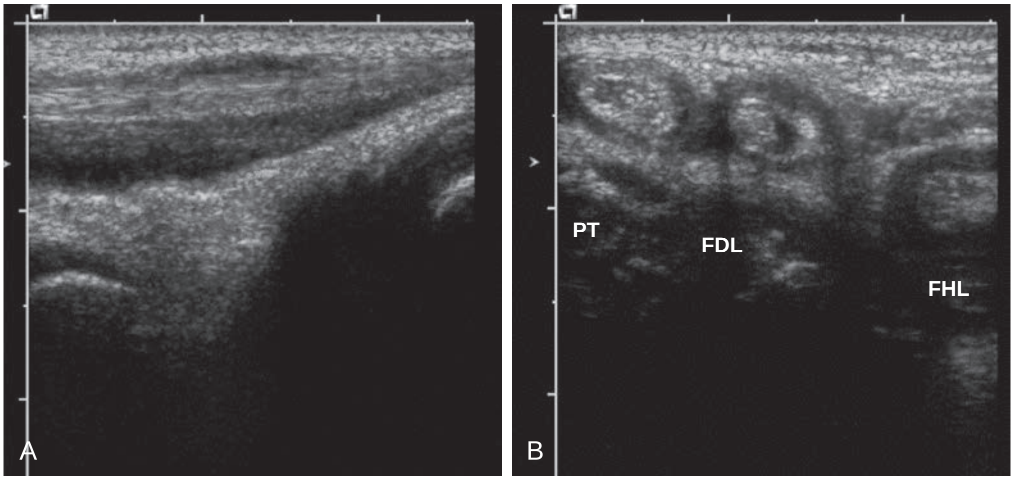

**Figure 136.10. Polyarticular juvenile idiopathic arthritis in a 10-year-old girl.** (A) Longitudinal sonogram along the medial aspect of the patient's left ankle shows an increased amount of fluid within the posterior tibialis tendon. (B) Corresponding transverse sonogram demonstrates tenosynovitis involving the posterior tibialis *(PT)*, flexor digitorum longus *(FDL)*, and flexor hallucis longus *(FHL)* tendons of this ankle.

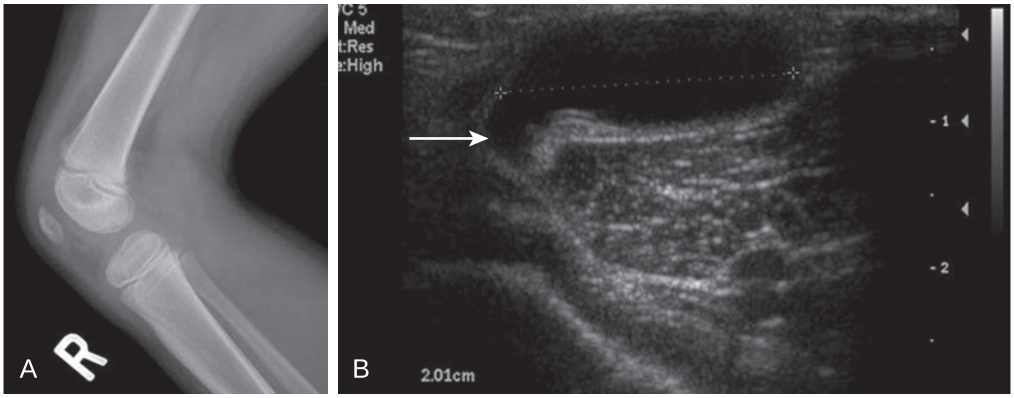

**e-Figure 136.11. Bakers cyst.** A 4-year-old girl with an asymptomatic lump in the popliteal fossa of the right knee. Lateral radiograph (A) shows increased soft tissue density in the popliteal region. Transverse sonogram through the popliteal fossa (B) demonstrates a large cyst with a tail *(arrow)* extending between the medial head of the gastrocnemius and semimembranosus tendons.

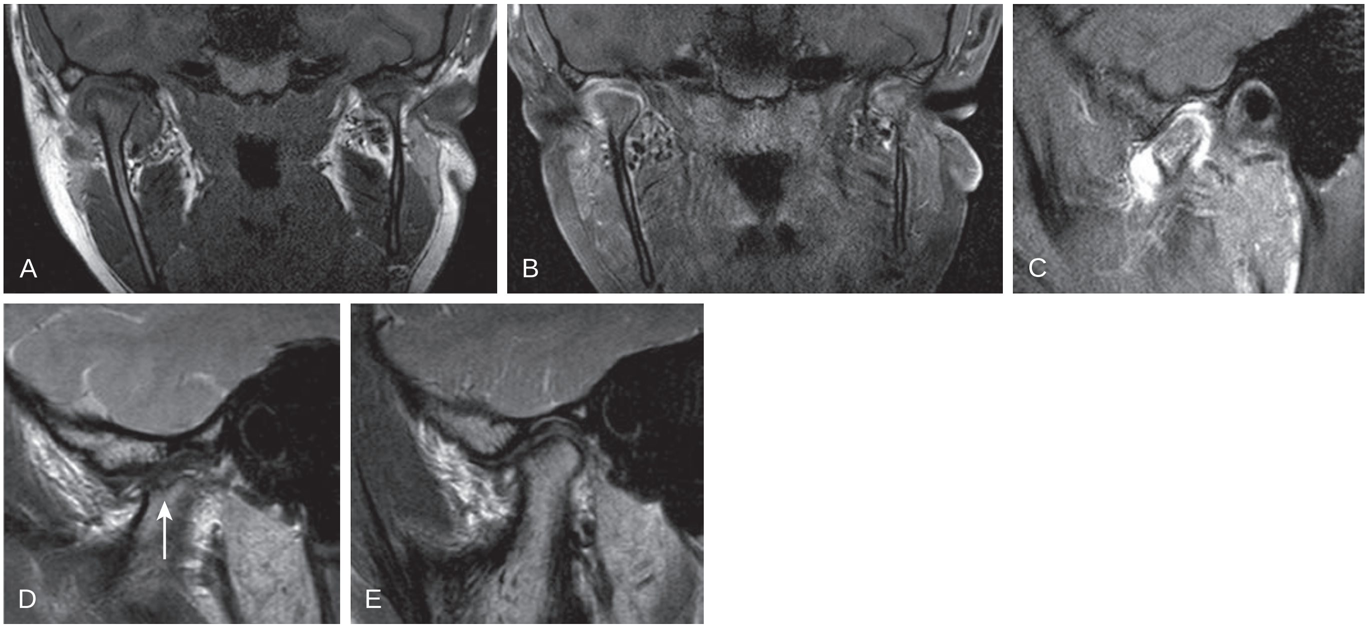

**Figure 136.12. Temporomandibular joint involvement in longstanding juvenile idiopathic arthritis in a symptomatic 12-year-old girl.** Coronal T1 image (A), a contrast-enhanced coronal T1 spectral presaturation inversion recovery (SPIR) image (B), a sagittal contrast-enhanced T1 SPIR image of the right temporomandibular joint (TMJ) (C), sagittal proton density images of the right (D) and left (E) of the TMJs, show moderate right acute TMJ synovitis and mild left acute synovitis. Erosive changes are present *(arrow)*. Note a hypoplastic left mandibular ramus in (A) and (B).

With regard to intraarticular corticosteroids, studies have shown that as many as 70% of patients with oligoarthritis do not have reactivation of disease in the injected joint for at least 1 year, and 40% do not have reactivation for more than 2 years.[98–100] Radiographic and MRI studies have shown a marked decrease in synovial volume after injection without deleterious effects on the cartilage.[101]

## Imaging in the Assessment of Response to Therapy

Once therapy has begun for patients with JIA, imaging can be a helpful adjunct to assess disease activity and response to therapy. To date, several studies have examined radiographic changes before and after initiation of therapy, whereas more recent studies have used CT and/or MRI to describe joint changes and to use more quantitative measures of disease activity.

**Radiography.** Radiography is able to demonstrate epiphyseal overgrowth and osteopenia after the injection of intraarticular triamcinolone hexacetonide.[102] Carpal length, defined as the radiometacarpal length plotted against the length of the second metacarpal bone on a chart with normal growth carpal scores, as described by Poznanski et al.,[103] is another parameter that has been used in follow-up with an interval increase in carpal length (a positive change) indicating improvement.

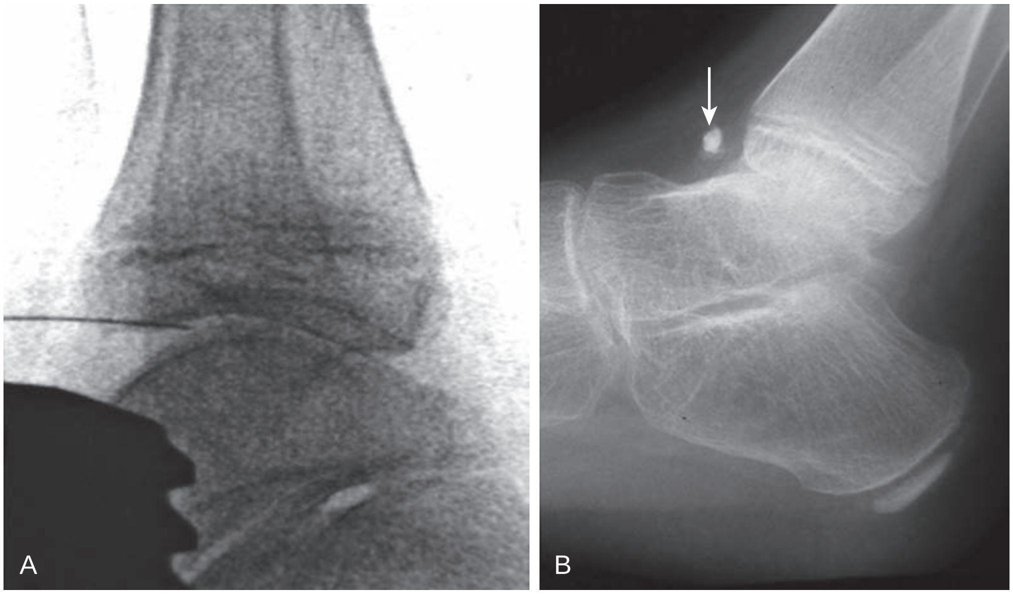
**Ultrasound.** In a small study of 15 joints, Eich et al.[102] used ultrasound to determine the presence of effusion, pannus, popliteal cysts, and lymphadenopathy before and after intraarticular therapy and concluded that ultrasound was as sensitive as MRI in demonstrating joint effusion and/or pannus but that differentiation between the two was difficult, particularly in the hip joint. Spârchez et al. showed power Doppler ultrasonography correlated with physician global assessment of disease activity on visual analogue scale (PhGA) and to be more sensitive than erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels in assessing disease activity.[104]

**Magnetic Resonance Imaging.** Although CT is able to demonstrate joint space narrowing, erosions, and condylar flattening,[105] MRI is the modality of choice to document changes before and after therapy. MRI can be used to monitor cartilage and bone erosions, effusion, pannus, and synovial volumes.[40] In studies of children with arthritis who received intraarticular steroid injections, MRI has shown a long-lasting beneficial effect, with suppression of synovial inflammation and reversion of pannus formation.[101,102,106]

Quantitative dynamic contrast-enhanced MRI can be used to evaluate disease activity in the knee. A study of pharmacokinetic parameters and synovial volumes showed significant decreases at 12 months after intraarticular steroid therapy; however, improvement in synovial volume appeared to lag behind dynamic parameters, reflecting delay or subclinical synovitis.[63] Of all the imaging modalities, MRI has been shown to be the most sensitive modality in the assessment of temporomandibular joint arthritis in children and has been used as a reference standard measure for comparison of clinical examination and ultrasound in clinical studies.[46] Ultrasound has been shown to be less useful than clinical examination to exclude active temporomandibular joint arthritis in patients with JIA.[46] Standardized and validated assessment systems are still are being developed.

## Complications and Adverse Effects of Joint Injections

It is difficult to determine whether other postinjection changes in JIA patients reflect the underlying severity of the disease or the effects of the local treatment.[107] The most common radiographic finding after injection is intraarticular calcification (e-Fig. 136.13). This calcification can resolve or persist for some time. It typically does not impair joint function. Damage to cartilage during the procedure is a potential complication.[101] Additional complications of intraarticular steroid injections include skin depigmentation, overlying skin atrophy, and iatrogenic infection.



**e-Figure 136.13. Juvenile idiopathic arthritis with symptomatic tenosynovitis.** (A) Steroid injection of the tibiotalar joint under fluoroscopy. On a subsequent radiograph (B), periarticular calcification *(arrow)* is seen within the anterior aspect of the left ankle of this patient.

## ENTHESITIS-RELATED ARTHRITIS

### Etiology, Pathophysiology, and Clinical Presentation

Enthesitis-related arthritis (ERA) affects 1% to 7% of patients with JIA and includes patients with arthritis *and* enthesitis, or with arthritis *or* enthesitis, as well as two of five defined criteria, including a history of sacroiliac joint tenderness and/or lumbosacral pain, the presence of the HLA-B27 antigen, the onset of arthritis in a male patient older than 6 years, uveitis, or a history of ankylosing spondylitis, inflammatory bowel disease, or uveitis in a first-degree relative.[1] The term "ERA" was introduced in lieu of the term "pediatric spondyloarthropathies" to emphasize that (1) axial skeletal involvement in children is rare and large joint appendicular involvement is more common at presentation, and (2) the disease commonly involves tendon/ligamentous insertions and origins in children.

### Imaging

#### Radiography

Radiographic findings of ERA and other spondyloarthropathies are similar to those encountered in other forms of JIA with the exception of sacroiliitis and enthesitis, which are more specific for spondyloarthropathy (Box 136.4).[108,109] In the appendicular skeleton, radiography typically shows asymmetric involvement of the large joints of the lower limb, that is, the hip, ankle, knee, and tarsal joints. The interphalangeal joint of the hallux is also frequently involved. Radiographs may be normal initially or can demonstrate soft tissue swelling, effusion, ossification and epiphyseal overgrowth, erosions (Fig. 136.14), osteopenia, joint space narrowing, or, rarely, fusion. Bone erosions may be associated with irregular bone apposition at joint margins, referred to as "whiskering." With hip involvement, these proliferative changes are noted at the junction of the femoral head and neck. Dactylitis may be seen with soft tissue swelling and periosteal reaction along the shaft of metacarpals, metatarsals, or phalanges.

Enthesitis refers to inflammation at insertion of tendons or ligaments and can present with soft tissue swelling, localized osteopenia, and bone erosion and/or spur formation. Common sites include Achilles tendon insertion, plantar aponeurosis origin, or at the origin/insertion of the patellar tendon. Periostitis also may be seen.

In ERA, changes in the spine and sacroiliac joints generally are not seen until the latter part of the second decade or even adulthood. It is unusual for ERA to present initially with spinal involvement in children. Spinal involvement includes localized osteitis, erosions, and sclerosis, particularly at vertebral margins. Syndesmophytes and atlantoaxial subluxation are rarely seen in children. Radiographs may demonstrate unilateral or bilateral sacroiliitis (see Fig. 136.14) with indistinct articular margins (also known as pseudowidening), erosions, and sclerosis, particularly on the iliac side of the joint. Radiography shows asymmetric sacroiliac joint space widening initially, but eventually the classic bilateral, symmetric joint involvement can be seen, with joint space narrowing and ankylosis. Radiographic evaluation of the sacroiliac joints is especially difficult in teenagers. Diffuse osteopenia of the pelvic bones is a late change.

**BOX 136.4** Radiographic Features of Enthesitis-Related Arthritis and Spondyloarthropathies

**PERIPHERAL JOINTS**

- Asymmetrical involvement of large lower limb joints
- Involvement of interphalangeal joint of the hallux
- New bone at the margins of erosions
- Affected joints show swelling, effusion, epiphyseal overgrowth, erosions, osteopenia, cartilage space narrowing, and rarely fusion
- Dactylitis-swelling and periosteal new bone of fingers or toes
- Periosteal new bone—for example, metatarsals, proximal femur

**ENTHESES**

- Especially tibial tubercle and posterior aspect of calcaneus
- Swelling, erosion, new bone formation

**SACROILIITIS**

- Radiographic changes generally delayed until late teens
- Asymmetrical involvement may occur early, then become symmetrical
- Erosions occur first on the iliac side of the sacroiliac joint
- "Pseudowidening" occurs as a result of erosion
- Sclerosis and finally ankylosis develop

*From Jacobs JC, Berdon WE, Johnston AD. HLA-B27-associated spondyloarthritis and enthesopathy in childhood: clinical, pathologic, and radiographic observations in 58 patients.* J Pediatr. *1982;100:521–528.*

#### Sonography

On sonography, enthesitis may show loss of the normal fibrillar echotexture of the tendon and irregular fusiform thickening.[110] Doppler sonography can be used to assess hyperemia at the cortical bone insertion of entheses and along the adjacent synovium in children before and after treatment.[83,111]

#### Magnetic Resonance Imaging

Bone marrow edema, tenosynovitis, granulation tissue, or cortical erosion at the site of enthesitis in the appendicular skeleton may be seen with MRI.[39] MRI can demonstrate early inflammatory changes in the sacroiliac joints and spine and is especially sensitive for evaluation of subchondral bone marrow edema not shown on other types of imaging.[112]

On MRI during active inflammation, low signal on T1-weighted images, with high signal on T2-weighted and postcontrast sequences, can be seen and often in adjacent soft tissues (Fig. 136.15). The need for postcontrast images in certain joints, the sacroiliac (SI) joints in particular, has been questioned.[113] Chronic sclerosis is low signal on T1- and T2-weighted sequences. MRI also may demonstrate erosions in articular cartilage.[39] Whole-body MRI allows widespread anatomic assessment and is promising for early detection and monitoring of disease activity, which may guide treatment in the future.[114]

#### Computed Tomography

CT can show findings of sclerosis and erosive disease of ERA that are not evident on radiographs. However, MRI is preferable due to the lack of ionizing radiation and the ability to detect edema related to inflammation in the bone marrow and adjacent soft tissues.

### Treatment and Follow-up

Evidence for the optimal treatment of enthesitis-related arthritis is lacking.[97] Conventional treatments frequently offer limited efficacy. Treatment with nonsteroidal antiinflammatory drugs and corticosteroids may provide symptomatic improvement but do not alter disease progression. Sulfasalazine has been shown to be no better than placebo[115] and methotrexate has not been demonstrated to modify disease course.[116] Treatment directed

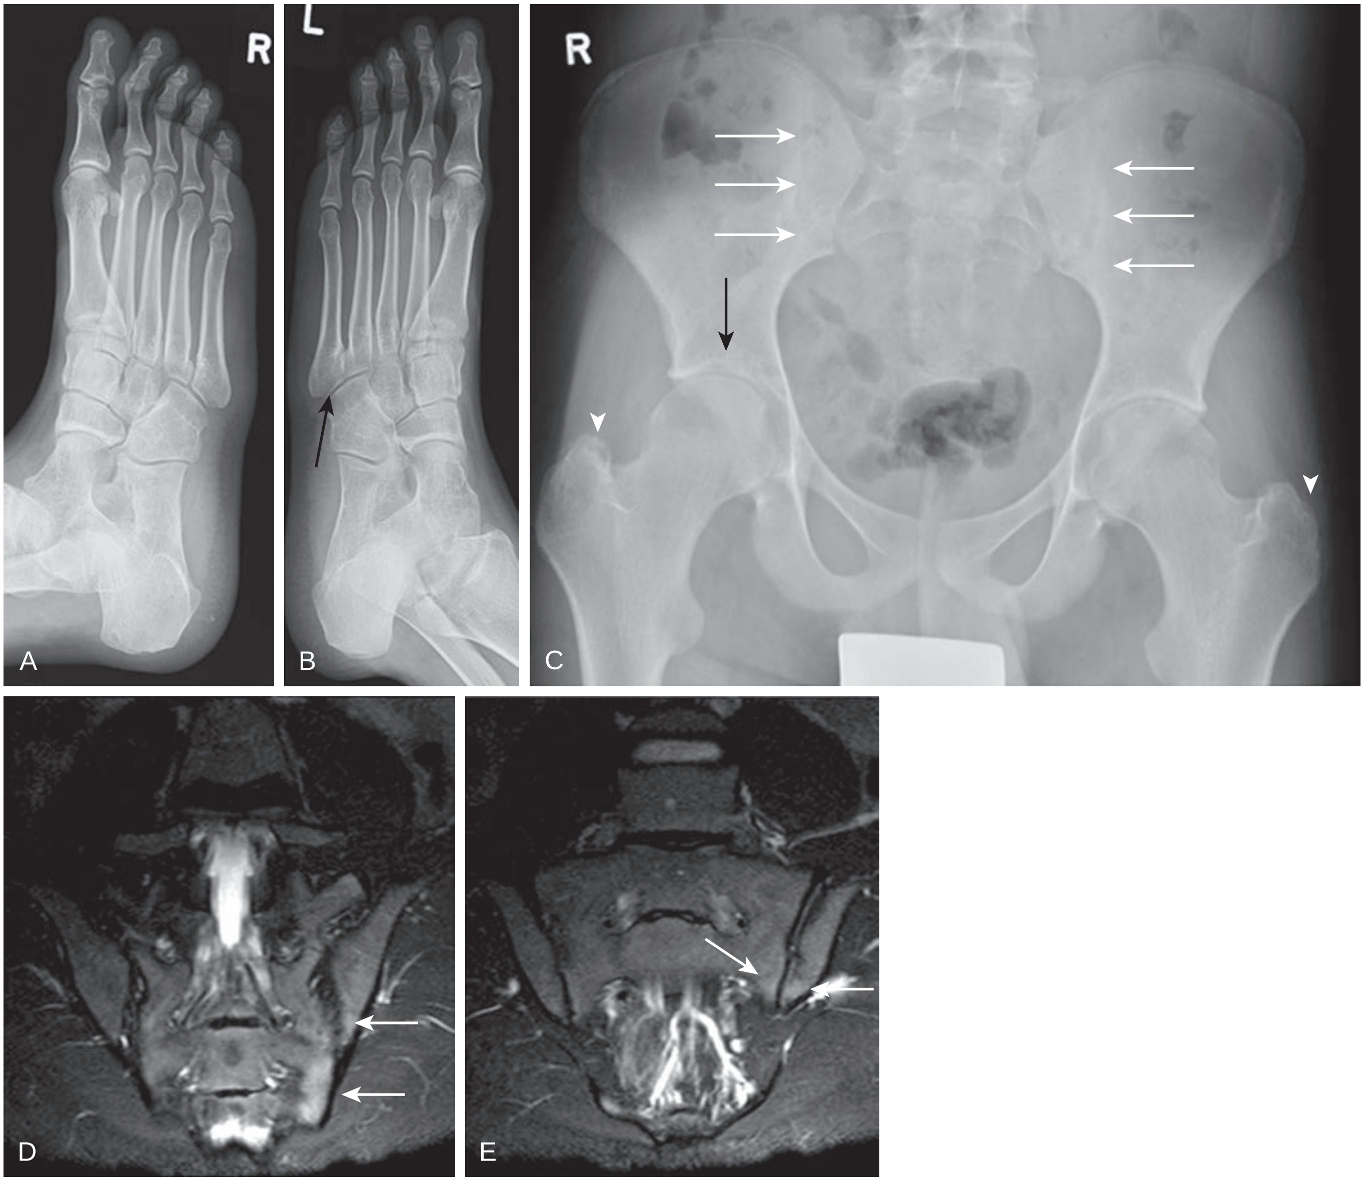


**Figure 136.14. Enthesitis-related B27 negative arthritis in a 16-year-old boy.** (A) Oblique radiographs of the feet show irregularity of the right calcaneal tuberosity at the Achilles tendon insertion consistent with erosive changes, compare to the normal contralateral side in (B). (B) Mild narrowing is noted at the left fifth tarsometatarsal joint *(arrow)*. (C) Frontal radiograph of the pelvis shows slight irregularity and sclerosis along both sacroiliac joints *(white arrows)* suggestive of bilateral sacroiliitis. Uniform narrowing is noted in both hip joints in association with erosions and a subchondral cyst *(black arrow)* along the superior acetabulum and erosive changes at both greater trochanters *(arrowheads)*, representing signs of enthesitis. (D and E) Coronal T2-weighted fat-saturated MR images obtained 2 months after the radiographs show heterogeneous high bone marrow signal involving the iliac and sacral aspect of the left sacroiliac joint *(arrows)* confirming the presence of sacroiliitis.

against tumor necrosis factor-α seems to significantly improve the arthritis and enthesitis.[116,117] Infliximab treatment yielded responses in young adults with peripheral enthesitis inflammatory heel pain.[118]

## PSORIATIC ARTHRITIS

### Etiology, Pathophysiology, and Clinical Presentation

Psoriatic arthritis involves 2% to 15% of patients with JIA and may involve either larger joints such as the knees and ankles or interphalangeal joints of hands and feet, resulting in the characteristic “sausage digits.”[20] Unlike in adults, in children, arthritis actually may precede skin manifestations.

### Imaging

#### Radiography

Radiographs obtained in the initial phase of the disease may be normal or show juxtaarticular osteoporosis. Characteristic radiographic features of psoriatic arthritis include asymmetric involvement, sausage digits (Fig. 136.16), joint erosions, joint space

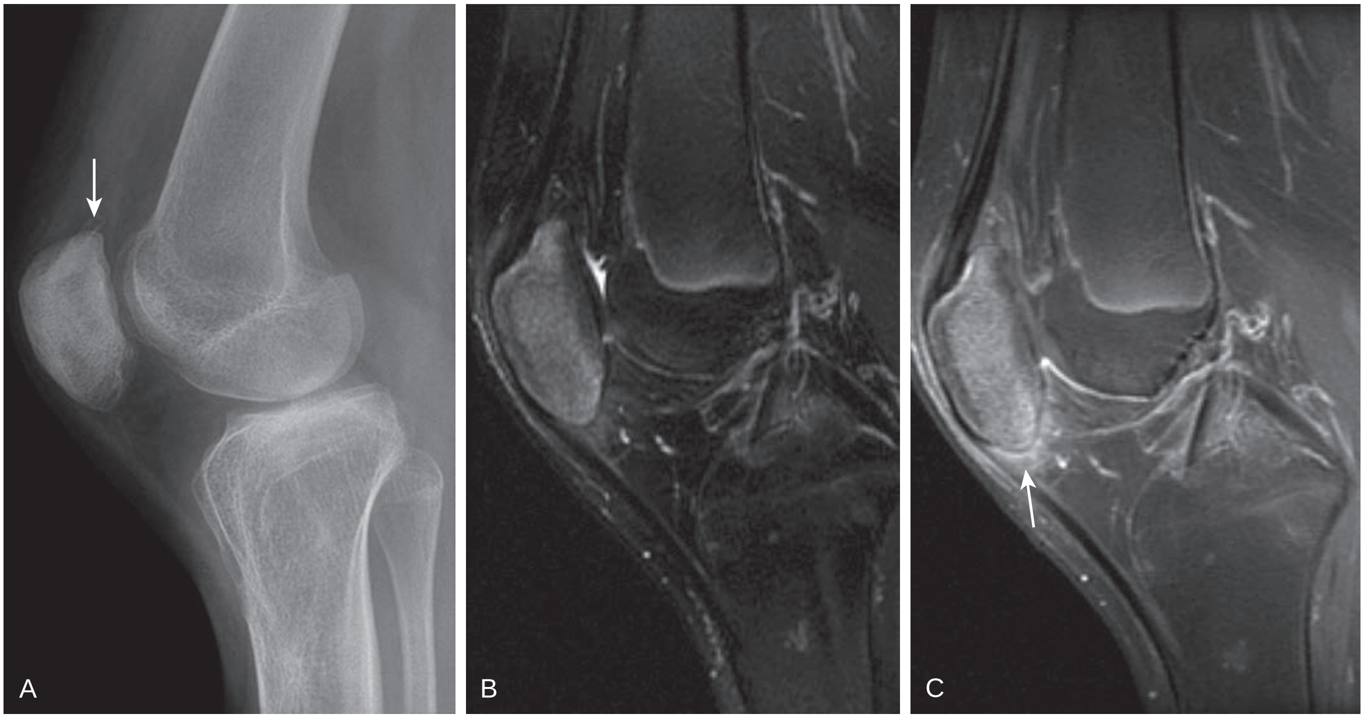

**Figure 136.15. Enthesitis-related arthritis in a 13-year-old boy.** (A) Lateral radiograph shows spurring at the upper aspect of the patella *(arrow)*. Corresponding sagittal T2 fast spin echo fat-saturated (B) and contrast-enhanced sagittal T1-weighted fat-saturated (C) MR images reveal increased signal intensity in the patella and postcontrast enhancement at the origin of the patellar tendon and adjacent Hoffa's fat pad *(arrow)*.

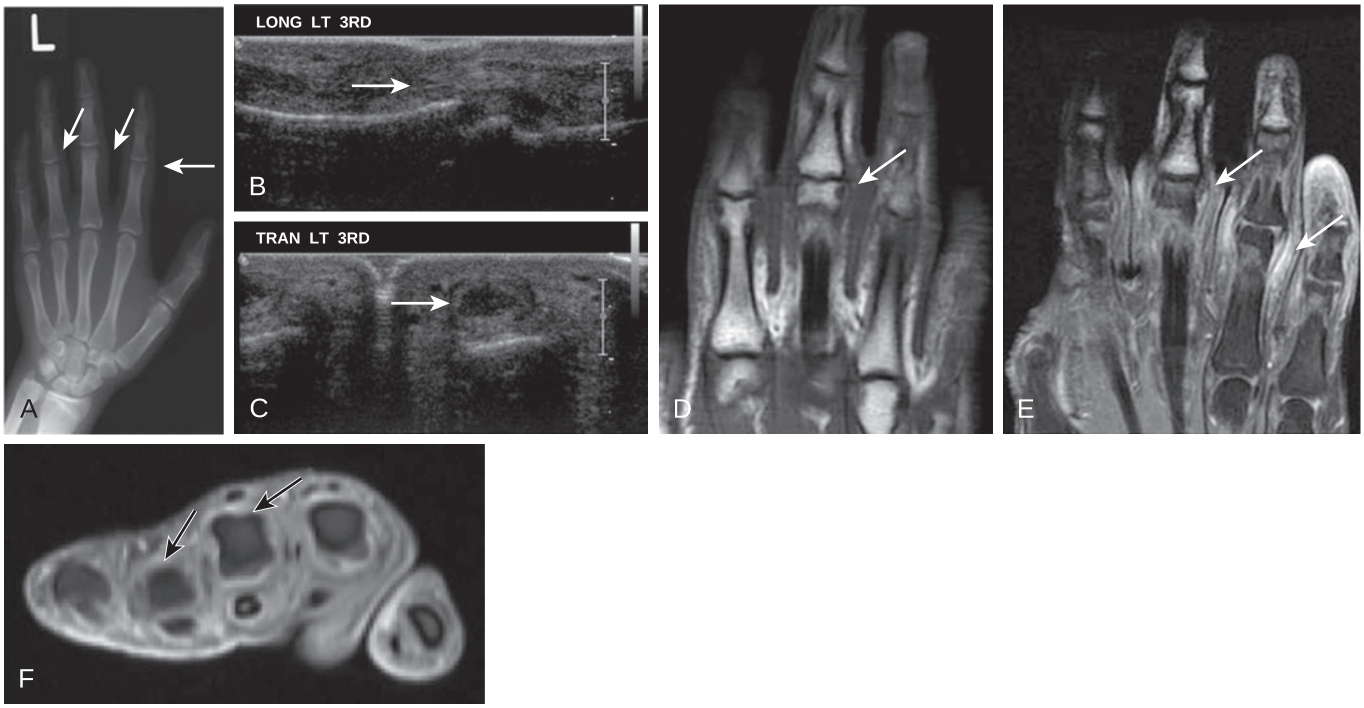

**Figure 136.16. Psoriatic arthritis in a 16-year-old boy.** (A) Frontal radiograph of the left hand shows soft tissue swelling at the proximal interphalangeal joint level at the right second, third, and fourth digits. Corresponding longitudinal (B) and transverse (C) ultrasound images demonstrate fusiform swelling surrounding the proximal interphalangeal joints of the right hand. Localized echogenic thickened tissue compatible with synovial and tenosynovial hypertrophy is seen *(arrows)* within and around the left third interphalangeal joint. Corresponding unenhanced coronal (D) and contrast-enhanced fat-saturated coronal (E) and axial T1-weighted MR images (F) of the left hand show prominent synovial hypertrophy and soft tissue enhancement *(arrows)* of the left third and fourth proximal interphalangeal joints.

narrowing, bony proliferation including periarticular and shaft periostitis, enthesitis, osteolysis including "pencil-in-cup" deformity (e-Fig. 136.17), acro-osteolysis, spur formation, and ankylosis.[36] The bone erosions tend to be larger and more asymmetric than those seen in persons with JIA, but the radiographic features may be indistinguishable from other forms of JIA. The characteristic adult changes seen at the distal interphalangeal joints are uncommon in children.

Sacroiliitis and vertebral involvement typically manifest later with progression of the disease. The sacroiliitis of juvenile psoriasis is usually asymmetric and resembles reactive arthritis. Syndesmophytes, paraspinal calcification, and atlantoaxial subluxation are rare in children.[36]

### Sonography

Sonography with Doppler evaluation is more sensitive than clinical examination to detect abnormalities in the hands and wrists, along with calcaneal enthesitis of adults with psoriatic arthritis. It is a reliable tool for assessing response to therapy with biological agents.

### Magnetic Resonance Imaging

In persons with psoriatic arthritis, MRI demonstrates erosive changes, joint space narrowing, ligament disruption, tenosynovitis, synovitis, and adjacent soft tissue inflammation (e-Fig. 136.18). Sausage digits are seen in patients with psoriatic arthritis and reactive arthritis. These swollen fingers or toes result from tenosynovitis, soft tissue edema, and synovial proliferation.[119] MRI may also be used to evaluate the responsiveness of therapy as noted by a significant reduction in gadolinium uptake after treatment with infliximab.[120]

### Computed Tomography

CT may be useful in assessing spine disease, but it has little role in the assessment of peripheral joints. Previous studies have shown that CT is as accurate as MRI for assessment of erosions in the sacroiliac joints but is not as affective for identifying synovial inflammation.[121] CT can be used to guide sacroiliac joint injection.[120]

# HEMOPHILIC ARTHRITIS

## Etiology, Pathophysiology, and Clinical Presentation

Hemophilia, an X-linked recessive disorder characterized by abnormality of the coagulation mechanism, affects 20 in every 100,000 males in North America.[122] It may be a result of a deficiency in factor VIII as in classic hemophilia (hemophilia A) or result from a deficiency of factor IX in persons with Christmas disease (hemophilia B).[122]

Hemarthrosis occurs in 75% to 90% of patients with hemophilia[123,124] and starts in the first and second decades of life. The most commonly affected joints include the knee, elbow, and ankle. Recurrent joint bleeding leads to secondary inflammation and hypertrophy of the synovium in response to blood products, and the cartilage degeneration and development of erosions and subchondral cysts[125] are similar to a primary inflammatory arthritis. Hemophilic pseudotumors, which are often intramuscular in location, may also develop in these patients.

## Imaging

### Radiography

The radiographic changes may be identical to those in children with JIA, but clinical findings and typical joint involvement help distinguish these entities.[126] Radiodense joint effusions and subchondral cystic changes are more common in persons with hemophilic arthropathy. In the knee, the classic radiographic findings include squaring of the femoral condyles (Fig. 136.19), multiple erosions, a widened intercondylar notch, and squaring of the patella.[25]

### Magnetic Resonance Imaging

MRI can detect acute and subclinical prior hemarthrosis.[123] In a cohort study evaluating ankles, elbows, and knees of 24 boys with severe hemophilia at a median age of 8.8 years (range, 6.2–11.5 years), hemosiderin deposition was detected in 26% of joints (ankles, 63%; elbows, 16%; and knees, 12%) with no history of clinically evident bleeding.[126]

Acute hemarthrosis and chronic joint effusion may be indistinguishable with a low signal on T1-weighted images and a high signal on T2-weighted images.[127] Subacute hemarthrosis usually has a high signal on both T1- and T2-weighted images, which is related to the presence of extracellular methemoglobin.[127] Hemosiderin deposition can occur in persons with JIA but is more frequently seen with other disorders, including hemophilic arthropathy, PVNS, synovial venous malformation, and posttraumatic synovitis.[128–130]

Gradient echo sequences are most sensitive in detecting synovial hemosiderin deposition, with signal loss occurring because of increased magnetic susceptibility (see Fig. 136.19). Synovitis that contains hemosiderin appears very low in signal on all MRI sequences, and this finding is accentuated on gradient echo sequences.[131,132] The synovial thickening often has areas of low signal on T1- and T2-weighted imaging related to fibrosis or hemosiderin deposition (Fig. 136.20).[127] Postcontrast images better delineate the extent of synovial thickening, which shows less enhancement compared with rheumatoid arthritis but adds little in the evaluation of hemophilic arthropathy.[133]

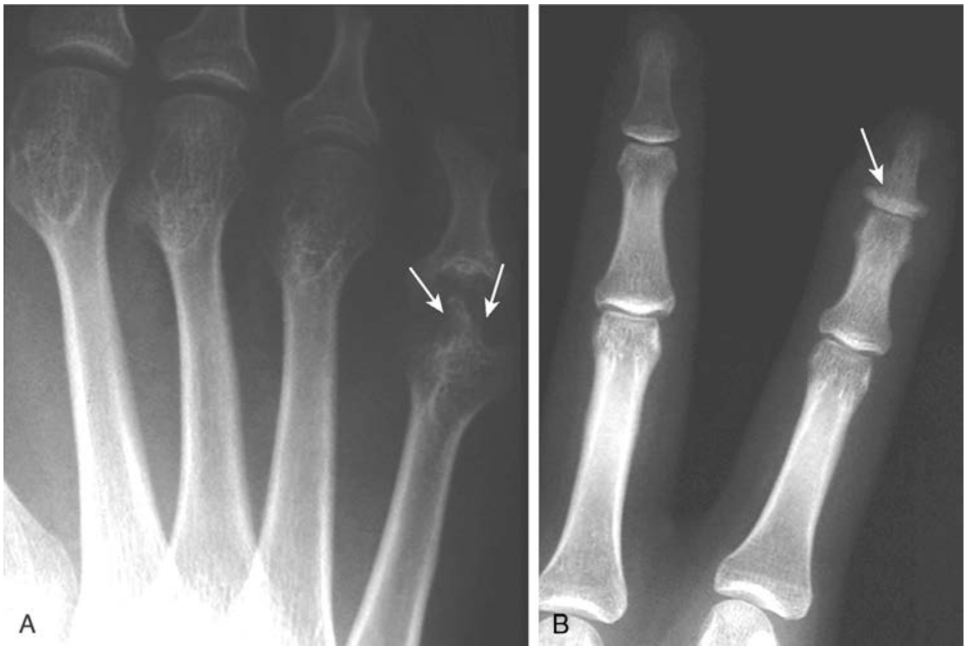
### Sonography

One potential advantage of ultrasound over MRI in the assessment of hemophilic joints is the lack of interference of susceptibility artifacts, which are seen commonly on gradient echo MRI sequences[134] that may obscure the synovium in the joint (e-Fig. 136.21). Recently, systematic protocols for ultrasound imaging of hemophilic joints have been developed,[135–137] which enable systematization of imaging protocols and future comparative clinical trials. Although a prior study found a close relationship between ultrasound and MRI in the assessment of the synovium and a good correlation between ultrasound and radiographs in evaluation of the progression of bone changes,[138] further investigation is required to determine the value of ultrasound for assessment of cartilage changes. Ultrasound has limitations in the assessment of deep cartilage abnormalities that are expected to occur in early stages of hemophilic arthropathy, given the centrifugal progression of cartilage degeneration.[139,140]

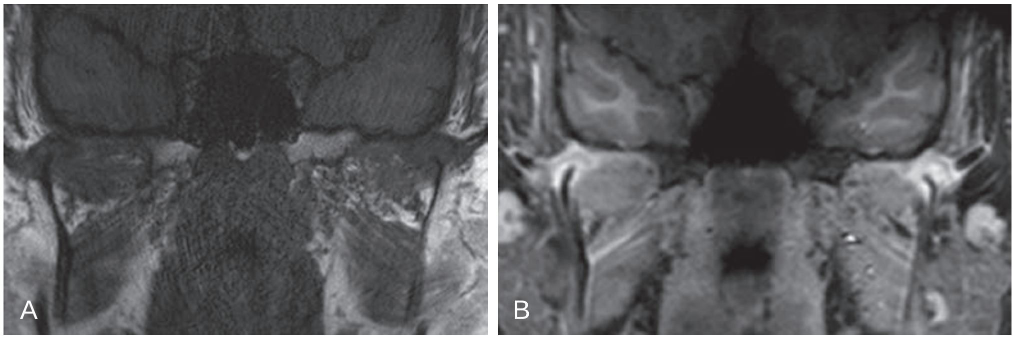
## Treatment and Follow-up

Treatments for hemarthrosis include coagulation factor replacement, cryotherapy, arthrocentesis of intraarticular blood, and arterial embolization (in cases of active bleeding).[141] Radioactive injections into joints (radionuclide synovectomy) initially were used in cases of JIA but have been shown to be effective in reducing bleeding and effusion in selected cases of hemophilic arthropathy. Radionuclide synovectomy has low complication rates, but concern remains that the radiation exposure in young children could lead to radiation necrosis or tumor induction.[142]

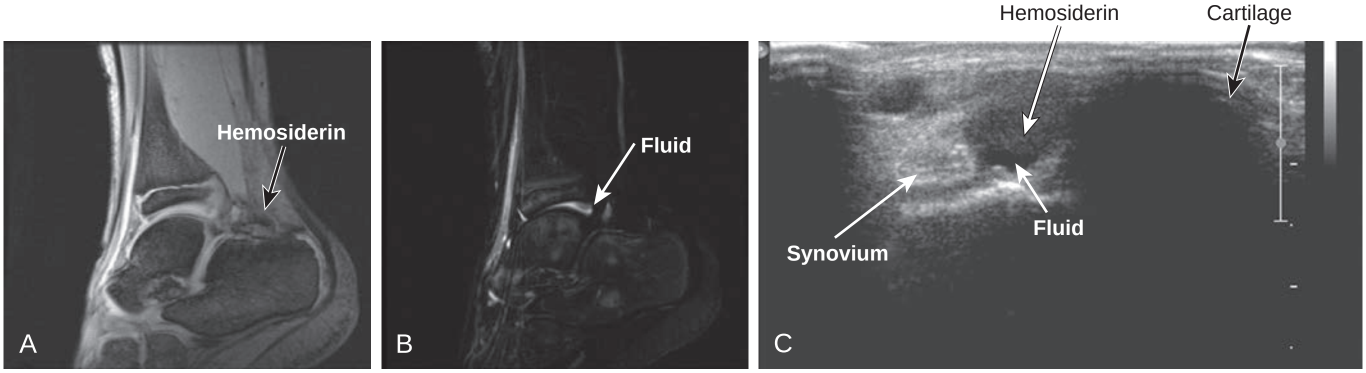
Prophylaxis is the first therapeutic option in noninhibitor hemophilic patients.[143] This therapy reduces the joint symptoms



**e-Figure 136.17. Advanced psoriatic arthritis.** Radiograph of the foot (A) shows extensive erosive changes at the distal end of the fifth metatarsal, resulting in a “pencil-in-cup” appearance at the metacarpal-phalangeal joint *(arrows)*. Radiograph of the hand (B) shows bony proliferation at the base of the distal phalanx *(arrow)*.



**e-Figure 136.18.** Newly diagnosed psoriatic arthritis in a 15-year-old boy with longstanding symptoms who presented with micrognathia on physical examination. Precontrast and postcontrast coronal T1-weighted MR images demonstrate severely dysplastic mandibular condyles with tapering of the mandibular condyles bilaterally (A). Intense pericondylar synovial enhancement is noted bilaterally after administration of intravenous gadolinium (B).



**e-Figure 136.21. Hemophilia.** Sagittal gradient echo (A) and T2-weighted (B) MR images of a hemophilic ankle show a mild amount of hemosiderin deposition and joint effusion. Only minimal “blooming” (susceptibility artifact) is noted within the posterior synovial recess of the ankle; however, the synovium is not promptly identified on the gradient echo images. A corresponding sonogram (C) allows discrimination between synovium (echogenic, “white”), hemosiderin (hypoechoic, “gray”), and fluid (anechoic, “black”).

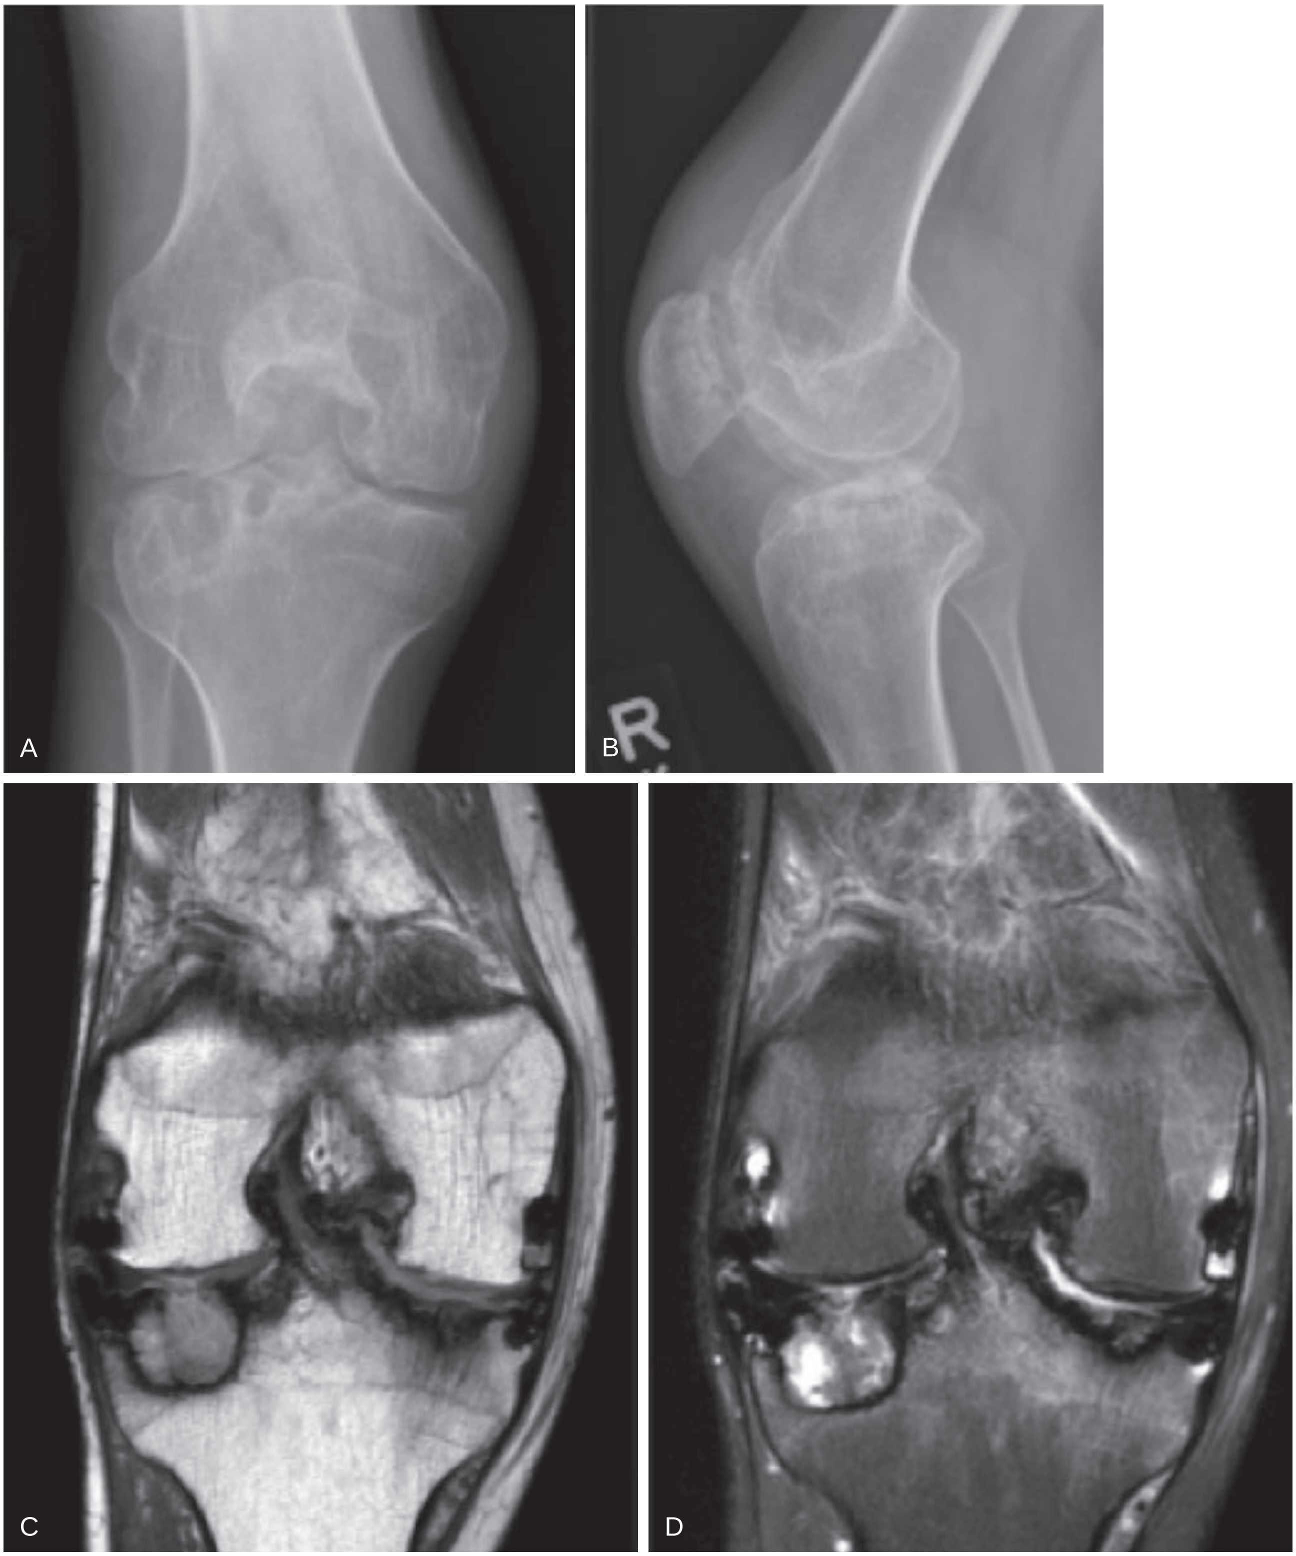


**Figure 136.19. Hemophilic arthritis in a 17-year-old boy.** Frontal (A) and lateral (B) radiographs demonstrate widening of the intercondylar notch, squaring of the femoral condyles, tricompartmental degenerative changes with extensive erosions, and subchondral cystic changes. A joint effusion is also seen on the lateral view (B). Coronal T1-weighted (C) and fat-suppressed T2-weighted (D) MR images show erosive changes of the distal femur and proximal tibia and a large subchondral cyst in the lateral tibial condyle. There is low signal intensity lining the joint on both sequences that "blooms" on the sagittal gradient echo sequence (E).

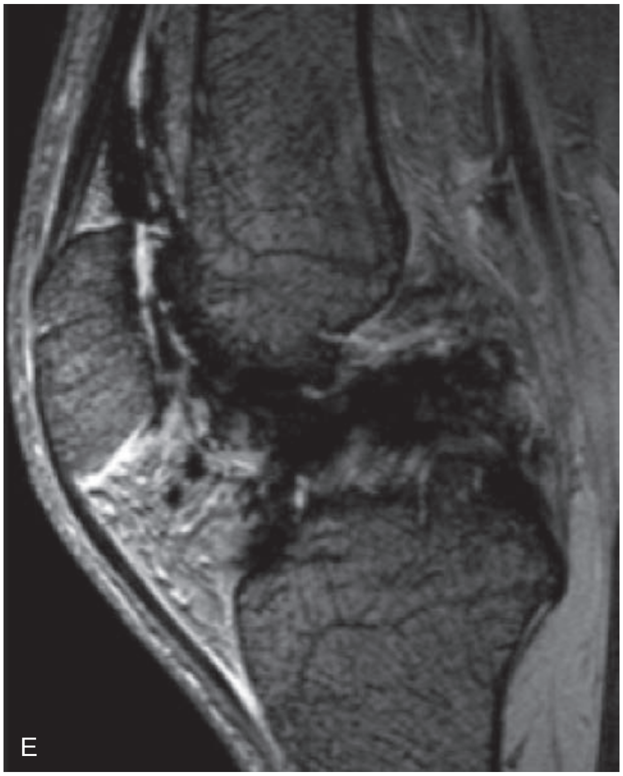

Figure 136.19, cont'd.

and avoids further degeneration of the joints and should be started before the development of cartilage lesions. MRI is used to detect early hemophilic disease and to help direct the appropriate therapy. The role of ultrasound for detecting early cartilage lesions is still under investigation.[144]

## TRANSIENT SYNOVITIS

### Etiology, Pathophysiology, and Clinical Presentation

Transient synovitis is the most common cause of childhood hip pain and can be mimicked by a number of more serious hip disorders, including Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, JIA, septic arthritis, and malignancy.[145] Transient synovitis is an acute, self-limiting disorder of unknown origin.[145]

### Imaging

Imaging is usually performed with conventional radiography or ultrasound. It has been proposed that radiography should not be used in the primary evaluation of most children with hip pain because the results are generally normal or show only subtle findings of joint effusion. Exceptions should be made in infants younger than 1 year of age and in children older than 8 years because of the lower incidence of transient synovitis in these age groups, with the higher risk of child abuse and septic arthritis in infancy, and the occurrence of slipped capital femoral epiphysis in the older age group.[145] Although sonography is a sensitive and noninvasive method of detecting hip joint effusion in persons with transient synovitis (Fig. 136.22),[146] it is unable to distinguish between different types of synovitis. Thus the combination of the patient's age, history of fever, and laboratory studies is useful to distinguish transient synovitis and septic arthritis.[147]

Nevertheless, the major contribution of ultrasound is to confirm the presence of joint effusion.[147] An ultrasound joint space thickness difference greater than 2.0 mm between asymptomatic and symptomatic hips has been considered valid for the presence of effusion.[148] Other modalities such as bone scans, CT, and MRI are not used initially in the evaluation of irritable hips because of their higher cost and limited benefit.[25]

### Treatment and Follow-up

Aspiration is required if infection is a consideration and is readily accomplished with ultrasound guidance.[149] Treatment for hip pain related to transient synovitis can include traction of the hip in 45 degrees of flexion, which may minimize intracapsular pressure. Treatment with ibuprofen may shorten the duration of symptoms.[150]

## MALIGNANCIES

### Etiology, Pathophysiology, and Clinical Presentation

Any of the childhood malignancies, especially the leukemias and neuroblastoma, can mimic rheumatic disease. These malignancies may (Fig. 136.23) or may not involve the joint itself. Leukemic arthritis typically presents with transient arthralgias and joint pain, often involving the knees, shoulders, and ankles.[31] Joint effusion is postulated to occur in relation to either synovial infiltration with leukemic cells and/or an autoimmune response related to the leukemia. However, differentiation of leukemic and septic arthritis is not possible by imaging, and aspiration may be necessary.

### Imaging

Although radiologic findings often are normal, they can include joint effusion, osteopenia, periostitis, lytic or sclerotic bone lesions, and metaphyseal radiolucent bands.[151,152] Diffuse abnormal signal intensity of bone marrow, which is low on T1-weighted sequences and high on T2-weighted sequences, can be seen on MRI (see Fig. 136.23).

## PIGMENTED VILLONODULAR SYNOVITIS (TENOSYNOVIAL GIANT CELL TUMORS)

### Etiology, Pathophysiology, and Clinical Presentation

PVNS is a benign proliferative disorder of uncertain etiology that affects synovial lined joints, bursae, and tendon sheaths. PVNS mostly occurs in the third and fourth decades of life[153] but can affect persons of any age.[154] The latest World Health Organization Classification of Tumors of Bone and Soft Tissues no longer uses the term PVNS but refers to these lesions as tenosynovial giant cell tumors with subclassifications based on whether the lesion is focal or diffuse. By convention, we continue to use PVNS in this chapter.

Gross pathologic features include a thickened synovium with a variable combination of villous and nodular proliferation. PVNS can either be focal or diffuse (i.e., involving nearly the entire synovial lining). On microscopy, PVNS is characterized by the presence of hemosiderin-laden, multinucleated giant cells, along with lipid-laden macrophages, fibroblasts, and other large mononuclear cells. Hemosiderin is found within the surrounding tissues. The ubiquitous presence of hemosiderin lends the tissue a characteristic pigmented appearance. The lesions tend to be hypervascular and demonstrate synovial hyperplasia.[154] PVNS typically invades local tissues and has the potential for extensive local destruction, even though it rarely metastasizes.[155]

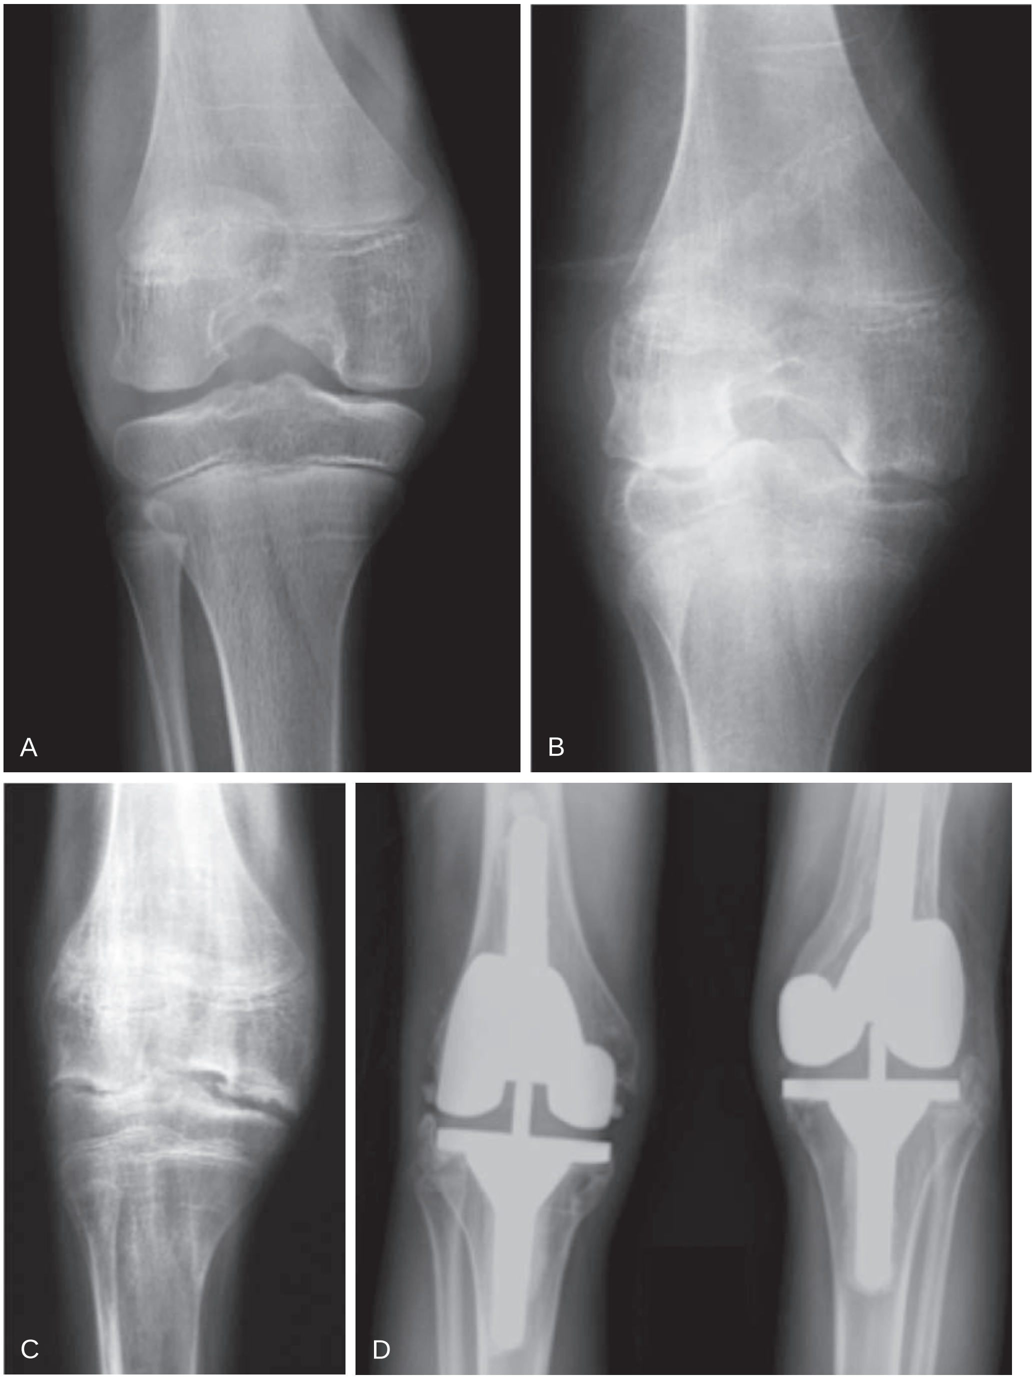

**Figure 136.20. Hemophilia.** Frontal radiograph of the right knee of a boy with hemophilia at 10 years of age (A) shows widening of the intercondylar notch and mild overgrowth and squaring of the femoral condyles. Subsequent radiographs at 12 years (B) and 14 years (C) of age show progressive degenerative changes with joint space narrowing and marked condylar irregularity. Similar findings were present in the left knee, and he subsequently underwent bilateral knee replacements (D). Frontal radiograph of the right shoulder in the same child at 16 years of age (E) shows widening of and soft tissue density within the acromiohumeral interval, suggestive of a joint effusion. Axial T2-weighted (F) and gradient echo (GRE) (G) MR images of the same shoulder show a large joint effusion and synovitis with low signal intensity lining the joint that “blooms” on the GRE sequence *(solid arrows)*. Also note the fluid-fluid level (*dashed arrow* in G) and intraarticular chondral body (*arrowhead* in F). (H) Coronal proton-density fat-saturated MR image shows loss of articular cartilage of the humeral head with subchondral cyst formation *(solid arrow)* and low signal intensity thickened synovium in the axillary recess *(dashed arrow)*. Arthroscopy was performed due to pain and limited mobility. Arthroscopic images (I) show hemosiderin stained synovium *(left image)* and areas of extensive synovial proliferation *(right image)*. (J) Coronal proton-density fat-saturated MR image at 18 years of age shows end-stage degenerative joint disease with full-thickness loss of articular cartilage and subchondral cystic changes in the humeral had and glenoid.

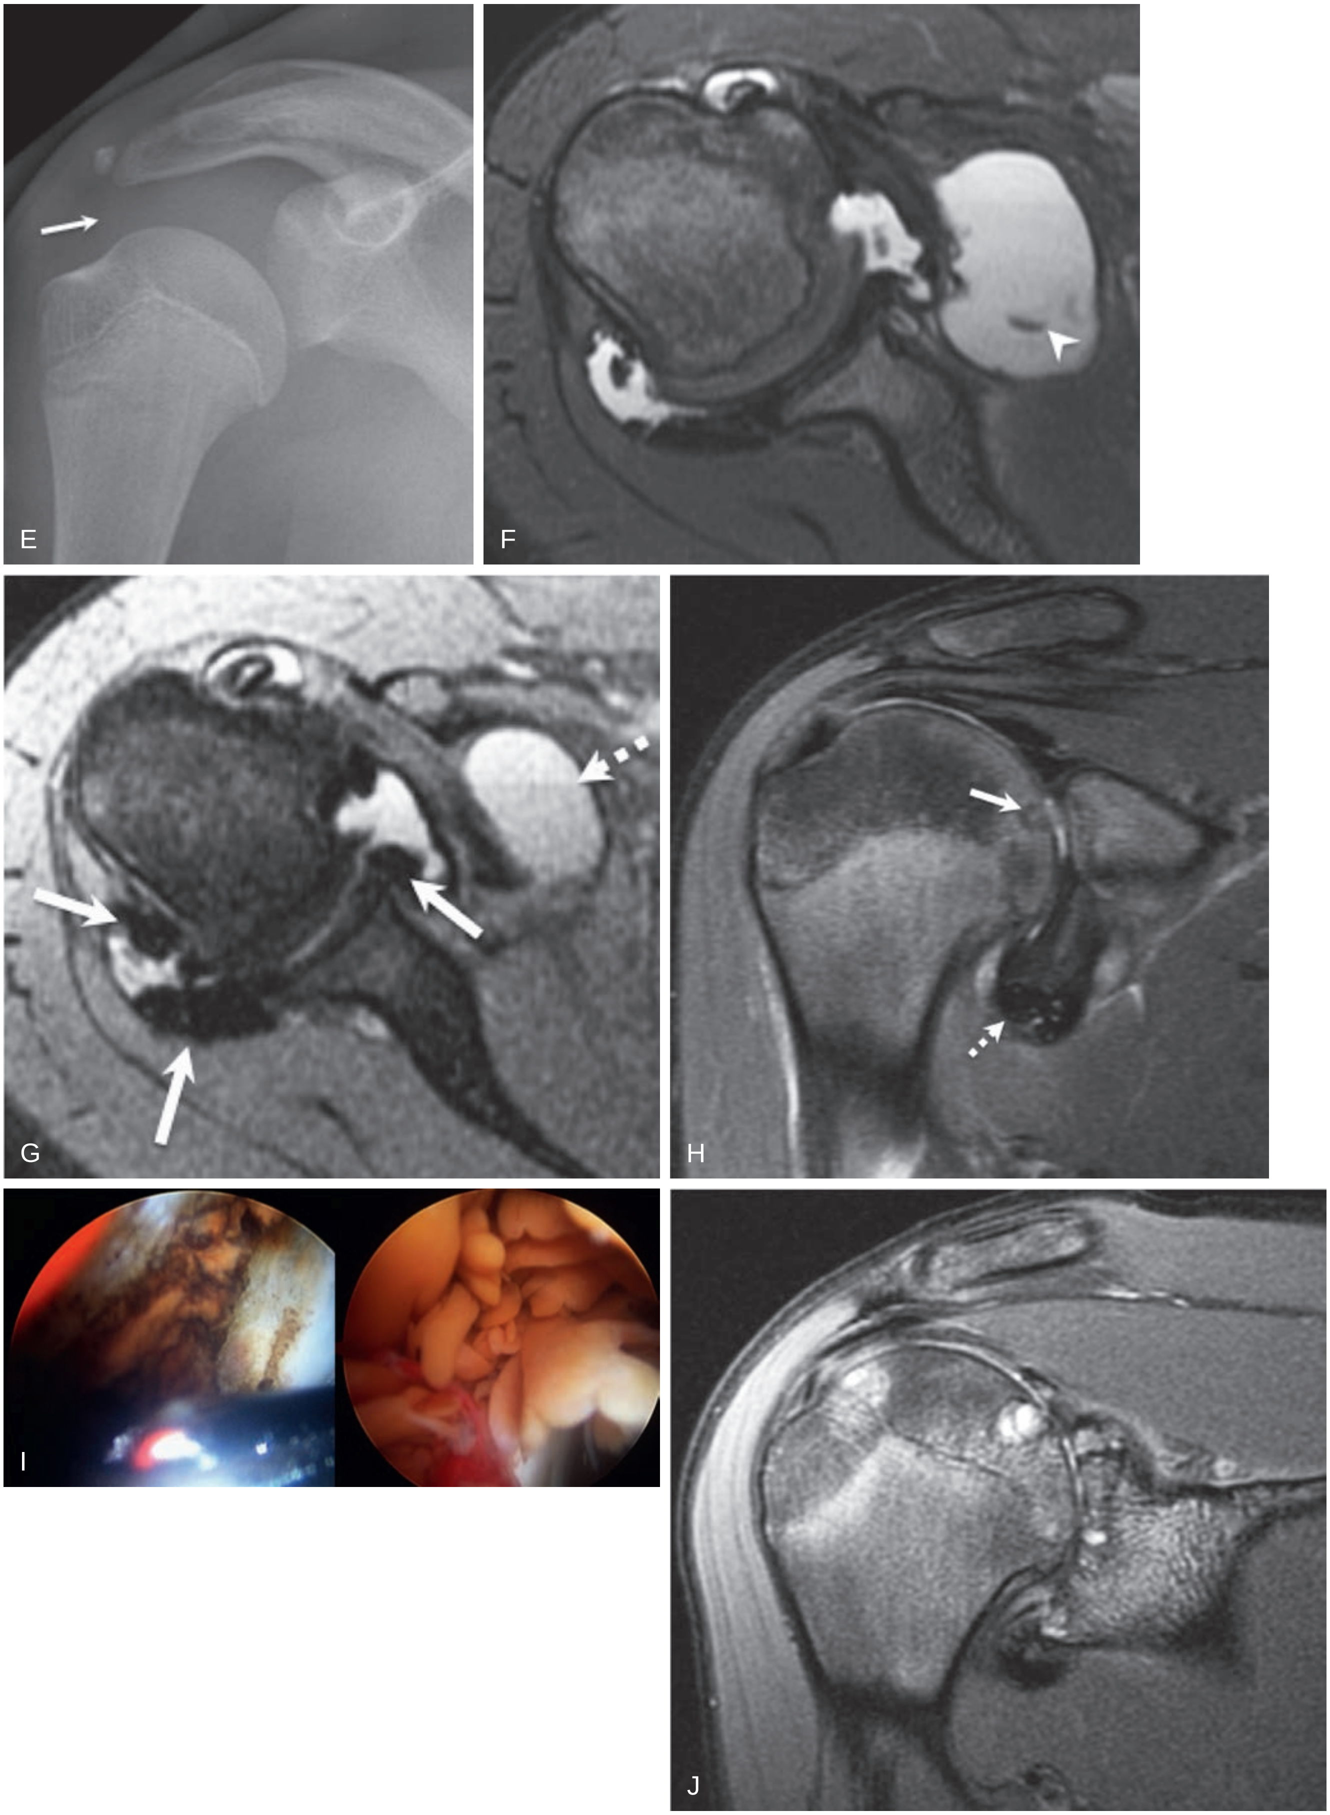

Figure 136.20, cont'd.

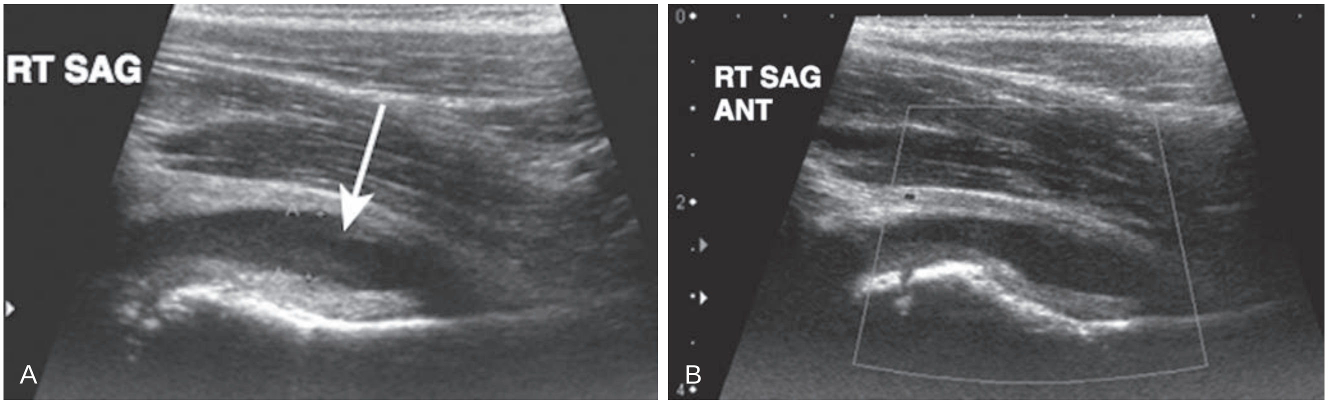

**Figure 136.22. Transient synovitis in a 7-year-old girl.** (A) Longitudinal sonogram of the right hip shows a joint effusion *(arrow)* and synovial hypertrophy. (B) Longitudinal color Doppler sonogram shows no significant synovial hyperemia. *ANT,* Anterior; *RT,* right; *SAG,* sagittal.

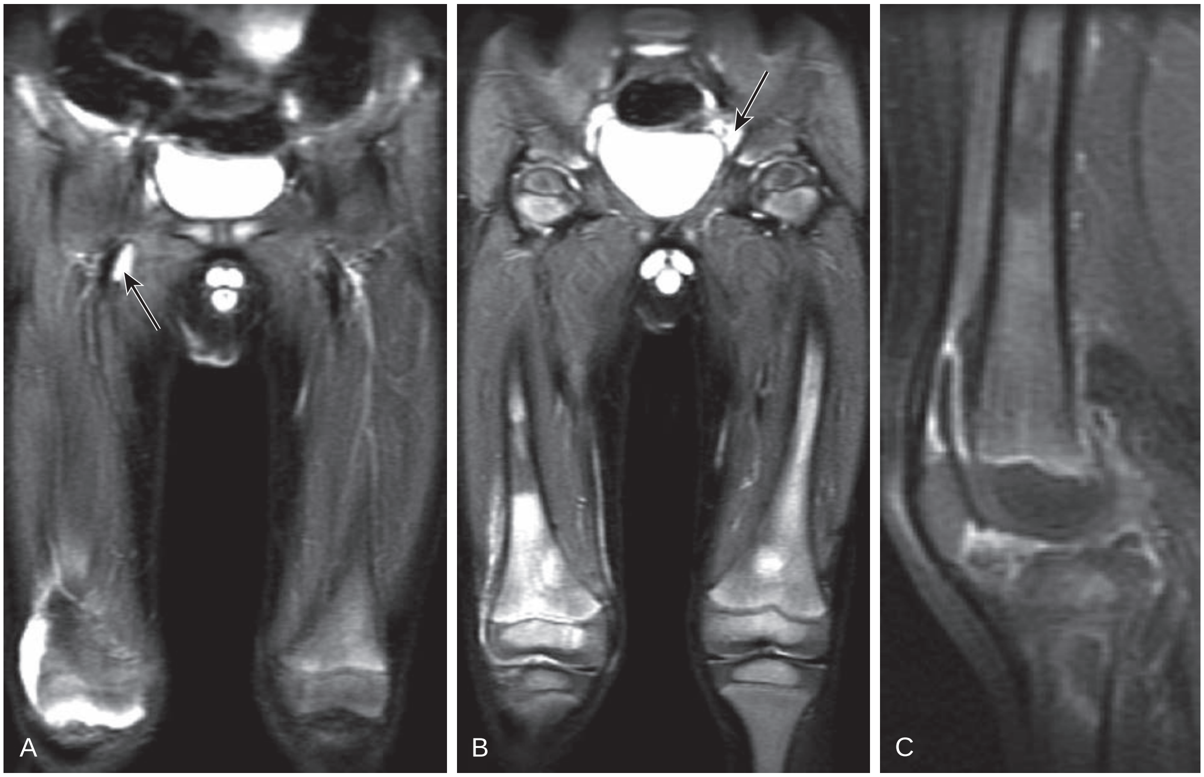

**Figure 136.23. Leukemia.** Coronal inversion-recovery (A and B) and contrast-enhanced sagittal T1-weighted fat-saturated (C) MR images of the lower extremities show a large right joint effusion (A) with synovial enhancement representing synovitis (C). Diffuse heterogeneous signal abnormality is seen within the bone marrow of the femora and proximal tibias, along with generalized adenopathy *(arrows)* (A and B). This patient was diagnosed with acute lymphocytic leukemia.

## Imaging

Radiographs show soft tissue swelling without calcification; in advanced stages, findings are of degenerative arthritis, including bony erosions and subchondral cysts. The invasion of the subchondral bone, with resultant cyst formation, is a characteristic finding.[156] When PVNS involves relatively constricted joint spaces such as the hip, erosions related to intraarticular mass effect may be seen earlier compared with more capacious joints such as the knee.

On MRI, diffuse or nodular synovial thickening is noted, with low to intermediate T1 signal. Thick frondlike synovial excrescences often are identified extending into a joint effusion. Hemosiderin deposition results in low signal on T1- and T2-weighted sequences, particularly at the periphery of the thickened synovium, which shows “blooming” artifact on gradient echo sequences. On postcontrast imaging, there is typically synovial enhancement (Fig. 136.24).[20,157] Focal PVNS usually is a well-defined solitary masslike lesion that superficially may not appear to arise from synovium (Fig. 136.25).

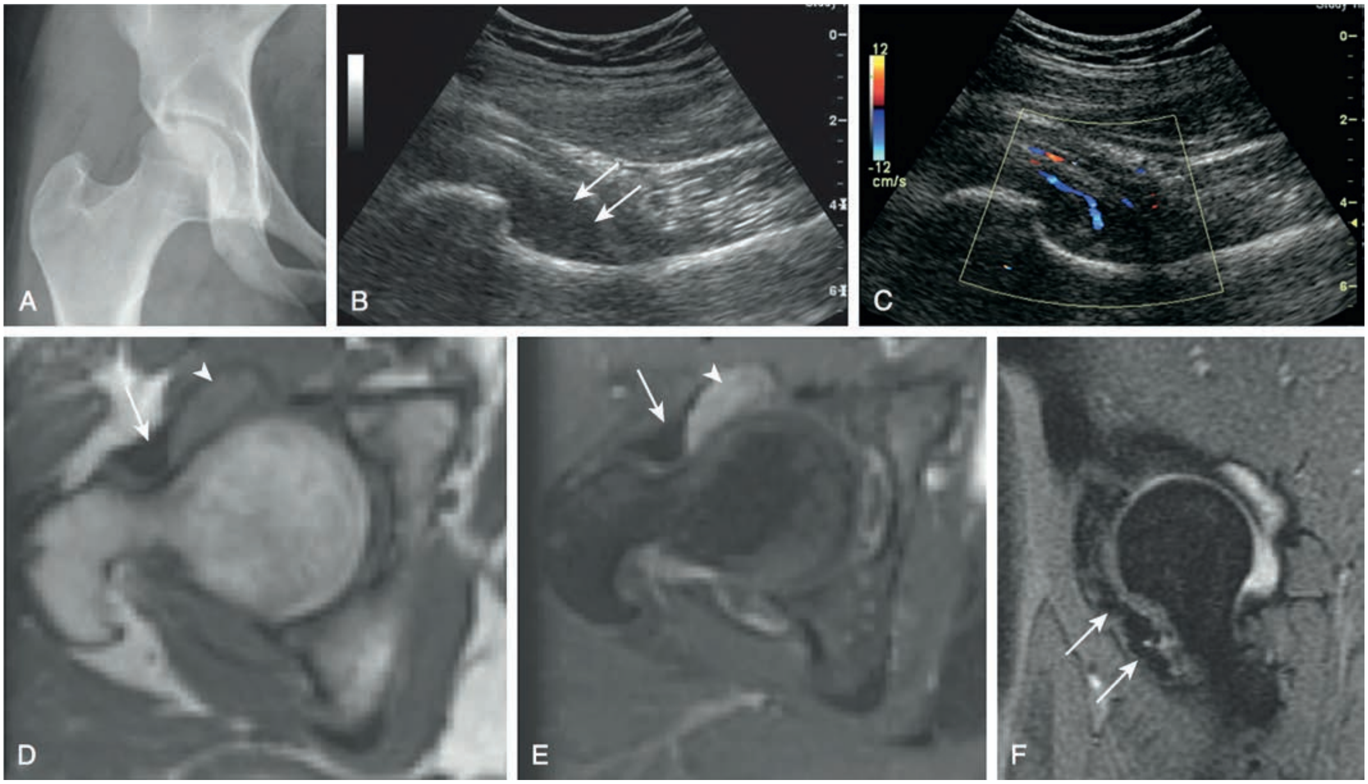

**Figure 136.24. Pigmented villonodular synovitis (PVNS).** A 17-year-old girl with a history of right hip pain for 3 years and a biopsy-proven diagnosis of PVNS. Frontal radiograph of the pelvis (A) shows a slight increase in the right femoroacetabular joint space medially. A subsequent longitudinal ultrasound of the right hip (B and C) demonstrates an area of synovial thickening within the anteroinferior aspect of the right hip with fine internal solid echogenicity (B, *arrows*) and internal vascularity on color Doppler (C). A small right hip effusion was confirmed on the corresponding MR examination. Unenhanced (D) and contrast-enhanced fat-saturated (E) axial T1-weighted MR images of the right hip reveal moderate thickening and enhancement of the synovium *(arrowheads)*. A sagittal multiplanar gradient-recalled acquisition (F) MR image shows synovial and capsular thickening and blooming artifact consistent with hemosiderin deposition *(arrows)*. Also note the mild erosive changes of the anterior femoral neck.

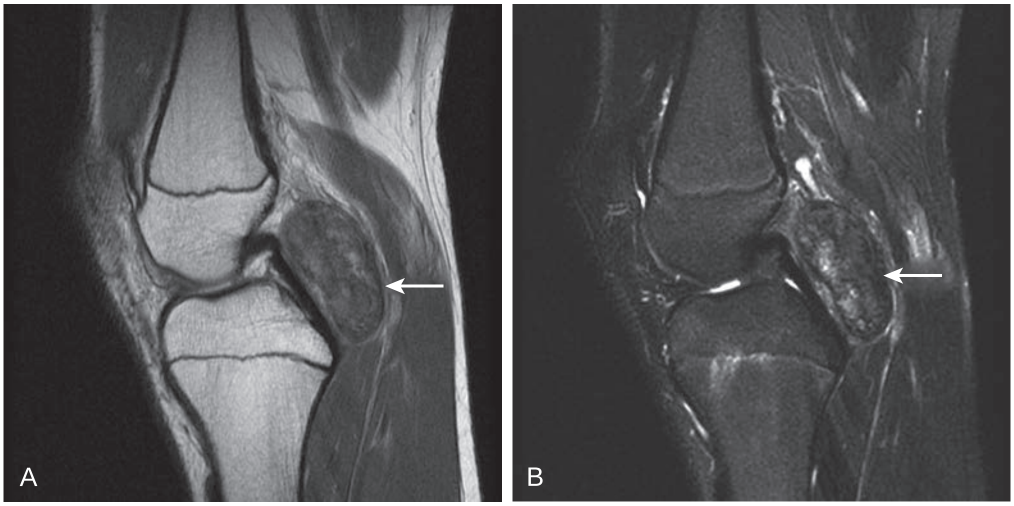

**Figure 136.25. Focal pigmented villonodular synovitis (PVNS) in a 15-year-old girl.** Sagittal proton density (A) and T2-weighted fat-saturated sagittal (B) MR images of the knee demonstrate a well-circumscribed mass in the posterior joint space extending into the popliteal region with heterogeneous signal intensity *(arrow)*.

## Treatment and Follow-up

Definitive treatment requires synovectomy, but there is a high (up to 50%) incidence of local recurrence.[157]

# SYNOVIAL CHONDROMATOSIS/ OSTEOCHONDROMATOSIS

## Etiology, Pathophysiology, and Clinical Presentation

Synovial chondromatosis/osteochondromatosis is a benign condition of unknown etiology characterized by synovial membrane proliferation and metaplasia. This can occur within joints, tendon sheaths, or bursa. It is rare in children[158,159] and mostly occurs in the third to fifth decades of life.[160] The synovium undergoes neoplastic nodular proliferation, and fragments may break off into the joint. There, nourished by synovial fluid, the fragments may grow, remain cartilaginous, or ossify. The fragments may be found free within the joint cavity, or they may be embedded within the proliferating synovium, which may extend into the surrounding soft tissues.[160] The natural history of synovial osteochondromatosis is gradual progression of disease, joint deterioration, and secondary osteoarthritis.

## Imaging

Imaging findings depend on the degree of mineralization of the chondroosseous bodies. Ossification (synovial osteochondromatosis) is seen in 70% of patients.[20] Unlike with adults, children rarely present with radiographically detectable ossified loose bodies. Therefore the initial diagnosis often is suggested from MRI, where these particles may mimic pannus, rice bodies, or PVNS. On MRI, a noncalcified lesion is seen as an isointense T1-weighted and high T2-weighted signal mass. If ossified lesions are large enough, focal areas of yellow marrow signal may be detectable (Fig. 136.26).[20]

When intraarticular particles are relatively uniform in size, the term *primary synovial osteochondromatosis* may be used. When the intraarticular particles are nonuniform and are heterogeneous in size and shape, secondary synovial osteochondromatosis should be considered. Secondary causes include trauma, infection, and nonpyogenic inflammatory arthritis.

## Treatment and Follow-up

Synovial osteochondromatosis is usually treated by surgical resection of the proliferative synovium and removal of the loose bodies, but the local recurrence rate is up to 23%.[160]

# LIPOMA ARBORESCENS

## Etiology, Pathophysiology, and Clinical Presentation

Lipoma arborescens is a rare intraarticular lesion of unknown etiology characterized by replacement of synovial cells by fat cells, producing villous transformation of the synovium. It is not a true neoplasm and most commonly affects the suprapatellar bursa of the knee in patients between the fifth and seventh decades of life.[161,162] Patients present with painless joint swelling and effusions.[161]

Lipoma arborescens associated with degenerative joint disease and chronic inflammatory arthritis (secondary lipoma arborescens) is more common in the adult population, whereas primary lipoma arborescens (without a primary etiology) is seen predominantly in a younger population.[163]

## Imaging

The characteristic MRI appearance is frondlike synovial proliferation with fat signal intensity on all pulse sequences (Fig. 136.27), but it is best seen on T1-weighted and fat-suppressed T2-weighted sequences.[161,162]

## Treatment and Follow-up

Lipoma arborescens is typically treated with synovectomy,[164] but yttrium-90 radiosynovectomy[165] treatments have been described.

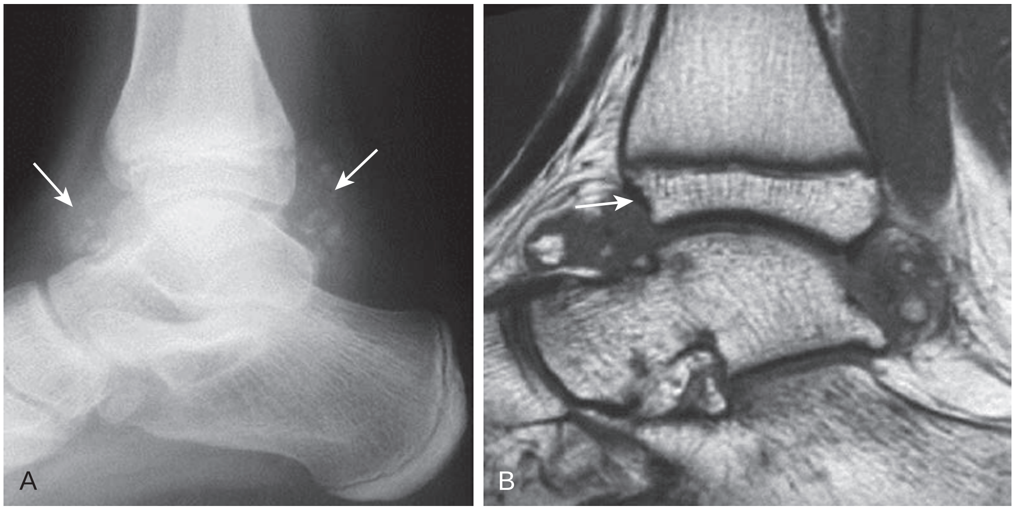

**Figure 136.26. Synovial osteochondromatosis.** An adolescent had a history of pain in the right ankle for years. Lateral radiograph (A) shows soft tissue swelling with multifocal calcific concretions within the anterior and posterior synovial recesses of the ankle *(arrows)*. The corresponding sagittal T1-weighted MR image (B) of this ankle demonstrates large nodular synovial proliferation within the anterior and posterior synovial recesses with ossified fragments, which contain yellow marrow, seen within the synovial tissue. There are associated incipient erosive changes at the anterior distal tibial epiphysis *(arrow)*.

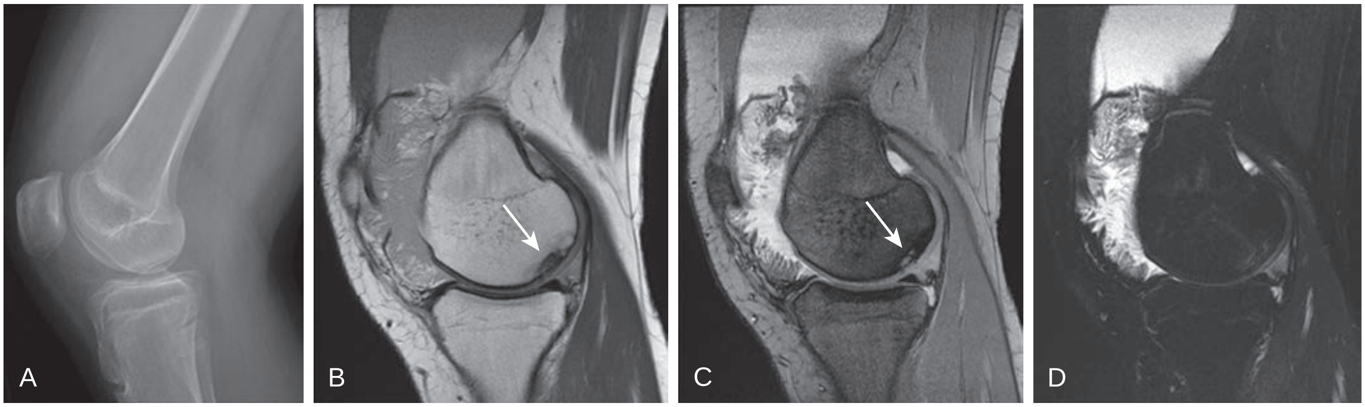

**Figure 136.27. Psoriatic arthritis, lipoma arborescens, and osteochondritis dissecans in a 15-year-old girl.** Lateral radiograph of the right knee (A) shows a large joint effusion and an osteochondral defect in the medial right femoral condyle. Corresponding sagittal proton-density (B), multiplanar gradient-recalled acquisition (C), and T2-weighted fat-saturated fast spin echo (D) MR images demonstrate, in addition to the osteochondral defect *(arrows)*, a large effusion and frondlike synovial proliferation, which follows signal intensity of fat on all sequences, indicating lipoma arborescens.

## VASCULAR MALFORMATIONS

### Etiology, Pathophysiology, and Clinical Presentation

Vascular malformations are benign lesions that usually are diagnosed in childhood or young adulthood. The Mulliken and Glowacki classification for these lesions separates these lesions as high flow (arteriovenous malformations and fistulas) and low flow (venous, lymphatic, capillary) lesions and reserves the term *hemangioma* for vascular tumors that present during infancy.[166] The most frequent vascular malformation that may present with arthropathic changes is a venous malformation with synovial involvement,[167] although these lesions often are erroneously referred to as "synovial hemangiomas."[168] Clinically, they mimic chronic arthritis because of recurrent synovial bleeding, and not uncommonly the diagnosis is delayed. They may have associated cutaneous lesions, recurrent hemarthrosis, and arthropathy. The knee is the most commonly affected joint, but other joints such as the elbow, wrist, and ankle also can be affected, along with tendon sheaths. These lesions often have both a synovial component and a large extrasynovial component.[167]

### Imaging

Radiography can demonstrate phleboliths, a soft tissue mass, joint effusion, osteoporosis, advanced epiphyseal maturation, leg length discrepancy, arthropathy simulating hemophilia, and periosteal reaction.[167]

The MRI appearance varies from slightly lobulated, nonencapsulated masses to infiltrating serpentine vascular masses to a combination of these morphologies. They are usually isointense to hypointense to muscle on T1-weighted images and hyperintense on T2-weighted images, with variable contrast enhancement.[167,168] Venous components tend to enhance but may demonstrate areas of nonenhancment and hematocrit levels within their tubular channels related to sluggish flow and microthrombi. Phleboliths are characteristic of venous malformations and typically present with low signal intensity on all sequences. Intraarticular fluid-fluid levels, synovial blooming artifact on gradient echo images because of the presence of hemosiderin, or bone erosions due to a reactive arthritis as a result of the presence of intraarticular blood may be present (Fig. 136.28).

### Treatment and Follow-up

Intraarticular vascular malformations, particularly venous malformations, have a propensity to bleed. When these lesions bleed, the blood products cause an inflammatory response, and the presentation in a child may be that of inflammatory arthritis. Therefore treatment may be necessary to decrease bleeding incidence, including malformation resection or sclerotherapy, and synovectomy.

## JUVENILE DERMATOMYOSITIS

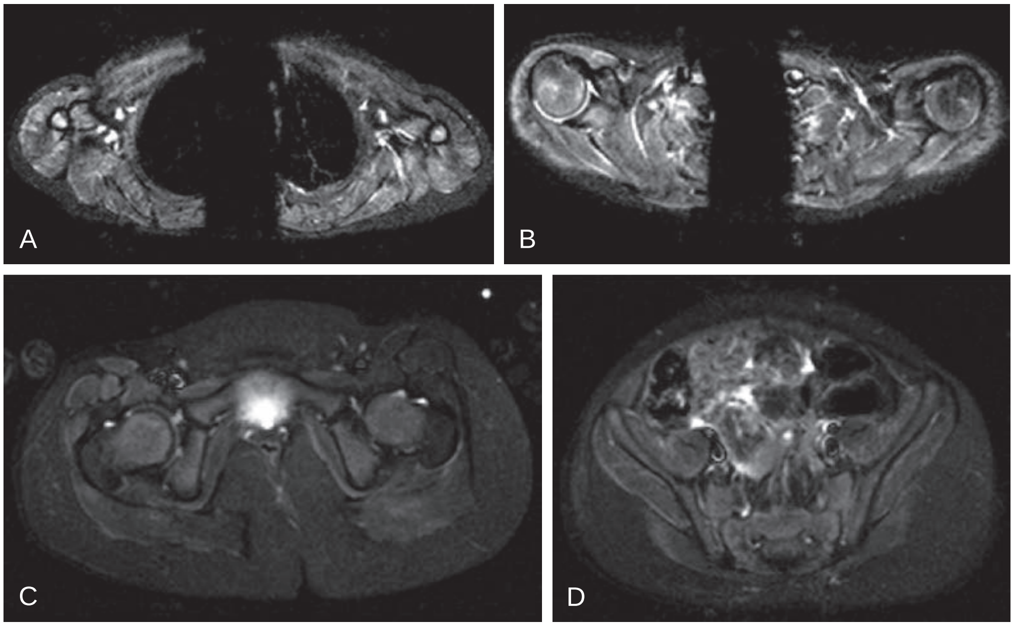
### Etiology, Pathophysiology, and Clinical Presentation

Juvenile dermatomyositis (JDM) is an autoimmune inflammatory myopathy characterized by diffuse nonsuppurative inflammation of muscle fibers and skin.[169] The inflammatory infiltrates are predominantly perivascular, in the interfascicular septa, or around the fascicles.[170] The incidence of JDM in the United States is 3.2 per million children per year.[171] The ratio of girls to boys is 2.3 : 1.[172] JDM most commonly presents between the ages of 5 and 14 years.[173] Clinical findings include severe proximal muscle weakness, fatigue, heliotrope rash (a pink or purple rash on the face and knuckles), and underlying vasculitic pathology.[173,174]

### Imaging

#### Radiography

In the acute stage, radiologic changes are minimal. However, incipient soft tissue swelling and subcutaneous edema represented by blurring of fat planes can be noted in the proximal appendicular skeleton in some cases. The muscles of the scapular and pelvic girdles are most frequently affected (e-Fig. 136.29 and Fig. 136.30).[175,176] In chronic disease, radiographs demonstrate soft tissue loss and muscle atrophy. Marked osteoporosis of the long bones and vertebral bodies also may be present. The most characteristic finding of chronic disease, however, is the deposition of calcium in the soft tissues (Fig. 136.31), which is identified in 25% to 50% of cases.[177] The calcium deposits may present as subcutaneous plaques, nodules, periarticular calcific foci, and large clumps or sheets of calcium within muscle or subcutaneous tissue.[178]



**e-Figure 136.29. Juvenile dermatomyositis in a 3-year-old girl.** Axial inversion-recovery MR images of the shoulder girdle (A and B) demonstrate diffuse bilateral increased signal intensity involving the deltoid, supraspinatus, infraspinatus, and triceps muscles bilaterally. In the pelvic girdle (C and D), faint asymmetric increased signal intensity is noted within the obturator externus, pectineus, rectus femoris, sartorius, vastus lateralis, and gluteus muscles, predominately on the right side.

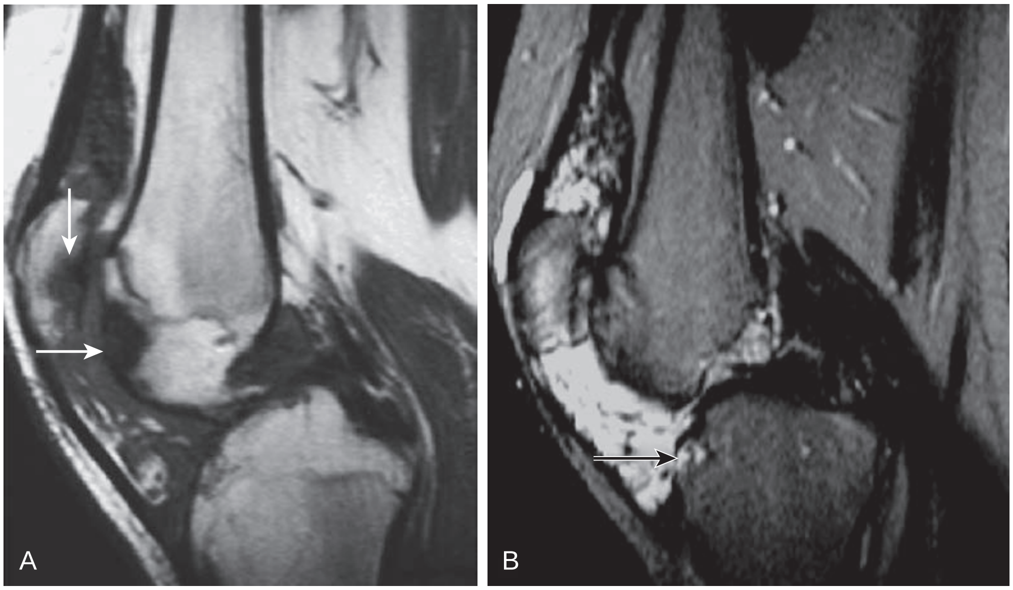


**Figure 136.28. Venous malformation.** An adolescent presented with chronic pain in the left knee. Sagittal T1-weighted (A) and T2-weighted fat-saturated (B) MR images show an extensive soft tissue mass with predominant low signal intensity on a T1-weighted image (A) and high signal intensity on a T2-weighted image (B) involving the suprapatellar bursa and Hoffa's fat pad. Focal areas of low signal intensity suggest the presence of hemosiderin deposition from previous hemarthrosis. There is diffuse articular cartilage loss with subchondral abnormalities *(arrows)* consistent with subchondral sclerosis and cystic changes as a result of inflammatory arthropathy generated by the presence of intraarticular blood products.

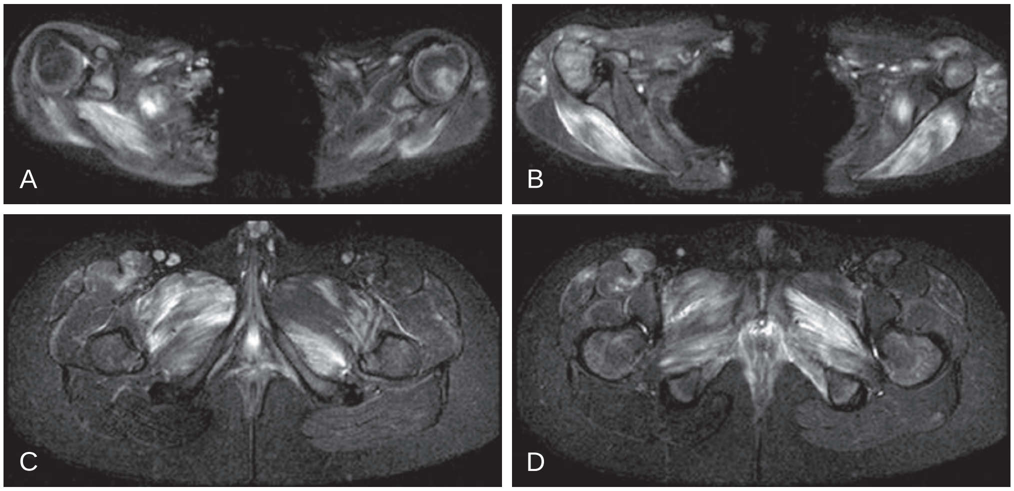

**Figure 136.30. Juvenile dermatomyositis in an 11-year-old boy.** Axial inversion-recovery MR images of the upper extremities (A and B) show patchy asymmetric involvement of bilateral deltoid muscles, pectoralis minor muscle, and supraspinatus, infraspinatus, and subscapularis muscles. Within the lower extremities (C and D), patchy asymmetric signal abnormality is present in the adductor compartment muscles, the internal obturator muscles with less signal abnormality within the quadriceps, tensor fascia lata, and left gluteus maximus muscles.

The arthritis associated with JDM is usually transient and nondeforming in nature.[178]

## Ultrasonography

Ultrasound scanning of the involved musculature shows diffusely increased echogenicity of the soft tissues and acoustic shadowing within the musculature in regions of calcium deposits. Histopathologically, muscle lipomatosis significantly correlates to muscle echogenicity.[170] Other sonographic findings include atrophy and decreased muscular bulk, soft tissue fasciculation, tenosynovitis, and soft tissue nodularities.[179]

## Magnetic Resonance Imaging

Ultrasound and MRI have a similar capacity to demonstrate the features of inflammatory muscle disease, but MRI is more sensitive for the detection of the edema and inflammation in the acute phase of the disease. Both MRI and ultrasound allow guided biopsy and aspiration of muscle abnormalities.[180–183] MRI reveals increased water content (edema) as increased signal intensity on T2-weighted and short-tau inversion recovery MR images (see e-Fig. 136.29 and Fig. 136.30) within infarcted muscles as a result of vasculitis.[184] T2 relaxation time can be used as a quantitative measure of muscle inflammation and correlates well with other

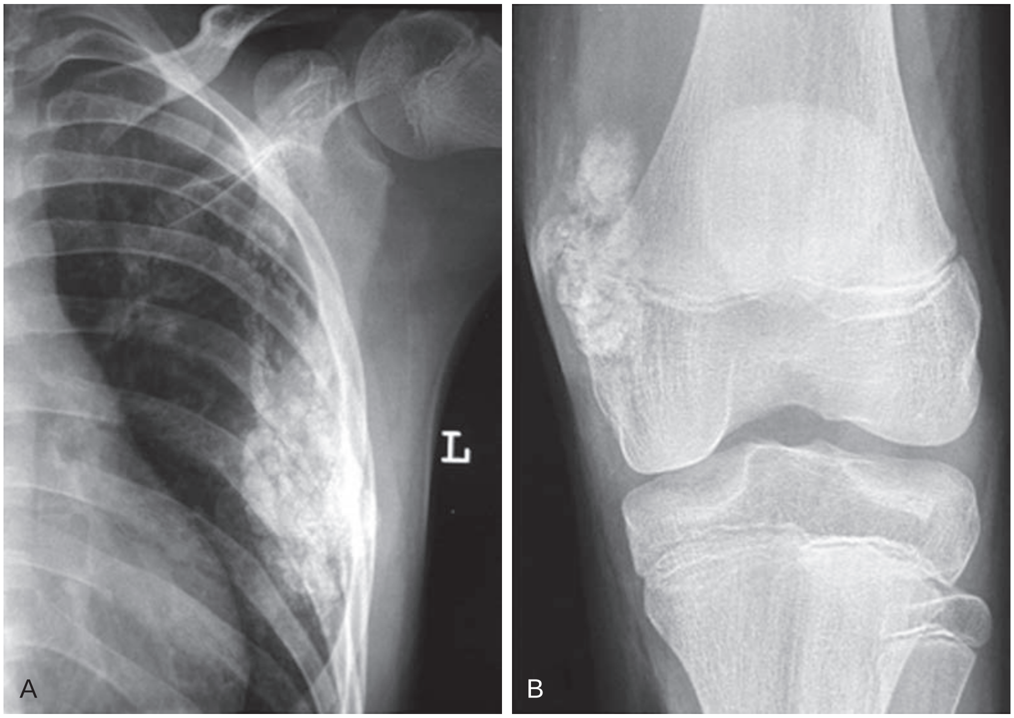

**Figure 136.31. Juvenile dermatomyositis and severe heterotopic calcifications in a 15-year-old boy.** Frontal radiographs of the left lateral chest wall (A) and left knee (B) show extensive soft tissue calcifications.

measures of disease activity.[185] Because physical exercise can induce changes that mimic inflammation of muscle, children with JDM should be at rest for at least 30 minutes before MRI to assess disease activity.[186] At least one study has shown that abnormal subcutaneous fat signal is an insensitive but specific marker of those children with JDM who will progress to a more aggressive chronic disease course.[187]

In chronic disease, focal areas of low signal intensity usually are seen on all MRI sequences, which represent calcific and fibrotic foci. Focal areas of increased signal intensity on T1-weighted images representing fatty replacement of muscles and tenosynovitis-related changes also may be identified.[184]

### Computed Tomography

Although CT does not detect inflammatory changes in muscle tissue, it is the modality of choice for identifying soft tissue calcifications in soft tissues associated with JDM.[188] It also allows quantification of muscle atrophy and fatty replacement in deep muscles.

### Scintigraphy

Whole-body thallium-201 chloride and technetium-99m-methylene diphosphonate ($^{99m}$technetium-MDP) muscle scintigraphy is a potentially useful tool to investigate occult muscle groups affected by dermatomyositis; however, further investigation in the pediatric population is required.[189,190] Furthermore, bone scans with $^{99m}$technetium-MDP can function as auxiliary tools to evaluate calcinosis in patients with JDM.[188–190]

## Treatment and Follow-up

Since the 1970s, standard treatment for JDM has been high-dose daily oral corticosteroids, which is continued until clinical and laboratory improvement are evident and then slowly reduced over at least a 2-year period.[191] Methotrexate is an important ancillary treatment. Early studies suggested that methotrexate improves strength and reduces other signs of disease activity in steroid-resistant patients[192] with acceptable adverse effects.[193,194] Other treatments, including cyclosporine, hydroxychloroquine, tacrolimus, azathioprine, mycophenolate mofetil, and cyclophosphamide for severe disease, have shown some benefit in cases of refractory disease.[195]

Biologic agents, which are used widely in persons with other rheumatic diseases, are being developed for the treatment of childhood myositis. Studies[196,197] of rituximab in persons with JDM suggest a favorable response; however, biologic agents currently are reserved for patients with recalcitrant disease.[198]

Physical disability from muscle weakness or contractures represents a significant problem. Physiotherapy plays an important role in the rehabilitation of patients with JDM.[199] Studies using MRI T2-weighted relaxation time suggest that moderate exercise does not increase muscle inflammation.[200] In another study,[201] aerobic exercise limitation in JDM was shown to correlate best with measures of disease damage.

# CHRONIC RECURRENT MULTIFOCAL OSTEOMYELITIS

## Etiology, Pathophysiology, and Clinical Presentation

Chronic recurrent multifocal osteomyelitis (CRMO) is a skeletal disorder of unknown origin mainly occurring in children and adolescents.[202] It is characterized by multifocal nonpyogenic inflammatory bone lesions, a course of exacerbations and remissions, and an association with other inflammatory disorders.[203] The association of CRMO with dermatologic disorders (such as psoriasis) and inflammatory bowel disease and its response to steroids suggests an autoimmune cause.[204–206] A genetic origin for CRMO has been suggested as a result of observation of disease in siblings and monozygotic twins.[207–209]

SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis) syndrome is considered by some to be the adult equivalent of CRMO.[210] Whereas CRMO typically manifests in the first decade

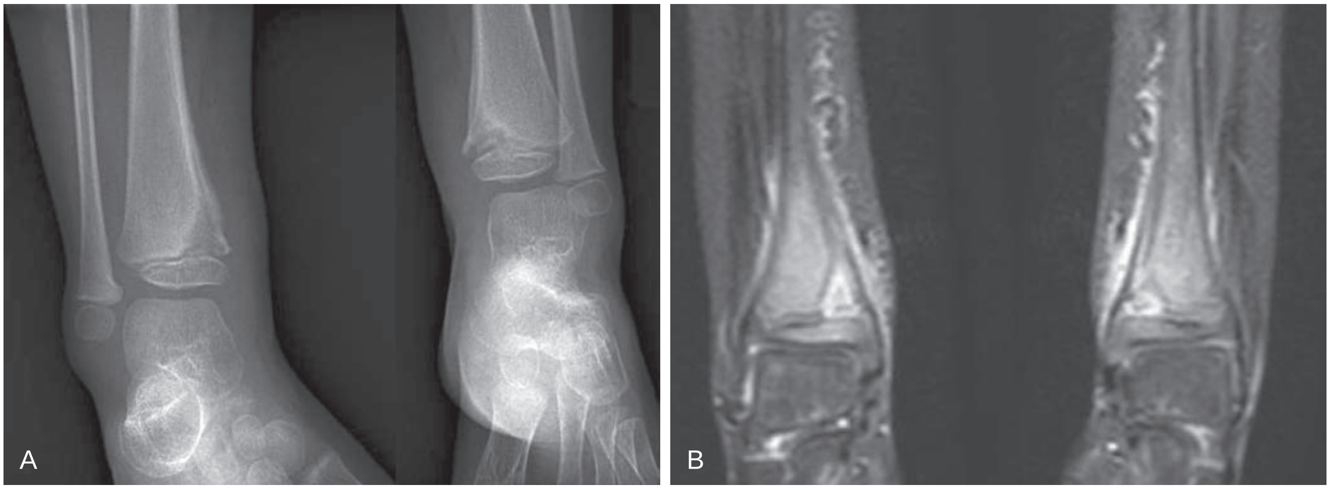

**Figure 136.32. Chronic recurrent osteomyelitis in a 4-year-old girl.** (A) Radiograph of the ankles shows lytic lesions in the bilateral tibial metaphyses with associated periosteal reaction. (B) Coronal STIR MR image of both ankles shows focal high signal intensity lesions in both tibial metaphyses, which involve the adjacent physes, and extensive surrounding bone marrow and periosteal edema.

of life, the mean age of onset for SAPHO syndrome is 28 years.[211] CRMO is a diagnosis of exclusion, distinct from bacterial osteomyelitis, based on the following criteria:

1. Bone lesions with a radiographic picture suggesting subacute or chronic osteomyelitis
2. Frequent multifocality
3. No abscess formation, fistula, or sequestra
4. Lack of a causative organism
5. Nonspecific histopathologic and laboratory findings compatible with subacute or chronic osteomyelitis
6. A characteristic prolonged, fluctuating course with recurrent episodes of pain
7. Occasional accompanying skin disease[202]

## Imaging

The imaging evaluation of CRMO should start with radiographic evaluation of the symptomatic sites. If the radiographs have negative findings in the presence of significant clinical symptoms, further evaluation with MRI should be considered to evaluate for bone marrow edema. Whole-body evaluation traditionally has been performed with $^{99m}$technetium bone scintigraphy,[212] although whole-body MRI is being increasingly used.[213] The diagnosis of CRMO typically is confirmed by means of image-guided bone biopsy.[214]

The three most common sites of disease at initial presentation are the lower extremities (39.7%) (Fig. 136.32 and e-Fig. 136.33), spine (25.9%), and pelvis (20.7%),[210] followed by the clavicle, the spine, the mandible (Fig. 136.34), and pelvic bones.[215,216] In tubular bones, metaphyseal lesions are the most common, accounting for 49% of all long bone lesions.[210]

The differential diagnosis of CRMO includes subacute and chronic infectious osteomyelitis, histiocytosis, hypophosphatasia, and malignancies such as leukemia, lymphoma, and Ewing sarcoma.[217] The imaging features may mimic pyogenic chronic osteomyelitis, and ultimately it may be necessary to perform a biopsy in clinically equivocal cases. Multifocal metaphyseal-based lesions favor a diagnosis of CRMO after pyogenic infection has been excluded.

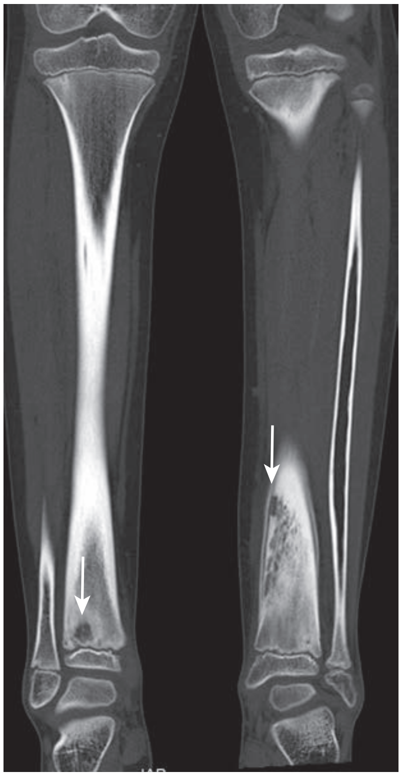
CRMO of long bones can result in orthopedic complications such as bony overgrowth, angular deformities, and limb-length discrepancy.[218] Because of its tendency to occur near the physes, CRMO can cause premature physeal closure, resulting in growth arrest. The hyperemia caused by chronic inflammation may result in diffuse demineralization, predisposing to fractures.[219]

## Treatment and Follow-up

Suggestion of the diagnosis by a radiologist could help avoid unnecessary diagnostic procedures and antibiotic therapy and initiate an appropriate therapy.[210] Many different treatments have been used in persons with CRMO, including nonsteroidal anti-inflammatory agents, corticosteroids,[220] azithromycin, tumor necrosis factor-blocker (infliximab),[221,222] and interferon.[223] Bisphosphonates have been used in persons with CRMO for pain relief and control of disease progression[224] and when simple therapies fail to control symptoms or disease progression.[224]

### KEY POINTS

- Clinical and laboratory diagnosis of early joint changes in children with JIA is suboptimal. Imaging, particularly with MRI and ultrasound, is important for early detection and for evaluating treatment response in children with JIA.
- Both MRI and ultrasound can detect JIA synovial hypertrophy, erosions, and joint effusions in peripheral joints and monitor clinically meaningful response to treatment.
- Ultrasound is generally less sensitive than MRI.
- Radiographic findings of ERA and other spondyloarthropathies are similar to those encountered in other forms of JIA, with the exception of sacroiliitis and enthesitis.
- Radiographic changes in hemophilic arthropathy may be identical to JIA, but clinical findings distinguish these entities.
- PVNS is a benign proliferative disorder characterized by synovial hyperplasia in joints, bursae, and tendon sheaths. PVNS shows variable villous and nodular synovial proliferation typically with low signal intensity within the joint (from hemosiderin) on MRI.
- In JDM, the muscles of the scapular and pelvic girdles are most frequently affected.
- CRMO is characterized by multifocal nonpyogenic inflammatory bone lesions that may be associated with other inflammatory disorders.



**e-Figure 136.33. Chronic recurrent multifocal osteomyelitis in an 8-year-old girl with bilateral distal tibial lytic lesions.** One lesion is located in the right distal tibial juxtaphyseal metaphysis, and a secondary lytic lesion is located in the left tibia metadiaphysis *(arrows)*. The left tibial metadiaphyseal lesion was biopsied to establish the diagnosis.

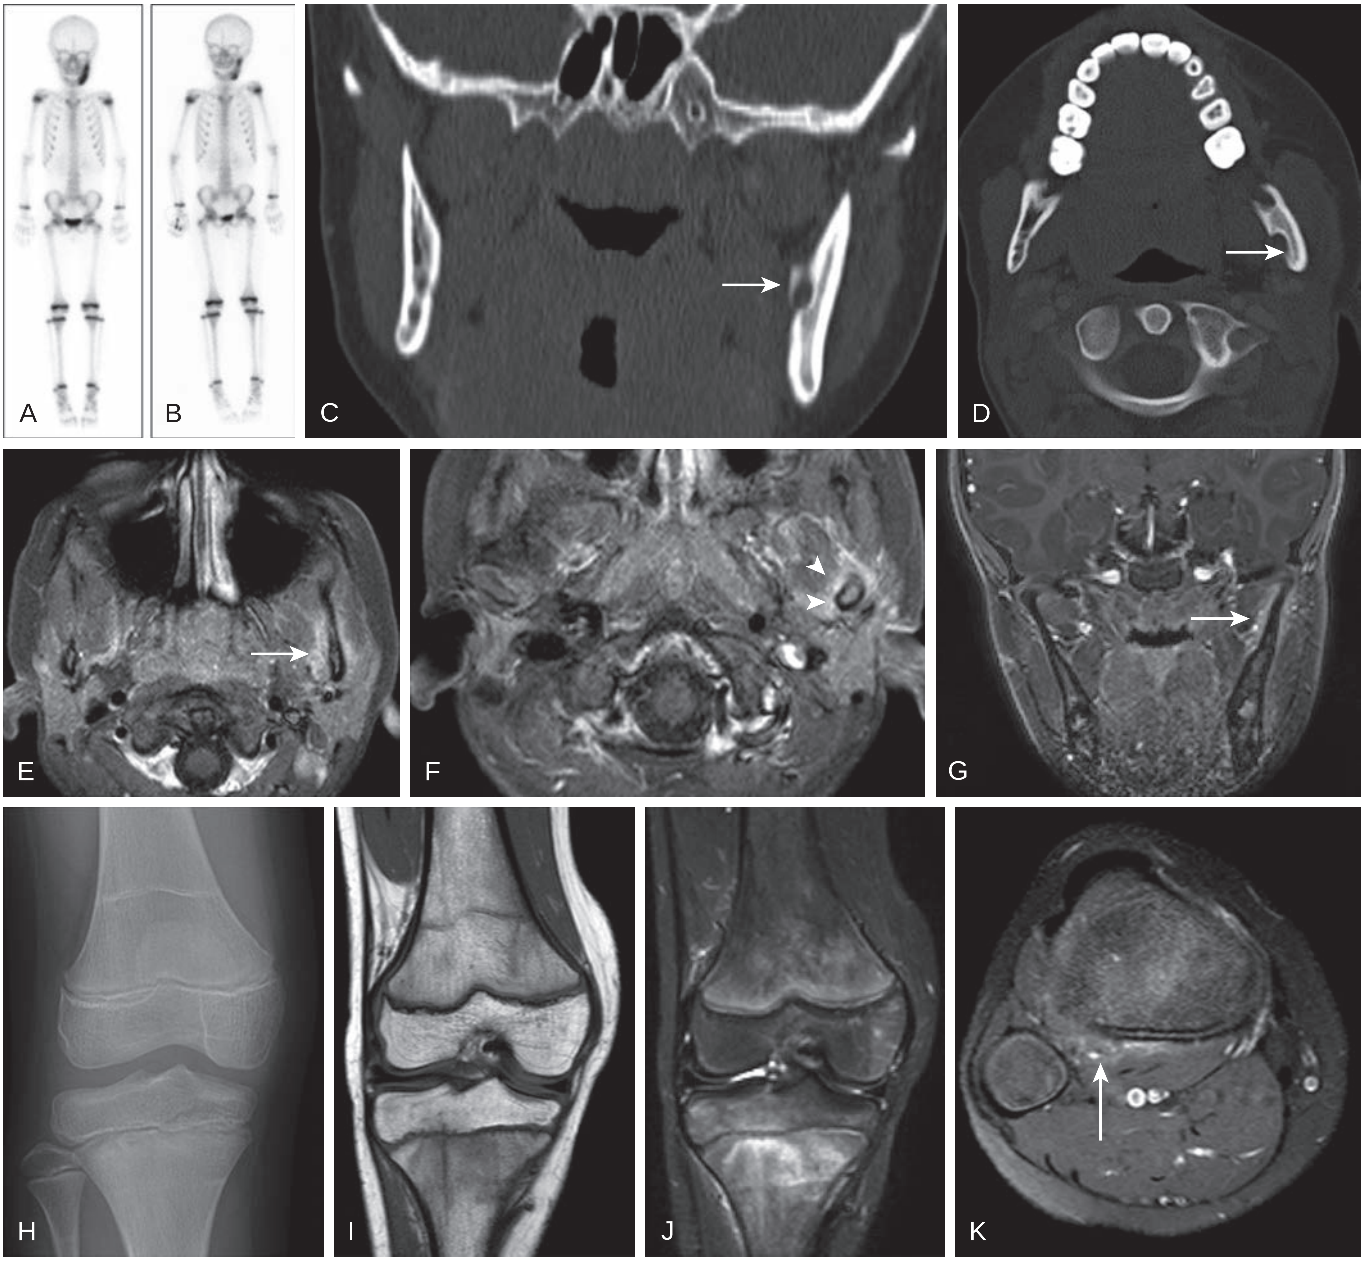


**Figure 136.34. Chronic recurrent multifocal osteomyelitis.** At the age of 6 years, this girl presented with pain in the left mandible. At that time, the bone scan (A) showed a increased uptake in the left mandibular ramus. Eight months later, persistent increased activity was still noted in the left mandible on a bone scan (B); however, it was less intense than in the previous study. Subsequently, the patient started treatment with pamidronate. Three years later, coronal (C) and axial (D) CT images of the mandibles showed a lytic left mandibular lesion posterior to an unerupted molar *(arrows)*. Postcontrast axial T1-weighted turbo spin echo spectral presaturation inversion recovery (SPIR), (E and F) and coronal T1-weighted three-dimensional fast field echo postcontrast (G) MR images performed 2 months after the CT scan shows increased marrow and adjacent soft tissue enhancement in the mid and superior aspects of the left mandibular ramus (*arrows* in E and G) with associated mild reactive synovitis (*arrowheads* in F) of the left TMJ. Three years later, pain started to develop in the right knee. The frontal radiograph (H) and MRI of the right knee coronal T1-weighted, (I) coronal short-tau inversion recovery (STIR), (J) and postcontrast axial T1-weighted SPIR, (K) shows decreased signal on the T1-weighted image and increased signal intensity on the STIR images in the proximal tibial metaphysis with mild adjacent soft tissue inflammation *(arrow)*.

# 137 Musculoskeletal Infections

J. Herman Kan, Arthur B. Meyers, and E. Michel Azouz

## OVERVIEW OF MUSCULOSKELETAL INFECTIONS

Musculoskeletal infections remain a diagnostic and therapeutic challenge. Historically, the workup and treatment of such infections has been based on clinical grounds supplemented by diagnostic aspiration and subsequent surgical incision and drainage. Today, imaging plays a critical role in the diagnosis and management of musculoskeletal infections.

This chapter will review the clinical presentation, pathophysiology, imaging, and treatment spectrum of osteomyelitis, septic arthritis, and soft tissue infections of the appendicular skeleton.

### Acute Pyogenic Osteomyelitis

***Etiology, Pathophysiology, and Clinical Presentation.*** Osteomyelitis may occur from direct or hematogenous inoculation; it may be iatrogenic, related to orthopedic implants; or it may be from secondary extension from primary septic arthritis or pyomyositis. Hematogenous osteomyelitis is a common disease in children; however, infantile and even neonatal cases are not uncommon. Bacteria are the most common inflammatory agents, but growing bones may also be invaded by other pathogens, including viruses, spirochetes, and fungi.

The incidence of pediatric osteomyelitis in the United States is 1 in 5150 and has increased 2.8-fold in 20 years.[1] This increased incidence is confounded, however, because of differences in access to health care and advances in imaging diagnosis. *Staphylococcus aureus* remains the most common causative organism of acute osteomyelitis in children. Unfortunately, community-acquired methicillin-resistant *S. aureus* (MRSA) strains are increasing in prevalence.[2,3] *Haemophilus influenzae* osteomyelitis and septic arthritis have become less common since the availability of effective vaccination (*H. influenzae* type B vaccine).[4]

In sickle cell disease, bone complications include osteonecrosis and osteomyelitis. Osteonecrosis is approximately 50 times more frequent than osteomyelitis.[5] The proposed mechanism of osteomyelitis is hematogenous, with bacteria gaining entrance to blood vessels through ischemic bowel and finding suitable culture material in foci of infarcted bone marrow. Both *S. aureus* and *Salmonella* commonly occur in sickle cell patients.[2]

In chronic granulomatous disease of childhood, an X-linked recessive disorder of leukocyte function, repeated infections occur in solid organs, skin, and bone. Approximately one-third of patients develop osteomyelitis. Phagocytes are unable to kill catalase-positive organisms such as *Staphylococcus* and fungi.[6–8]

Hematogenous osteomyelitis usually involves the highly vascularized metaphysis of the fastest growing bones, such as the distal femur and radius and the proximal tibia and humerus. The most common location for hematogenous osteomyelitis is about the knee (distal femur, proximal tibia).[2] Pain, localized signs, fever, reduced range of motion, and reduced weight bearing are the most common initial clinical features. A history of trauma is seen in approximately 30% of cases,[2] and the male-to-female ratio is approximately 1 : 8.

Organisms lodge most frequently in the terminal capillary sinusoids of the metaphyses (Fig. 137.1).[7] Rarely, they may locate initially in the epiphyses related to the terminal capillary sinusoids of the metaphyseal equivalent region immediately next to the spherical growth plate. A small abscess forms in the marrow of the metaphysis, followed by local decalcification and destruction of the adjacent bone. When focal abscesses are generated, multiple small foci of bone destruction develop and later coalesce. Inflammatory swelling increases the intraosseous pressure because of the rigid bony walls of the marrow cavity; this can force extension of the infected exudate into several sites, as indicated in Fig. 137.2. The most common route is via the haversian canals of the cortex to the subperiosteal space, where a subperiosteal abscess is formed. Simultaneously, spread also occurs farther within the medullary cavity. Rupture of the periosteal abscess is responsible for extension of infection into the adjacent soft tissues. Inflammation and rapidly increased intraosseous pressure may cause thrombosis of the vascular channels.

The most common location for direct inoculation osteomyelitis is the foot. Plantar puncture wounds secondary to walking on broken glass, metal (nail), or vegetable matter (thorn, toothpick) may result in infectious cellulitis, plantar fasciitis, and osteomyelitis, whether the foreign body is removed or retained. The calcaneus is often involved, and *Pseudomonas aeruginosa* is often found related to direct inoculation, usually with a history of a puncture through a shoe.[7]

***Imaging.*** Imaging guidelines for the evaluation of suspected osteomyelitis include radiographs first to exclude alternative etiologies, such as a fracture or neoplasm, as an explanation for symptoms. If radiographs are normal and symptoms are localized to an osteoarticular region, ultrasound (US) may be performed to evaluate for suspected septic arthritis. Targeted magnetic resonance imaging (MRI) of the affected region should be performed to identify underlying osteomyelitis and to guide surgical treatment.[9,10] Both MRI and US can also identify subperiosteal and soft tissue abscesses. When symptoms are not localizable a whole body MRI can be performed.[11] Three-phase bone scintigraphy is recommended when symptoms are nonlocalizable and there are relative contraindications to MRI such as the need for sedation.[12]

***Radiography.*** With acute osteomyelitis, the earliest change on radiographs is soft tissue swelling; osseous changes are seldom present until the second week of disease (Fig. 137.3).[13] The earliest bone changes seen on conventional images are one or more small radiolucencies, usually in the metaphyseal region, where necrosis and destruction of bone has occurred (Fig. 137.4). On serial examinations, these areas of bone destruction enlarge and become confluent.

With continuing appropriate antibiotic therapy, periostitis is visible when the periosteum begins to produce new bone on its undersurface after the second or third week (Fig. 137.5). Osteogenic function by the periosteum suggests that infection has been at least partly locally controlled. Subsequent healing may involve remodeling of the cortical new bone and reconstitution of the underlying bone or, if damage has been extensive, it may involve an increase in the amount of periosteal reaction to form an

## Abstract:

Musculoskeletal infections children are a diagnostic and therapeutic challenge. Imaging plays a critical role in the initial diagnosis and follow up of musculoskeletal infections. This chapter reviews the clinical presentation, pathophysiology, imaging, and treatment spectrum of osteomyelitis, septic arthritis, and soft tissue infections of the appendicular skeleton.

## Keywords:

Pediatric
osteomyelitis
septic arthritis
pyomyositis
cellulitis
fasciitis
imaging

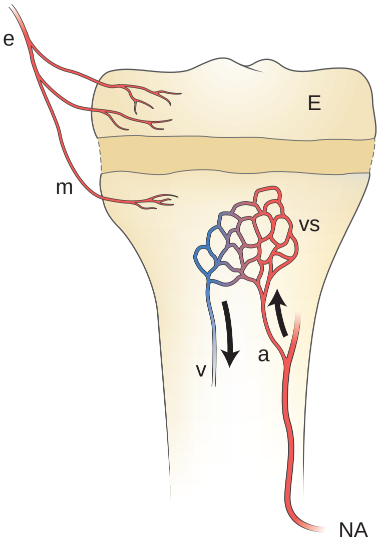

**Figure 137.1. Blood supply to the metaphysis and epiphysis of a child and the arterial channels through which invading organisms enter the growing bone.** An epiphyseal artery *(e)* supplies the epiphysis *(E)* and may branch to give minor metaphyseal vessels *(m)*. The major blood supply of the metaphysis comes from the nutrient artery. *a*, Arteriole; *NA*, nutrient artery; *v*, venule; *vs*, venous sinuses in the metaphysis.

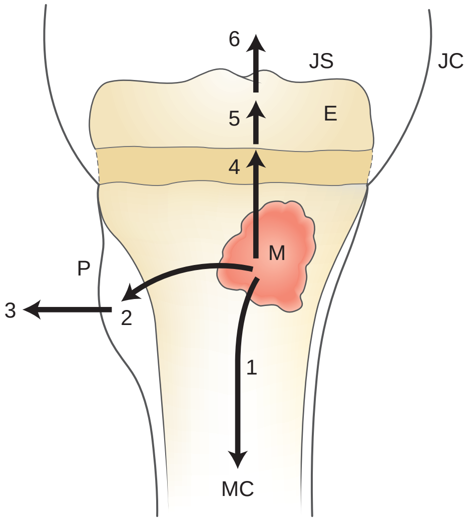

**Figure 137.2. Pathways of infection after hematogenous implantation in the metaphysis and formation of a metaphyseal focus *(M)* of bone infection (bone abscess).** (1) Spread to the medullary canal *(MC)*; (2) formation of a subperiosteal abscess; (3) penetration of the periosteum *(P)* and spread to the adjacent soft tissues; (4) through (6) spread across the growth plate to the epiphysis *(E)*, and eventually to the joint space *(JS)*. *JC*, Joint capsule.

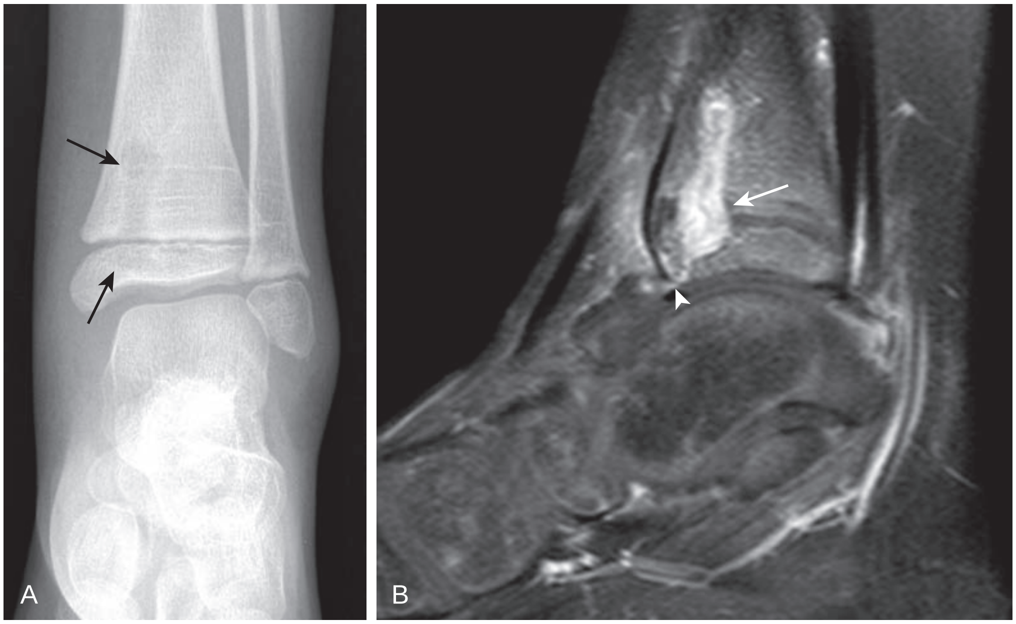

**Figure 137.3. Osteomyelitis in a 6-year-old girl.** (A) Frontal radiograph demonstrates a lytic lesion in the distal tibia metaphysis extending into the epiphysis *(arrows)*. (B) T1-weighted, fat-saturated, postgadolinium sagittal view demonstrates a thick, rim-enhancing lesion with a small amount of nonenhancing fluid consistent with early abscess formation with epiphyseal extension *(arrow)* and a small cloaca *(arrowhead)* extending to the tibiotalar joint.

involucrum (Fig. 137.6), a living bone sheath around the fragments of the old devitalized bone (sequestrum).

***Scintigraphy.*** Bone scans are particularly helpful in the evaluation of suspected osteomyelitis when symptoms are not localizable due to its ability to scan the entire skeleton. Early bone scans may demonstrate a “cold” metaphyseal lesion as a result of compression or occlusion of the metaphyseal vessels. In these cases, increased activity is observed toward the diaphysis, beyond the cold metaphyseal area, which subsequently becomes “hot” and merges with the adjacent increased activity (Fig. 137.7). The multiphase bone scan is very sensitive and is usually positive 24 to 48 hours after the onset of symptoms.[12] It can detect extension of metaphyseal osteomyelitis into the epiphysis through the growth plate (see Fig. 137.7).

Another application of nuclear medicine imaging of musculoskeletal infections is to evaluate for infection in the setting of orthopedic hardware. In this situation, MRI may be of limited value due to susceptibility artifact. A normal bone scan can rule out infection. However, increased activity on a bone scan in this situation may be due to infection or hardware loosening. If this occurs, then a radiolabeled leukocyte scintigraphy scan (white blood cell scan) can be performed in conjunction with a Tc-99m sulfur colloid scan. Areas of increased radiotracer uptake on the leukocyte scan that are normal on the sulfur colloid scan are consistent with infection.

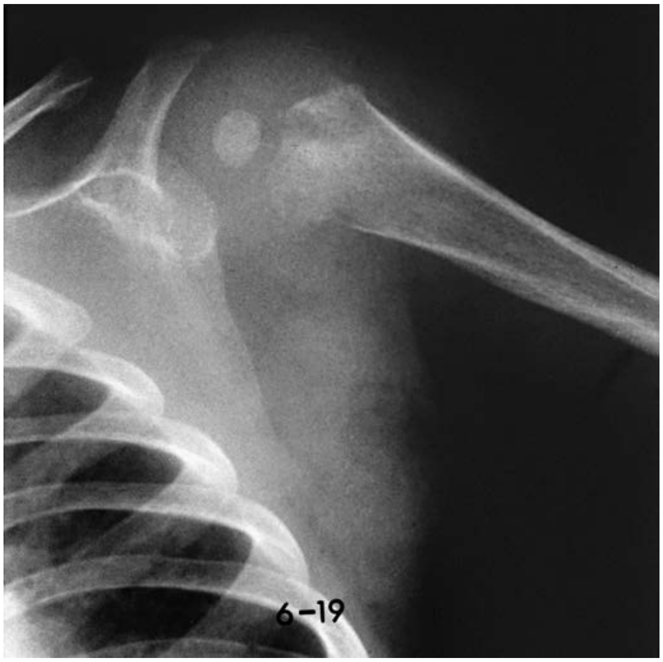

**Figure 137.4. Early radiographic changes of osteomyelitis in the proximal left humeral metaphysis.** This 9-month-old boy had fever and local signs and symptoms for 12 days. Metaphyseal areas of bone destruction are visualized as irregular, ill-defined lucencies.

***Computed Tomography.*** Computed tomography (CT) is of limited clinical value in acute osteomyelitis.[14] It is more useful in advanced or chronic disease to help determine the quality of bone stock, including determinations of cortical destruction, involucrum, and sequestra (see Fig. 137.6).

***Magnetic Resonance Imaging.*** MRI is the optimal study to evaluate for infection and alternative etiologies for symptoms, particularly when radiographs are normal. When precontrast MRI examinations are entirely normal and show no evidence to suggest osteomyelitis, routine postgadolinium images may not be necessary.[15,16] When abnormal, MRI can reveal marrow alterations and extent of disease in bone, soft tissues, or adjacent joints (Fig. 137.8).[17] Early MRI findings of osteomyelitis may have a tumefactive appearance and may be paradoxically hypointense on fluid-sensitive sequences (e-Fig. 137.9). Over time, the lesion may remain masslike and demonstrates the expected, more homogeneous hyperintense signal on fluid-sensitive sequences, indicative of its inflammatory nature (Fig. 137.10). Eventually, periostitis and adjacent soft tissue involvement may be seen in the early phase of osteomyelitis (e-Fig. 137.11). Subperiosteal abscess formation may be seen by sonography (Fig. 137.12) or MRI (Fig. 137.13), preceding radiographic bony changes. A salt-and-pepper appearance to the marrow may be seen in the late acute phase of osteomyelitis and is presumed to represent small areas of noncoalescent microabscess formation and early bone destruction (Fig. 137.14). It is difficult to distinguish acute osteonecrosis from osteomyelitis in the setting of sickle cell disease on MRI (Fig. 137.15).

Musculoskeletal infections typically have localizable symptoms to the area of involvement allowing performance of a focal MRI. However, these infections may present as fever without a source

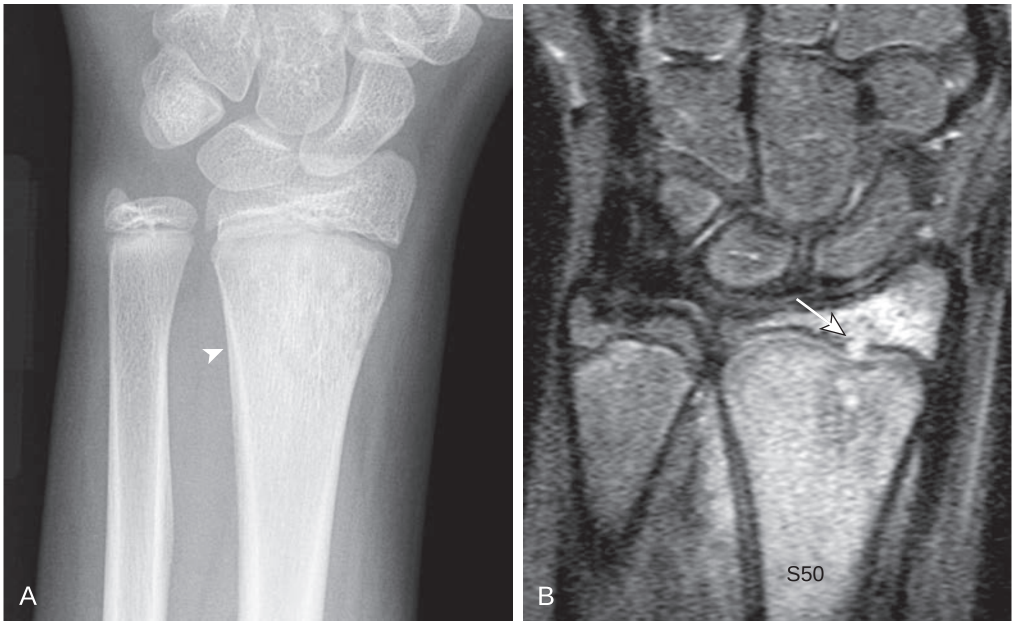

**Figure 137.5. Osteomyelitis in a 12-year-old boy.** (A) Frontal radiograph demonstrates distal radial moth-eaten bone destruction with periostitis *(arrowhead)*. (B) Coronal STIR magnetic resonance (MR) image demonstrates diffuse marrow edema with transphyseal extension *(arrow)* into the epiphysis.

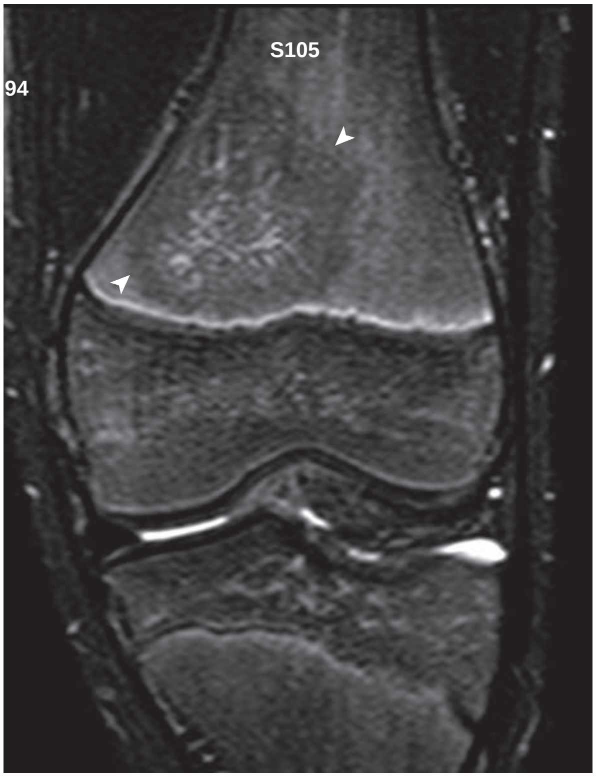
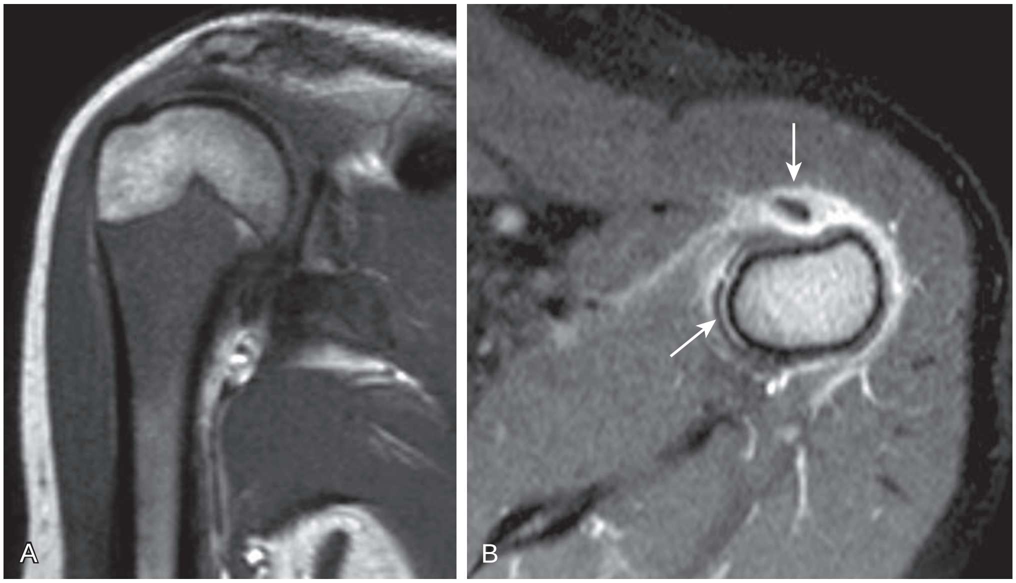


**e-Figure 137.9. Biopsy-confirmed osteomyelitis in a 13-year-old boy.** Coronal MR image demonstrates round masslike hypointensity in the distal femur metadiaphysis *(arrowheads)*.



**e-Figure 137.11. Proximal humeral osteomyelitis in a 12-year-old girl.** (A) Coronal T1-weighted MR image demonstrates diffusely decreased marrow signal in the proximal humerus. (B) Axial T1-weighted, fat-saturated, postgadolinium MR image demonstrates hyperenhancement in the periosteal and juxtacortical soft tissues and around the long head of the biceps tendon *(arrows)*.

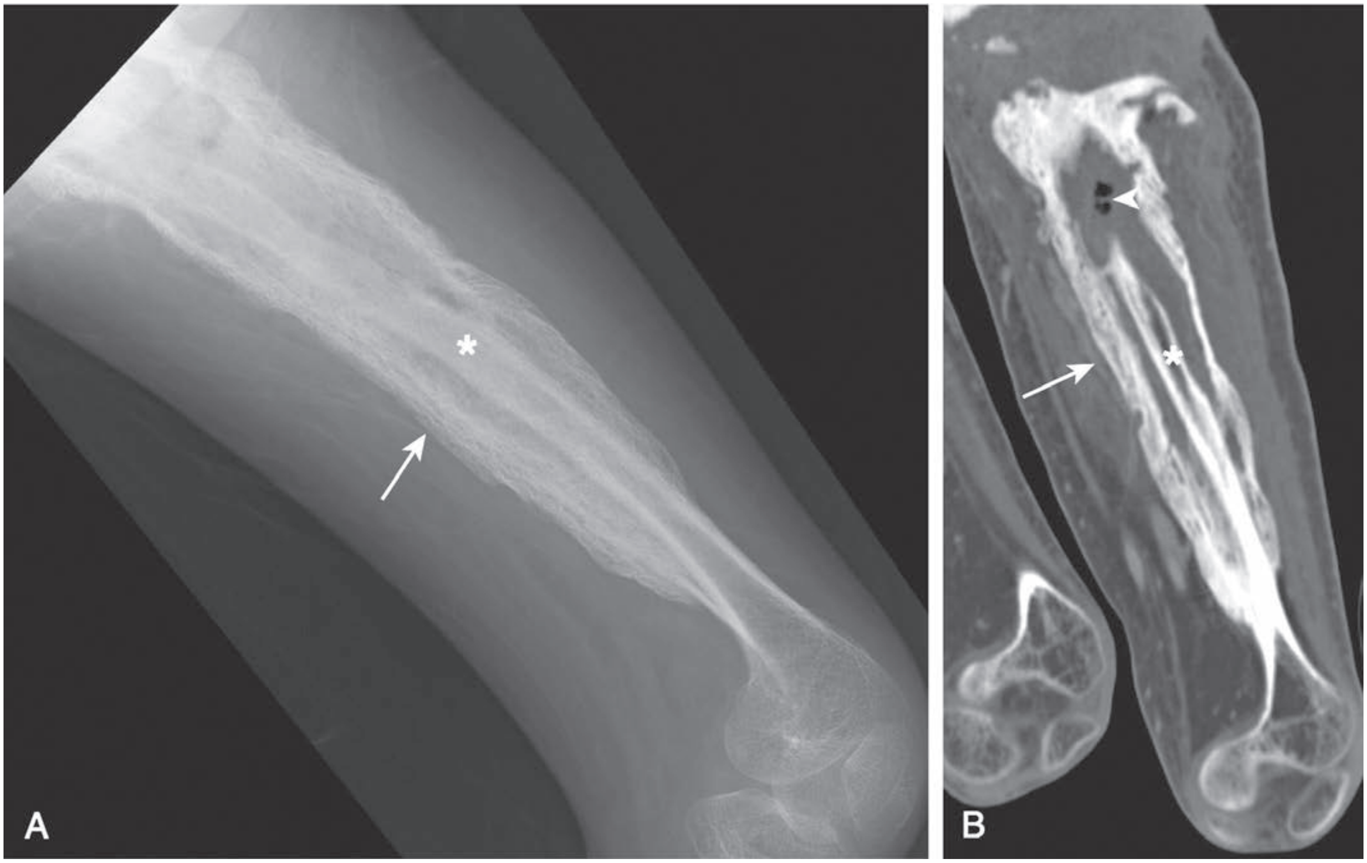


**Figure 137.6. Chronic osteomyelitis of the left femur in a 17-year-old boy.** Radiograph (A) and CT scan (B) demonstrate involucrum *(arrow)* that surrounds a sequestrum *(asterisk)*. Note air *(arrowhead)* within the proximal femoral diaphysis related to abscess formation.

or fever of unknown origin, particularly in very young children or developmentally disabled children who are not able to verbalize symptoms. One of the applications of whole body MRI is to evaluate for a nonlocalizable infection. Large field of view fluid-sensitive sequences, typically a short-tau inversion recovery (STIR) sequence, are typical of whole body protocols with the use of T1-weighted and diffusion sequences being used at some institutions. These allow for detection and localization of osteomyelitis (Fig. 137.16) and other musculoskeletal infections (e.g., septic arthritis, infectious myositis, cellulitis, and periosteal and soft tissue abscesses).[11]

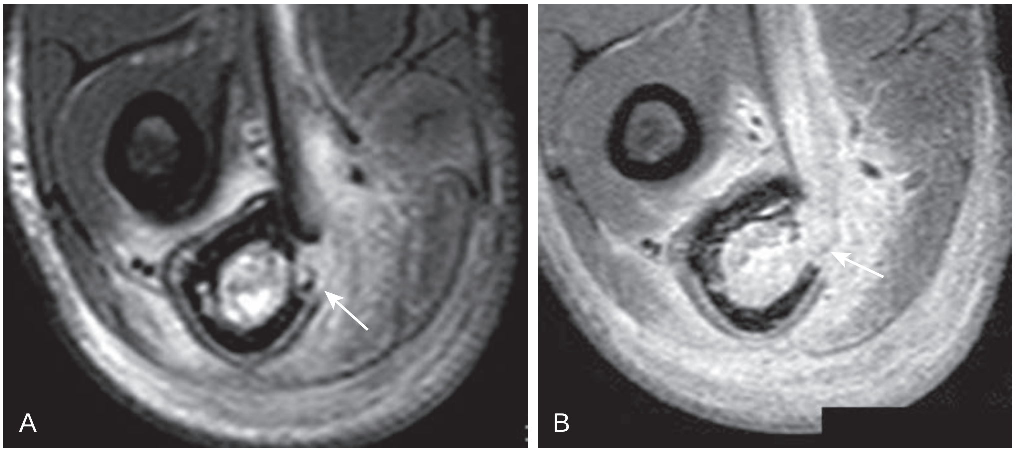
## Subacute and Chronic Osteomyelitis

Subacute or chronic osteomyelitis may develop as a result of partial host response to contain the infection. Distinguishing between subacute and chronic osteomyelitis is arbitrary.[18] The initial purulent exudate is replaced by granulation tissue, and the clinical manifestations are mild and consist mainly of local pain. A Brodie abscess may then develop, typically in the metaphysis and less commonly in the epiphysis, because the growth plate is only a partial barrier against the spread of infection. A Brodie abscess is characterized radiographically by a central or eccentric round or oval radiolucency.[19] The cavity may contain a small, dense sequestrum. On MRI, lesions have a characteristic layered appearance with a high-signal periphery as a result of edema (penumbra sign)[20] and a double-line sign (rim sign), which on fluid-sensitive sequences is delineated as a low-signal outer rim because of sclerosis; an inner rim of intermediate signal because of granulation tissue; and a central, hyperintense region related to abscess formation (Fig. 137.17).[21] With contrast-enhanced imaging, the inner granulation layer will show enhancement around the nonenhancing central abscess.

Adjacent soft tissue swelling and edema and periosteal new bone formation may be present. In spite of occasional growth plate involvement, the incidence of premature growth plate fusion after subacute osteomyelitis is rare.[22]

Cortical and trabecular bone sclerosis, cavities, involucra, and sequestra are characteristic of advanced osteomyelitis.[23] The affected bone is thickened, and its outline may be wavy, with or without periosteal cloaking of new bone. An involucrum of reactive, viable bone may cloak an area of infection (Fig. 137.18). The involucrum may be perforated by a cloaca, which is a tract or communication between bone and the surrounding soft tissues (e-Fig. 137.19). If the cloaca extends to the skin surface, it is termed a *sinus tract* (see Fig. 137.18).[24] The necrotic, devitalized bone of a sequestrum is surrounded by inflammatory granulation tissue and may be located within a bone abscess cavity. The dead bone of a sequestrum is relatively sclerotic. Sequestra may be demonstrated on radiography, CT, or MRI, but it is best seen with CT (see Figs. 137.6 and 137.18). Sequestration is now relatively rare owing to earlier diagnosis, largely because of advances in imaging and more effective antibiotic therapies.

Radiographs will suggest the diagnosis of subacute or chronic osteomyelitis and may be used to follow up for gross changes.



**e-Figure 137.19. Chronic osteomyelitis and cloaca in a 17-year-old boy.** Axial T2-weighted fat-saturated axial (A) and postgadolinium, T1-weighted, fat-saturated (B) MR images demonstrate cortical destruction with communication (*arrow* in A) between marrow and adjacent soft tissues (cloaca).

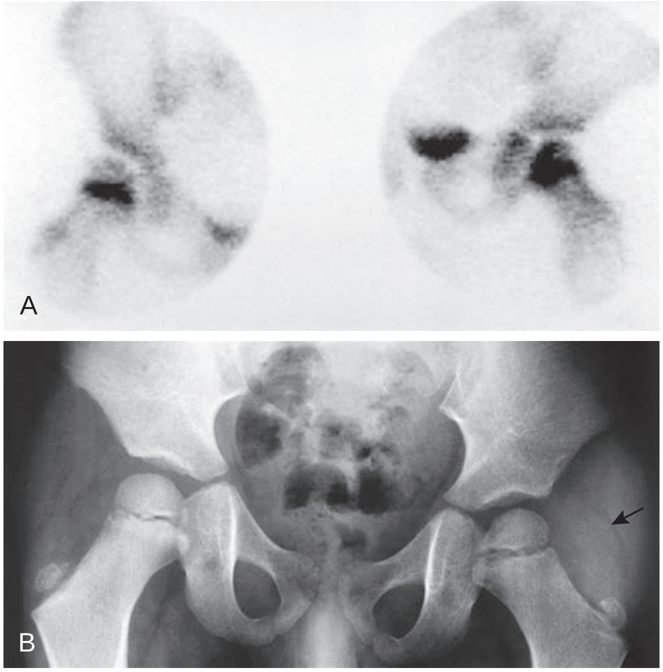


**Figure 137.7. Osteomyelitis in a 4-year-old boy with fever and inability to walk or move the left lower extremity for 6 days.** (A) Bone scan shows increased uptake in the femoral neck and head on the left side, likely resulting from extension of an initial metaphyseal focus of infection into the epiphysis. The right hip shows normal increased uptake in the region of the growth plate. (B) Radiograph of the hips 2 weeks after the beginning of symptoms shows osteopenia on the left side, and ill-defined medial metaphyseal and epiphyseal bone lucencies on each side of the growth plate. Also the lateral fat plane is displaced laterally *(arrow)*, which is indirect evidence of a joint effusion. Adjacent deep soft tissues also appear swollen and edematous compared with the normal right side.

Although CT is of limited clinical value in acute osteomyelitis, it is very useful in imaging chronic disease to evaluate bone stock quality and to detect cortical metaphyseal tracts and channels, sequestra, and bone destruction. Serial MRI after an established diagnosis of osteomyelitis has been made, and after medical or surgical treatment, has limited utility but can be useful in patients who do not respond to therapy or who have a persistently elevated C-reactive protein level.[25]

Not all marrow edema and granulation tissue identified on MRI represents a diagnosis of osteomyelitis; therefore a combination of imaging features and clinical history should be used in concert to arrive at such a diagnosis. Stress reaction may superficially mimic early osteomyelitis, and Ewing sarcoma may superficially mimic subacute or chronic osteomyelitis, with the mass related to Ewing sarcoma mimicking granulation tissue.

***Treatment.*** Although the mortality and morbidity of bone infection have decreased significantly, permanent sequelae do occur, largely as a result of delay in diagnosis or inadequate treatment with complications related to generalized bacterial sepsis.[26] Complications of bone infection include pathologic fracture through regions of bone destruction,[27] venous thrombosis,[28] premature physeal closure, and adjacent infectious arthritis and destruction of joints (Fig. 137.20).

Identification of a bacterial pathogen for underlying osteomyelitis ranges from 9% to 22% by blood culture and 40% to 50% by bone or joint aspiration.[26] MRI is useful for confirming or excluding the diagnosis of osteomyelitis, identifying fluid for culture, and preoperative planning for incision and drainage of potential intraosseous and extraosseous abscesses.[9]

To decrease the chance of complications, empiric antibiotic therapy is often initiated even before bacterial culture is isolated.[29] Treatment includes parenteral antibiotics followed by a long course of oral antibiotics, provided the child is not immunocompromised.[30]

Surgical drainage is recommended if the child has not responded to antibiotics after 48 to 72 hours or if a substantial abscess is

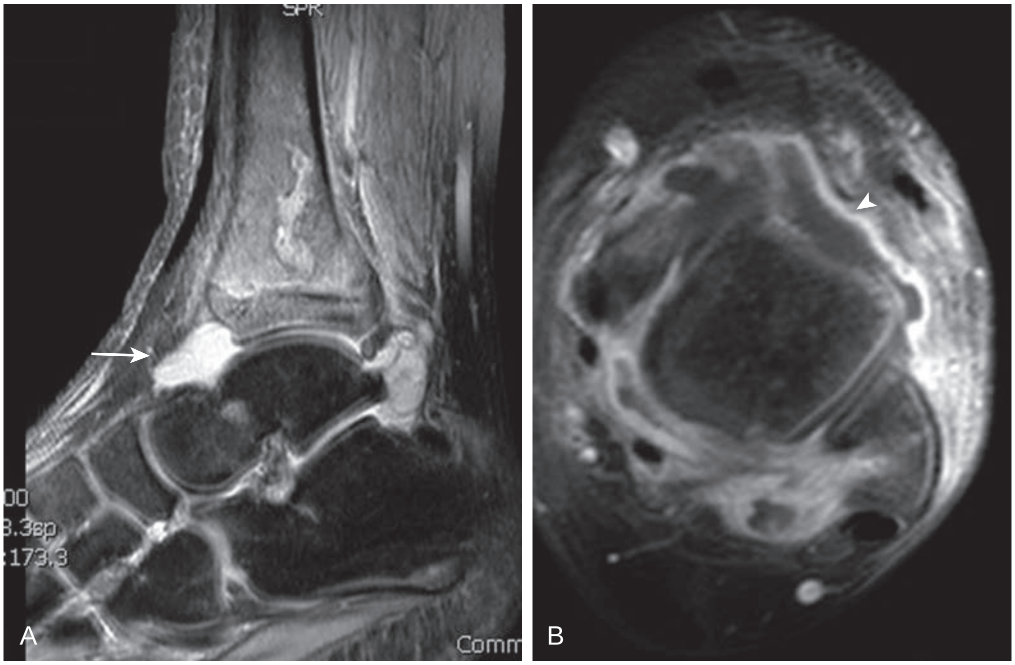

**Figure 137.8. Distal tibial osteomyelitis and tibiotalar septic arthritis in an 11-year-old boy.** (A) T2-weighted fat-saturated sagittal MR image demonstrates diffuse marrow edema that includes transphyseal extension to the epiphysis and juxtacortical soft tissue edema. A large joint effusion is present *(arrow)* with T1-weighted, fat-saturated, postgadolinium axial images (B) that demonstrate thick synovial enhancement *(arrowhead)*.

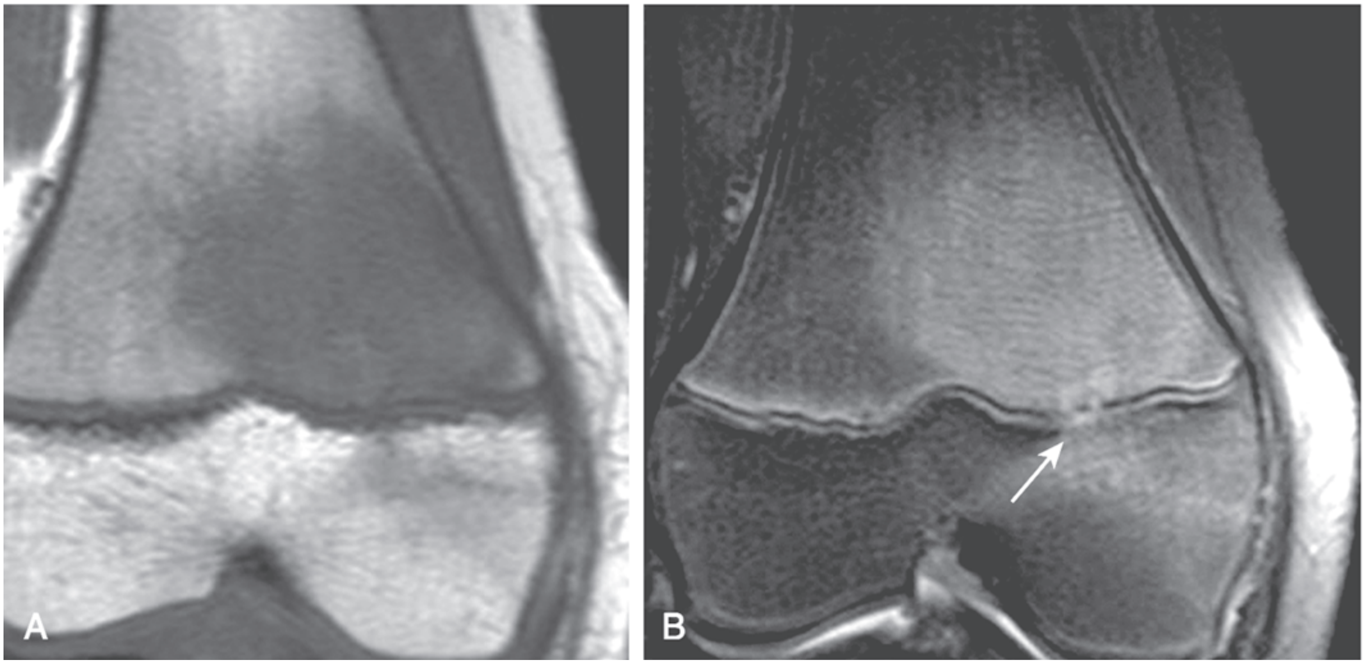

**Figure 137.10. Biopsy-confirmed osteomyelitis of the distal femur.** (A) Coronal T1-weighted MR image demonstrates tumefactive marrow replacement in the distal femur. (B) Coronal STIR MRI demonstrates diffuse homogeneous hyperintensity in the same distribution with early physeal extension of infection *(arrow)*.

identified by MRI.[26] If adjacent septic arthritis is present, the joint will need to be debrided as well.[5]

## Neonatal Osteomyelitis

In the young infants, the incidence of epiphyseal and joint involvement is higher (Fig. 137.21), and multifocal disease may be seen.[31] This is because of the persistence of metaphyseal vessels that cross the physis and extend into the intraarticularly located epiphysis. The most common causative organism is *S. aureus*. Other isolated organisms include *Escherichia coli*, group B streptococci, gram-negative rods, and *Candida albicans*.[31] The hip is frequently involved,[32] and neonatal calcaneal osteomyelitis may develop after heel pad puncture for blood drawing.[33]

## Epiphyseal Osteomyelitis

***Etiology, Pathophysiology, and Clinical Presentation.*** In tubular bones, the early changes of pyogenic hematogenous osteomyelitis are usually localized to the metaphysis, where capillary vascularization is very rich and blood flow is slow on the venous side of the sinusoidal loops. Infection may spread from the metaphysis through the growth plate to the epiphysis (see Fig. 137.2).[14] Epiphyseal osteomyelitis and septic arthritis occur more commonly in infants younger than 15 months of age, because metaphyseal vessels penetrate the growth plate and enter the epiphysis.[34]

***Imaging.*** Radiography usually demonstrates a focus of epiphyseal bone destruction (Fig. 137.22A). In subacute and chronic cases, a small round or oval epiphyseal abscess cavity with well-defined borders is seen. CT is useful for imaging of the bone cavity and detection of a sequestrum. MRI reveals the epiphyseal focus of infection as low signal on T1-weighted images and high signal on T2-weighted images (Fig. 137.22B). Imaging after gadolinium injection may show rim enhancement outlining the abscess cavity of the epiphyseal ossification center. Browne et al. showed epiphyseal cartilage involvement was seen in 52% of cases of *S. aureus* infections in children under 18 months of age.[35] Enhancement defects in the epiphyseal cartilage are commonly seen in the setting of osteomyelitis, but only one-fifth to one-third represent true epiphyseal cartilage abscesses (see Fig. 137.21).[34]

The differential diagnosis of an epiphyseal (or apophyseal) lucent lesion in a child includes infection, chondroblastoma, and Langerhans cell histiocytosis.

***Treatment.*** Epiphyseal osteomyelitis may lead to growth disturbance of the epiphyseal ossification center and physis.[35] Early osteoarthritis may also occur with epiphyseal and articular cartilage destruction. Because the epiphysis is an intraarticular structure, coexisting septic arthritis may be present. Surgically, these children will require exploration and debridement of both the epiphyseal bone and joint space, when those are involved, based on preoperative MRI. Care should be made to differentiate epiphyseal cartilage enhancement defects from true epiphyseal abscesses.[34]

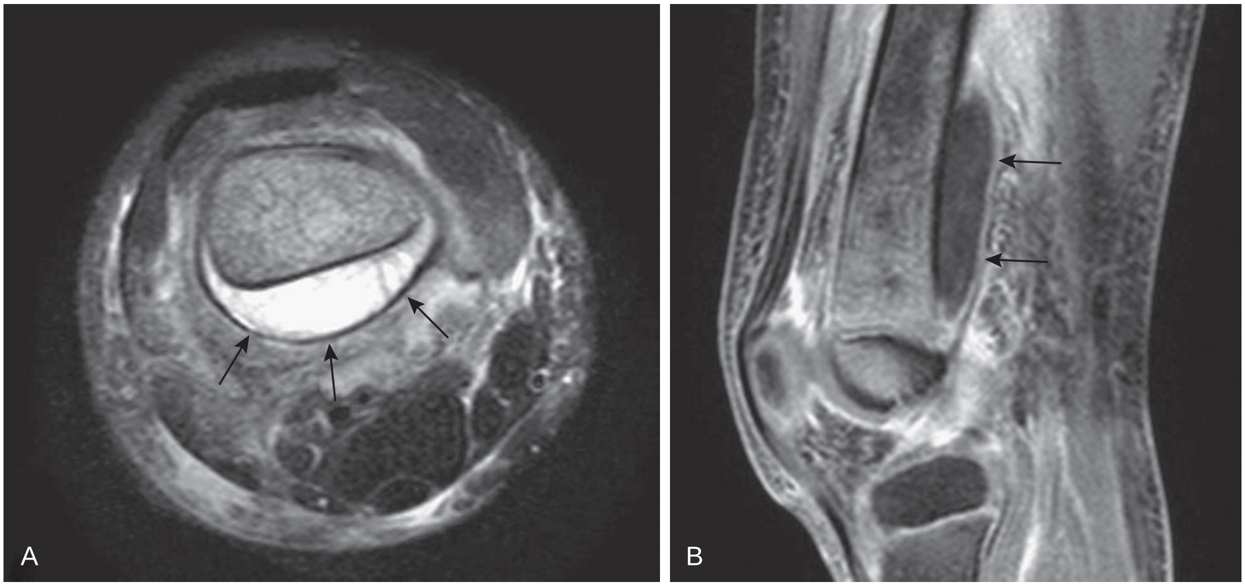

**Figure 137.13. Acute osteomyelitis of the distal femur in a 5-year-old boy.** (A) Axial T2-weighted fat-saturated MR image shows a large subperiosteal abscess *(arrows)* at the posterior aspect of the femur. Increased signal is seen within the bone, and there is adjacent soft tissue edema. (B) Sagittal T1-weighted, fat-saturated, post-gadolinium MR image shows the longitudinal extent of the subperiosteal abscess with peripheral enhancement *(arrows)*.

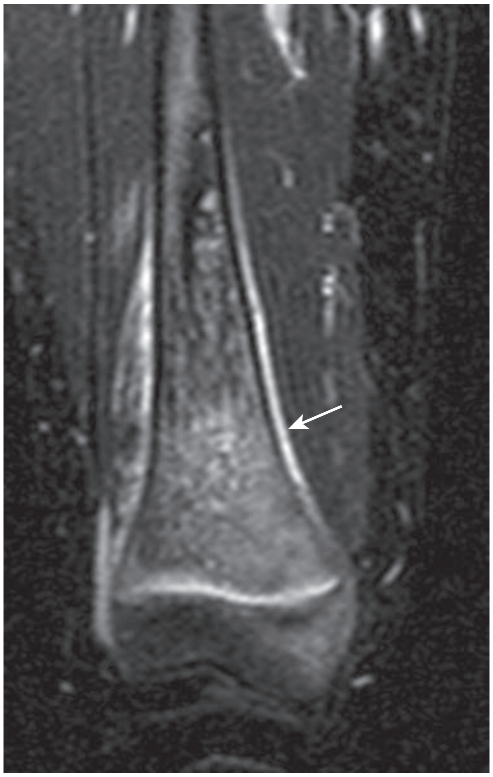

**Figure 137.14. Femoral osteomyelitis in a 13-year-old girl.** Coronal STIR MR image demonstrates a salt-and-pepper appearance of marrow edema and periosteal reaction *(arrow)*.

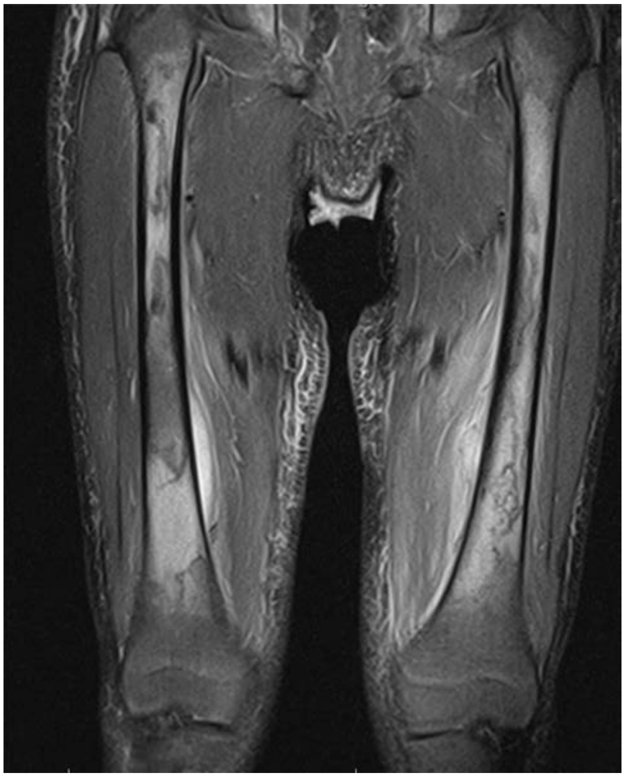

**Figure 137.15. Bilateral acute femoral osteonecrosis in a 5-year-old boy with sickle cell disease.** Coronal STIR MR image demonstrates heterogeneous marrow and juxta-cortical soft tissue edema. Juxta-cortical fluid collections along the medial aspects of both femurs are seen, which showed rim enhancement on postcontrast images *(not shown)*. Surgical biopsy demonstrated changes of osteonecrosis.

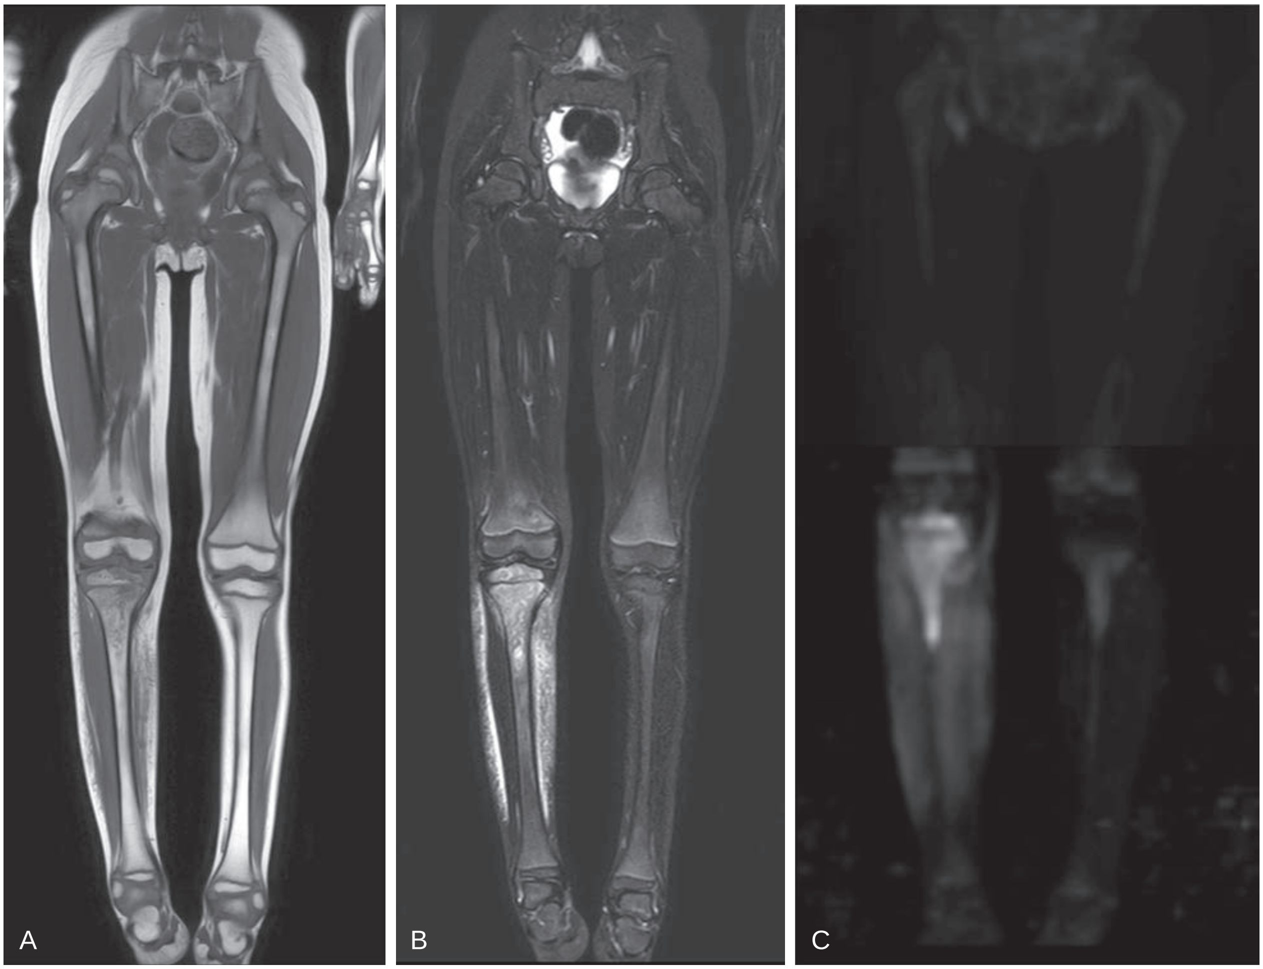

**Figure 137.16. Osteomyelitis in a 5-year-old girl with fever of unknown origin.** Lower extremity portion of a whole body MRI protocol including coronal T1-weighted (A), STIR (B), and diffusion-weighted whole-body imaging with background body signal suppression (DWIBS) (C) images show decreased signal intensity on T1-weighted images and increased signal intensity the STIR and DWIBS sequences within the right proximal tibial metaphysis, diaphysis, and epiphysis, and adjacent soft tissue edema. Biopsy confirmed osteomyelitis.

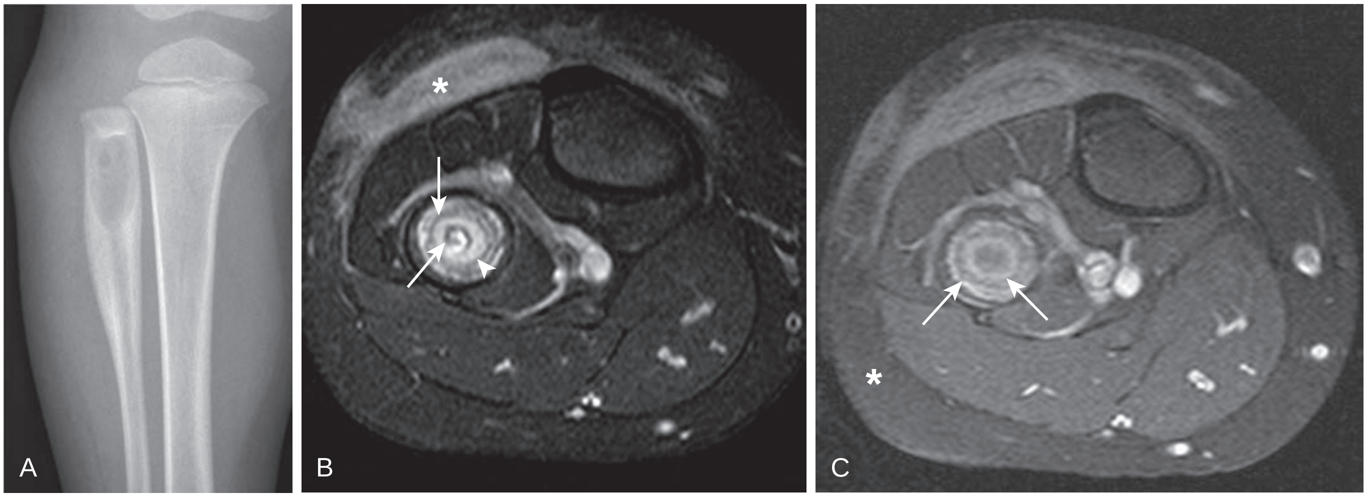

**Figure 137.17. Brodie abscess in a 3-year-old boy.** (A) Radiograph demonstrates a lytic lesion in the proximal fibula with laminated thick periostitis. Axial T2-weighted fat-saturated MR image (B) shows a layered appearance with intermediate signal *(arrowhead)* between inner and outer rims of lower signal intensity *(arrows)* and a more central hyperintense region. Also note the soft tissue phlegmon/early abscess formation *(asterisk)*. On an axial T1-weighted, fat-saturated, postgadolinium MR image (C) a rim of low signal sclerosis *(outer arrow)* surrounds an inner rim of enhancing granulation tissue *(inner arrow)*, which surrounds the nonenhancing abscess.

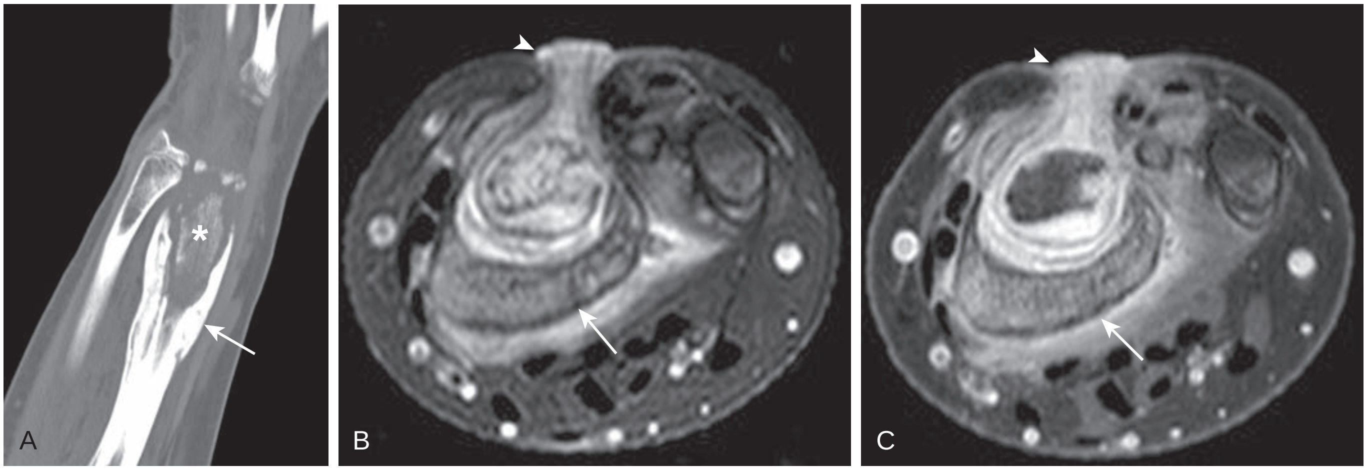

**Figure 137.18. Chronic osteomyelitis of the distal radius in a 13-year-old girl.** (A) Coronal reformat CT image shows involucrum *(arrow)* surrounding sequestrum *(asterisk)*. Axial T2-weighted fat-saturated (B) and T1-weighted fat-saturated (C) postgadolinium MR images show involucrum *(arrow)* that surrounds the nonenhancing sequestrum. Note granulation along the sinus tract that extends from the radial metaphysis sequestrum and abscess to the skin surface *(arrowhead)*.

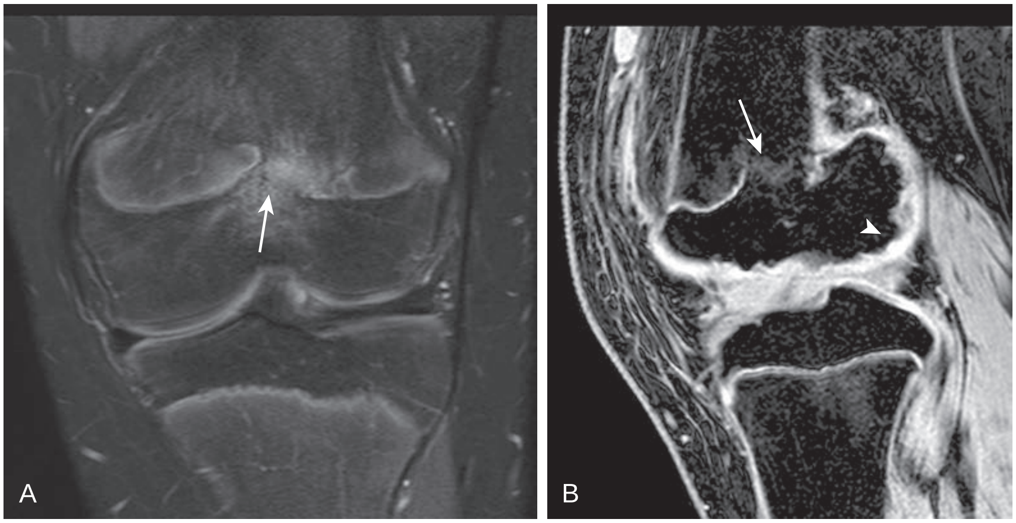

**Figure 137.20. Remote history of distal femoral osteomyelitis and septic arthritis in a 14-year-old boy.** Physeal bar *(arrows)* and femoral condylar epiphyseal irregularity *(arrowhead)* are seen on coronal T2-weighted fat-saturated (A) and gradient recalled echo sagittal (B) MR images.

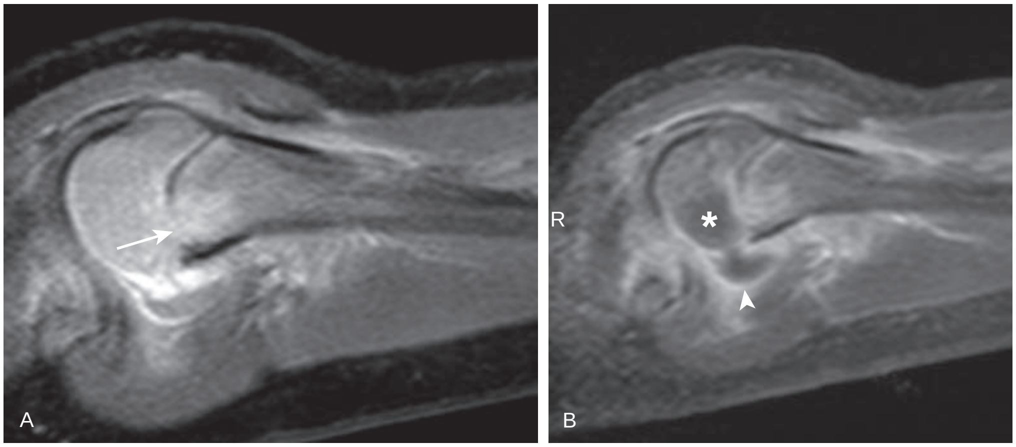

**Figure 137.21. Acute proximal humeral osteomyelitis and septic arthritis in a 3-month-old boy.** (A) Sagittal STIR MR image demonstrates proximal metaphyseal edema with physeal involvement *(arrow)*. (B) Sagittal T1-weighted postgadolinium MR image demonstrates glenohumeral effusion with synovial enhancement *(arrowhead)* and nonenhancing humeral epiphyseal cartilage, consistent with chondral involvement *(asterisk)*.

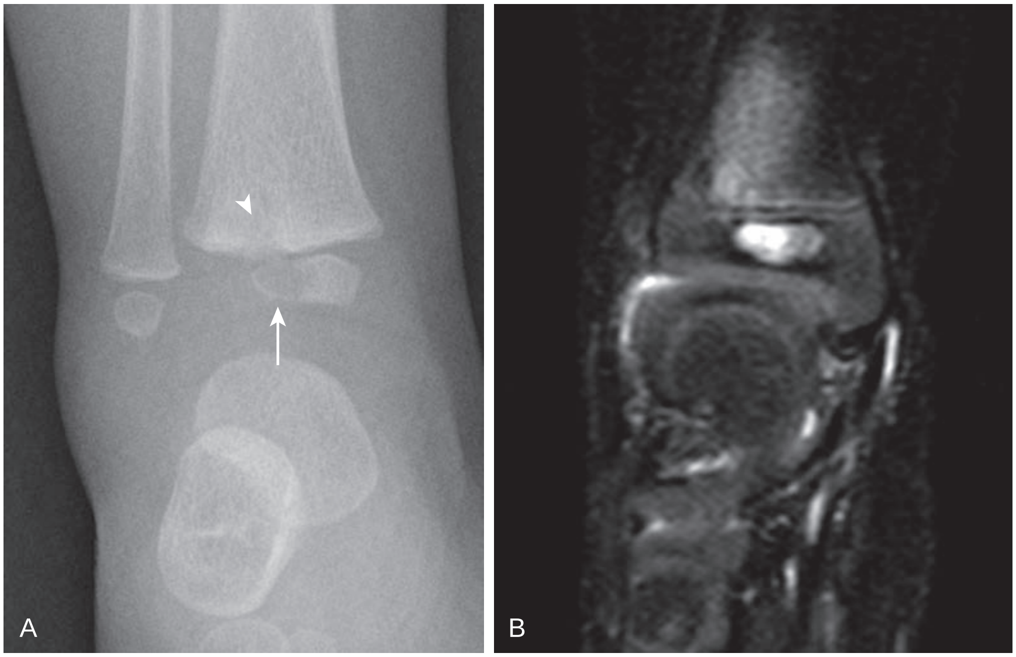

**Figure 137.22. Epiphyseal osteomyelitis in a 1-year-old girl.** (A) Radiograph demonstrates lucency within the epiphysis *(arrow)* and metaphysis *(arrowhead)*. (B) Coronal STIR MR image demonstrates epiphyseal bone abscess and metaphyseal edema.

## Fungal Osteomyelitis

Fungal infections of bone are becoming more common as the immunosuppressed population increases. *Aspergillus*, *Candida*, *Histoplasma*, *Blastomyces*, and other pathogens have been implicated. The radiographic changes are similar to those of chronic pyogenic osteomyelitis or tuberculosis (TB): destruction of bone and periosteal reaction with areas of cortical thickening and trabecular sclerosis. Fungal osteomyelitis may be multicentric, masslike, and may superficially mimic osteonecrosis.[32,36,37]

## Tuberculous Osteomyelitis

***Etiology, Pathophysiology, and Clinical Presentation.*** Although osseous TB is a relatively rare condition today, cases are still encountered that are not diagnosed until an extensive workup has been completed. Hematogenous metastases of tubercle bacilli to the skeleton may take place early during the active phase of the primary complex in the thorax or later from postprimary tuberculous foci. Musculoskeletal involvement of TB is seen in approximately 10% to 15% of all TB cases.[38] After implantation in the bone, an immediate active inflammatory reaction may develop, or the bacilli may be dormant for years until activated by local factors, such as trauma to the bone or joint. The synovial surface may be infected before the bones are involved; the infection may then spread from the joint into the contiguous epiphysis and metaphysis. In a large South African experience, the distribution of childhood skeletal TB is 60% to 70% vertebral, 20% to 25% large joints, and 10% to 15% tubular and flat bones.[39]

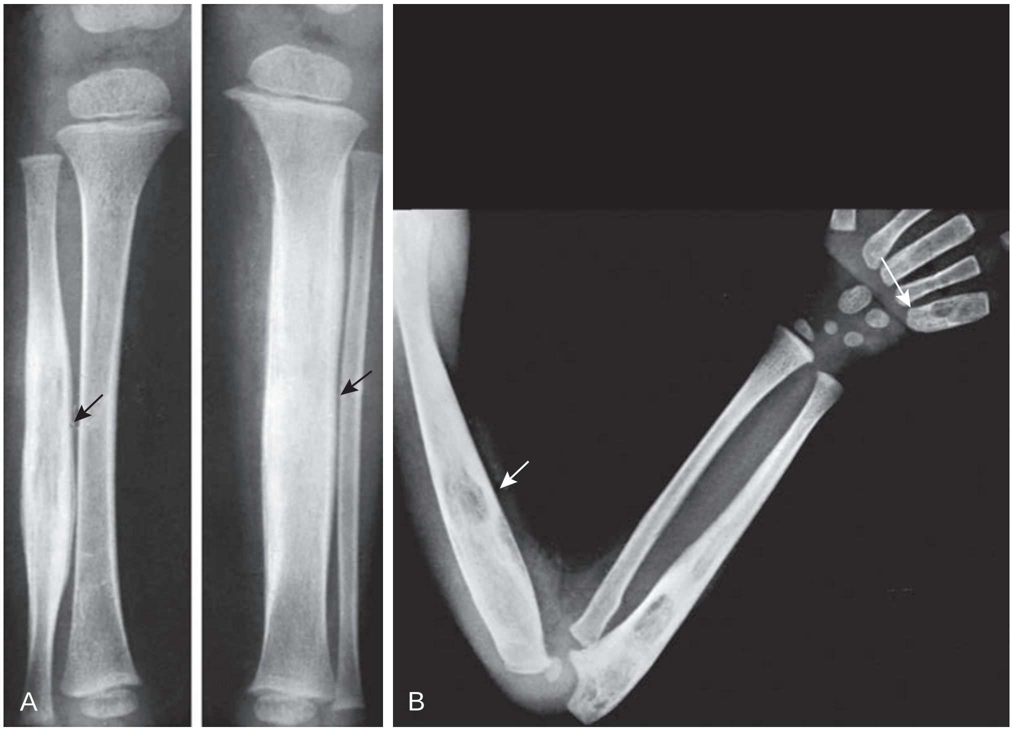
***Imaging.*** TB produces a chronic inflammatory reaction in the bones similar in its macroscopic aspects to chronic pyogenic osteomyelitis. Local necrosis of the intraosseous tissues develops at the site of implantation and is then followed by regional decalcification and bone destruction. Spread of infection takes place through the same pathways as those described in the pathogenesis of pyogenic osteomyelitis. During infancy and early childhood, when the epiphyseal cartilages are relatively thick, direct transfer of the infection from the joint to the bone, or infection across joints, is uncommon. The articular cartilages are preserved longer in tuberculous osteomyelitis and arthritis than in pyogenic arthritis because of the lack of a destructive proteolytic enzyme in tuberculous exudates.[40] Sinus formation and cold abscesses are common; involucrum formation and sequestration are rare.

The radiographic findings also are similar to those of chronic pyogenic osteomyelitis, so TB should be added regularly to the differential diagnosis of focal bone disease. Unlike pyogenic osteomyelitis, radiographs are usually abnormal at the initial clinical presentation of tuberculous osteomyelitis.[38]

Certain imaging features can suggest the diagnosis of TB. In the metaphyses and epiphyses, destruction of bone is more prominent than production of bone (Fig. 137.23).[40] The joint space is characteristically preserved in the early phases of tuberculous arthritis. The epiphysis is a site of predilection in primary skeletal TB. In the diaphyses of tubular bones, long segments may exhibit destructive and productive changes, whereas metaphyseal regions are unaffected (e-Fig. 137.24). Sometimes, sharply defined rarefactions are present that gave rise to the term *cystic TB* of bone. In the short bones of the hands and feet, tuberculous lesions may cause bone expansion, so-called spina ventosa (Fig. 137.25). Skeletal TB may affect multiple sites, and a bone scan is recommended to detect the presence of quiescent lesions. MRI is useful in certain cases and clearly demonstrates the full extent of the bone marrow, subperiosteal, and soft tissue involvement as well as any extension into the adjacent joint. TB joint and tenosynovial involvement can mimic juvenile idiopathic arthritis because of its chronic nature and because it can produce rice bodies.[41]

When multifocal at presentation, TB (osteitis cystica tuberculosa multiplex) and fungal infections may superficially mimic metastatic disease.

***Treatment.*** The standard treatment for TB is multidrug therapy inclusive of isoniazid, rifampin, pyrazinamide, and ethambutol for a minimum of 6 to 9 months.[38] Extrapulmonary TB treatment is



**e-Figure 137.24. Multiple sites of tuberculous diaphysitis with cold abscesses on the dorsal surfaces of the hands in an 18-month-old boy.** (A) Lower extremities. The left tibia and right fibula are enlarged; the medullary canals are expanded, and the overlying cortex is thickened *(arrows)*. (B) Left upper extremity. The distal half of the humerus is enlarged into a sausage-shaped contour, and the cortex is thickened; the medullary canal is expanded and exhibits cystic rarefaction *(short arrow)*. The proximal half of the ulna is enlarged and irregularly cystic; its cortex is thickened. The fifth left metacarpal is expanded and irregularly lytic and osteoporotic *(long arrow)*. All of these lesions healed slowly but completely. On images made 2 years later, the skeleton appeared to be normal.

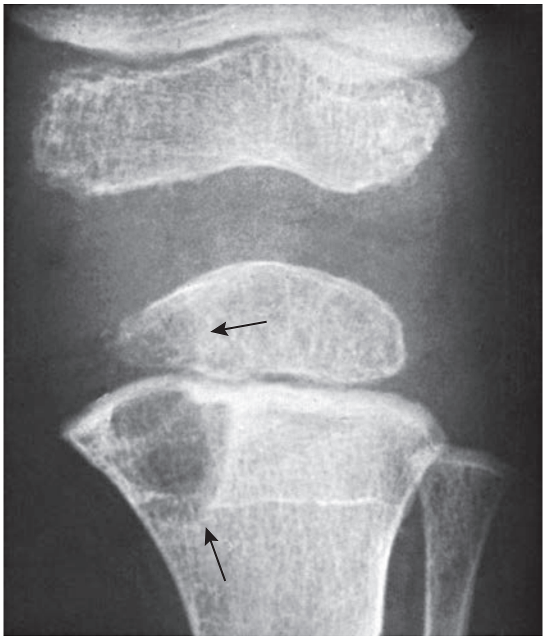


**Figure 137.23. Tuberculous metaphysitis and epiphysitis of the tibia and arthritis of the knee in a 3-year-old boy.** Large areas of destruction are present in the medial aspects of the metaphysis and the epiphyseal ossification center *(arrows)*.

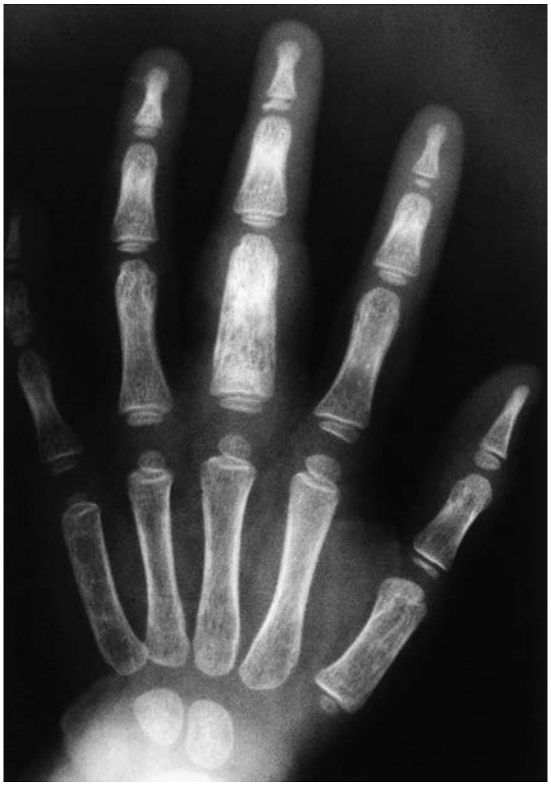

**Figure 137.25. Tuberculous dactylitis (spina ventosa) in the proximal phalanx of the third finger in a 2-year-old girl.** The whole diaphysis is involved, but the epiphysis is spared. Expansion of the rest of the phalanx shows mixed areas of bone destruction and sclerosis.

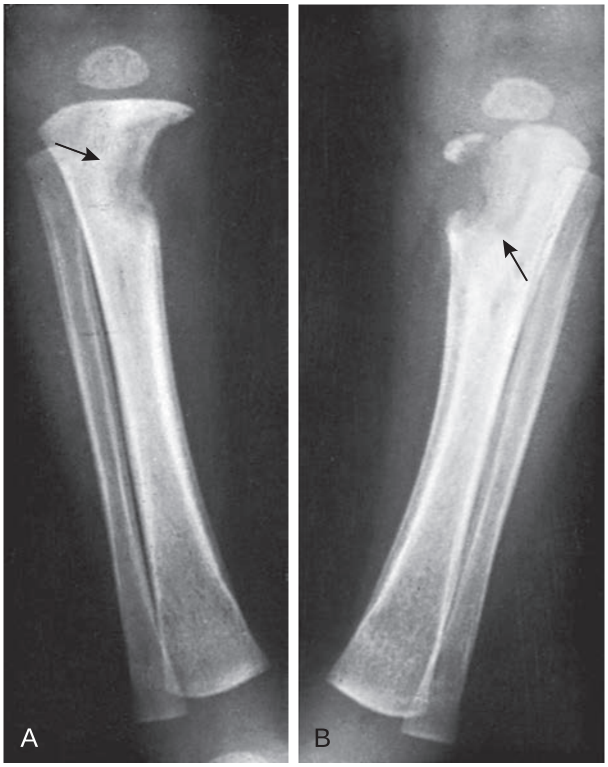

**Figure 137.28. Syphilitic metaphysitis of the proximal ends of the tibias (Wimberger sign) in a 2-month-old infant.** Frontal radiographs of the right (A) and left (B) legs show bilateral, symmetric, large areas of destruction of the spongiosa and overlying cortex are seen at the medial aspects of the tibias *(arrows)*. In the left tibia, the medial segment of the epiphyseal plate is partially destroyed. Note also diffuse periosteal thickening of the diaphyses.

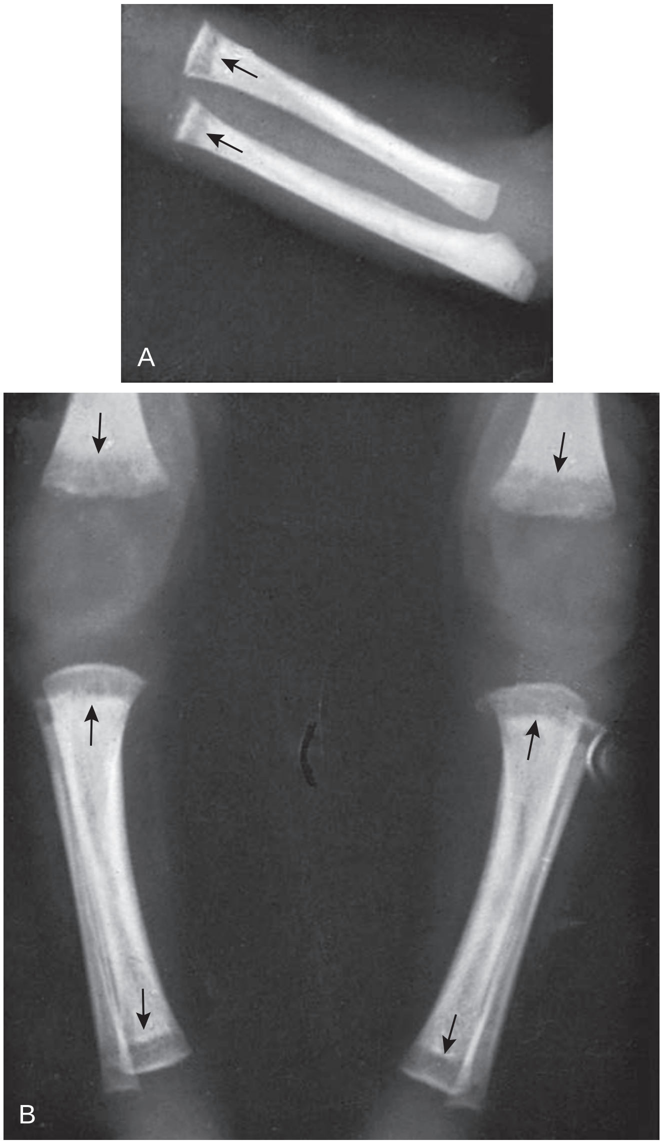
longer (12–18 months) because of relatively poor osseous and fibrous tissue penetration.

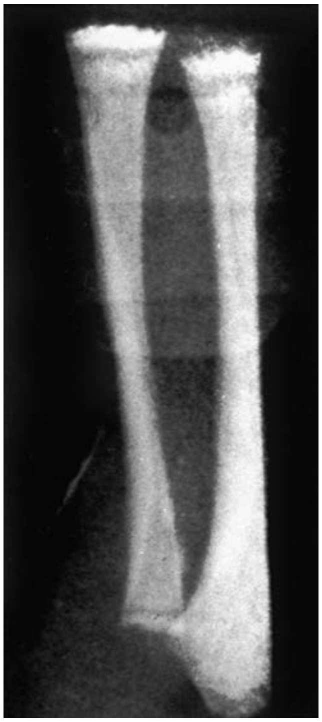
## Congenital Syphilis

***Etiology, Pathophysiology, and Clinical Presentation.*** Congenital syphilis (*Treponema pallidum*) causes hepatosplenomegaly, lymphadenopathy, skin rash, and anemia.[42] Bones are often involved, but this may not clinically or radiologically manifest in the first weeks of life. Bone pain in one or more extremities may be severe and result in lack of movement of those extremities, a condition termed *Parrot pseudoparalysis.* Syphilis of bone can be suggested on the basis of radiologic signs, when it has not been considered on clinical grounds. The diagnosis, however, still rests on appropriate serologic tests. Two main forms are observed, infantile and juvenile, and their radiographic features are different.

***Imaging.*** The unique imaging characteristic of *infantile syphilis* is multiple bone involvement with almost selective localization in the metaphyses. Broad bands of metaphyseal radiolucency were considered evidence of "metaphysitis" but are now known to be nonspecific responses to the stress of disseminated infection.[43] Syphilitic granulation tissue can, however, occur in these regions (e-Fig. 137.26). Radiographically, the two causes cannot be distinguished, but when associated with metaphyseal serration, the so-called sawtooth metaphysis (e-Fig. 137.27), the diagnosis of congenital syphilis is practically ensured. Similar diagnostic "specificity" is provided by the Wimberger sign after the newborn period, when destructive foci are found in the metaphyseal regions of tubular bones, particularly the medial tibial metaphyses at the knee (Fig. 137.28). Metaphyseal destructive lytic lesions may



**e-Figure 137.26. Syphilitic metaphysitis in a 1-month-old former premature infant.** Radiographs show deep segments of diminished density *(arrows)*. The spongiosa in these segments has been replaced by radiolucent syphilitic granulation tissue. (A) Upper limb. (B) Lower limbs.



**e-Figure 137.27. Newborn infant with congenital syphilis and sawtooth metaphysis.** This patient had a rash and mucocutaneous lesions characteristic of the disease.

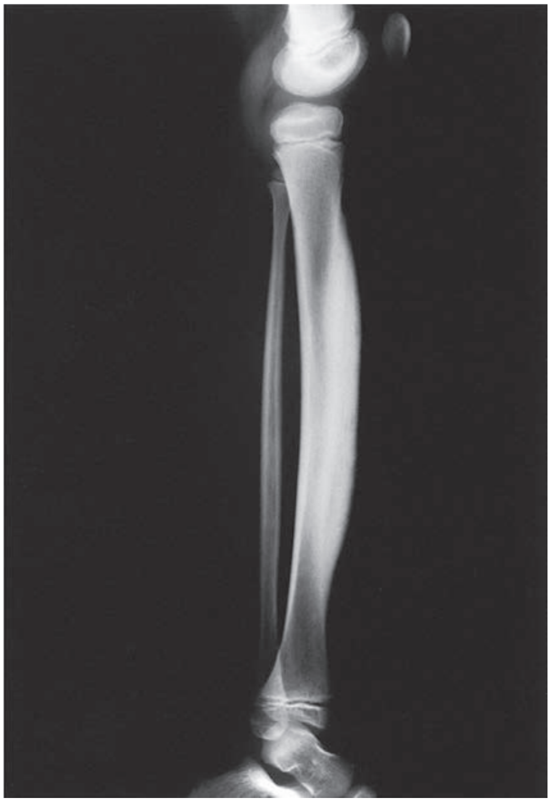


**Figure 137.30. Saber shin as a result of congenital syphilis in an 8-year-old boy.** Lateral view of the leg shows extensive anterior cortical and periosteal thickening of the tibial diaphysis.

lead to pathologic fractures, and child abuse is in the differential diagnosis.[44] Although metaphyseal lesions are characteristic of congenital syphilis, they are not pathognomonic and may be seen with ordinary osteomyelitis, hyperparathyroidism, skeletal infantile myofibromatosis, and metastases. Diaphyseal involvement, especially with periosteal new bone formation, also tends to occur after the first month and may be associated with destructive foci and even scattered focal cortical destruction and expansion of the medullary cavity (e-Fig. 137.29). The epiphyses are generally spared. Healing of the bone lesions in the infantile form of the disease occurs with or without therapy, usually without deformity.

Juvenile syphilis is observed radiographically in childhood and is manifested by diffuse or localized subperiosteal thickening of the cortex (Fig. 137.30). Associated focal destructive lesions, resembling cystic TB, occasionally are present. Thickening of the anterior cortex of the tibia is responsible for the "saber shin" deformity of congenital syphilis that appears in late childhood.[45]

## Septic Arthritis

***Etiology, Pathophysiology, and Clinical Presentation.*** The annual per capita incidence of septic arthritis in the United States is approximately 1 in 93,500.[1] *S. aureus* is the most commonly isolated organism, the majority of which are MRSA. The knee is most commonly affected joint (41.4%) followed by the hip (22.6%) and ankle (13.6%).

Bacterial entry into the joint can occur by two mechanisms: direct inoculation from a penetrating injury and hematogenous inoculation. The vascular synovium may be hematogenously inoculated.[14] Alternatively, inoculation may occur secondarily by way of osteomyelitis. This may occur with higher frequency in infants when transphyseal vessels extend from the metaphysis to the intraarticular epiphysis.[46]

Septic arthritis causes rapid cartilage loss and joint destruction and therefore is a medical and surgical emergency. Diagnosis is based on clinical grounds and laboratory data. A history of fever, nonweight bearing, an erythrocyte sedimentation rate above 40 mm/hour, and a white blood cell count greater than 12,000 cells/mm$^3$ are four consistent variables that occur frequently in the setting of septic arthritis as extensively studied in the hip.[47] When present in isolation, each of these individual variables has low accuracy for the diagnosis of septic arthritis, but when three or more of these variables are present at the same time, the chance of a positive diagnosis of septic arthritis of the hip is greater than 93%.[47]

Many nonbacterial entities may mimic septic arthritis; these include transient synovitis, juvenile idiopathic arthritis (JIA), Lyme arthritis, reactive joint effusions, posttraumatic arthritis, and epiphyseal osteonecrosis.

***Imaging.*** Radiography is the first line of imaging in the setting of suspected septic arthritis to rule out an obvious alternative cause for symptoms. The initial findings may be nonspecific soft tissue swelling about a joint. In certain joints—such as the elbow, knee, and ankle—a joint effusion may be seen and is best delineated on a lateral radiograph.

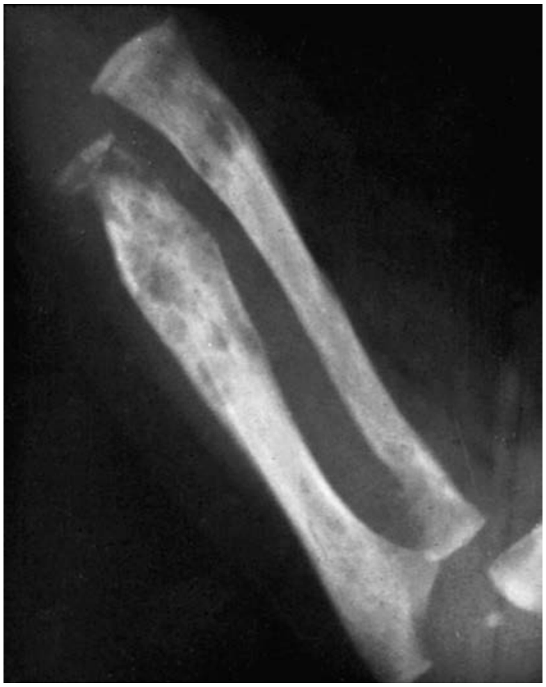
The role of US is to identify the presence or absence of an underlying joint effusion or to determine whether pathology is intraarticular or extraarticular, such as adjacent tenosynovitis.[48,49] When a joint effusion is present, no sonographic features are evident that predict the presence or absence of septic arthritis.[50–52] Capsular distension with anechoic or hypoechoic fluid is usually seen. Debris and septations within the joint, as well as hyperemic flow in the synovium, can be seen on power Doppler; but this can also be seen in JIA, transient synovitis (e-Fig. 137.31),[52] and posttraumatic arthritis.

The MRI findings of isolated septic arthritis are also nonspecific.[53,54] Synovial thickening, enhancement, effusions, and juxtasynovial soft tissue edema may be seen, but this is indistinguishable from transient synovitis and JIA. The role of MRI is not to diagnose septic arthritis but to identify the presence or absence of coexisting osteomyelitis (see Fig. 137.8), epiphyseal cartilage involvement (e-Fig. 137.32), and juxtasynovial muscle inflammation (Fig. 137.33) or abscesses, because this will affect medical and surgical management. Coexisting septic arthritis and osteomyelitis is frequent in children, particularly in children under 2 years of age.[55] When a joint effusion is present in the setting of metaphyseal osteomyelitis, the reported incidence of coexisting septic arthritis is approximately 75%.[56]

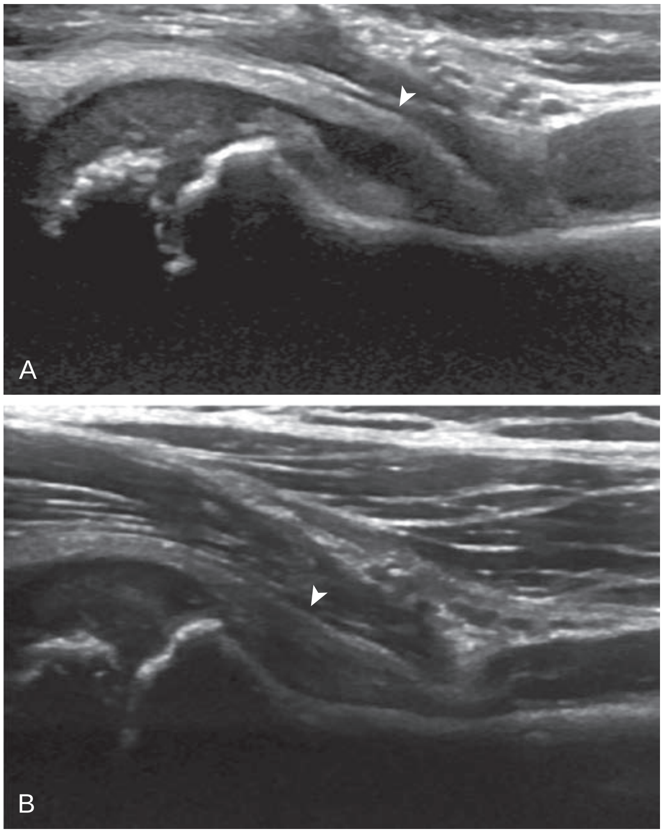
***Treatment.*** US may be used to both identify the presence or absence of a joint effusion and to provide needle guidance for diagnostic joint aspiration.[49] Emergent arthrotomy and washout is recommended to prevent complications of septic arthritis. If septic arthritis is a complicating feature of osteomyelitis, the underlying bone should also be debrided. Complications of septic arthritis include sepsis, chondrolysis, and osteonecrosis.[57] Antibiotic treatment is similar to the treatment of osteomyelitis at all ages: a total of 4 to 6 weeks of therapy.[58]

## Pyomyositis

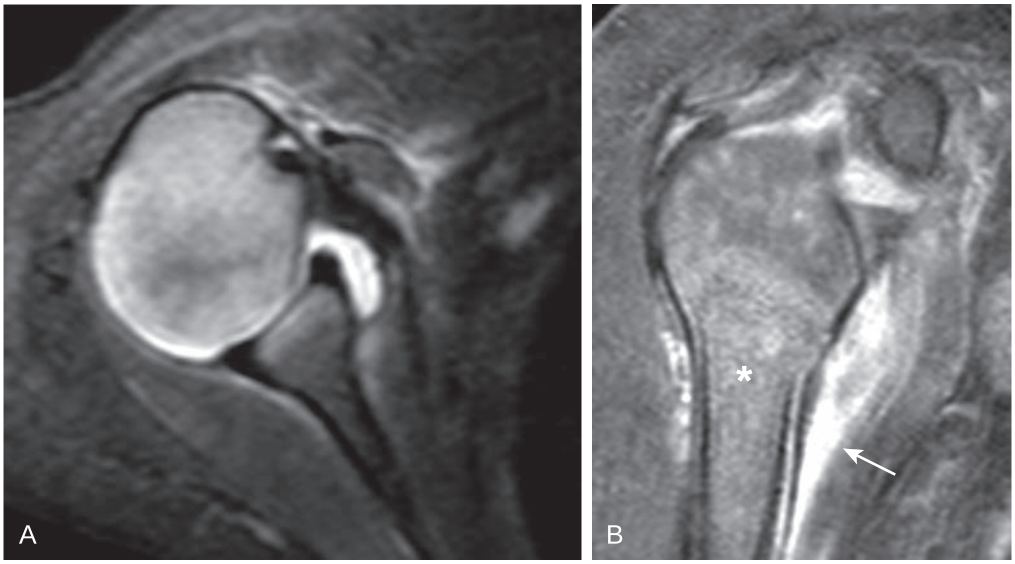
***Etiology, Pathophysiology, and Clinical Presentation.*** Pyomyositis is a localized primary infection of muscle characterized by progression to abscess formation that can mimic tumor, trauma (hematoma), osteomyelitis, septic arthritis, cellulitis, or thrombophlebitis. This disorder is endemic in Africa, South America, southeastern Asia, and the South Pacific; it is increasingly reported in temperate climates, including the northern United States. Pyomyositis occurs in otherwise healthy children and in those predisposed to infection by debilitating diseases,



e-Figure 137.29. Congenital syphilis with expansion and destructive metaphyseal and diaphyseal changes in a 3-month-old infant.



**e-Figure 137.31.** **Transient synovitis of the hip in a 1-year-old girl.** (A) Longitudinal sonogram of the symptomatic right hip shows capsular distension *(arrowhead)* because of a large effusion. (B) Sonogram of the asymptomatic left hip shows a normal appearance of the hip joint capsule *(arrowhead)* with only small amount of physiologic fluid.



**e-Figure 137.32.** **Glenohumeral septic arthritis related to humeral osteomyelitis in a 4-month-old boy.** (A) Axial T2-weighted fat-saturated MR image demonstrates a nonspecific glenohumeral joint effusion. B, Coronal T1-weighted, fat-saturated, postgadolinium MR image shows abnormal patchy enhancement of the proximal humeral epiphyseal cartilage, abnormal heterogeneous marrow enhancement *(asterisk)*, and periostitis with juxtacortical edema *(arrow)*.

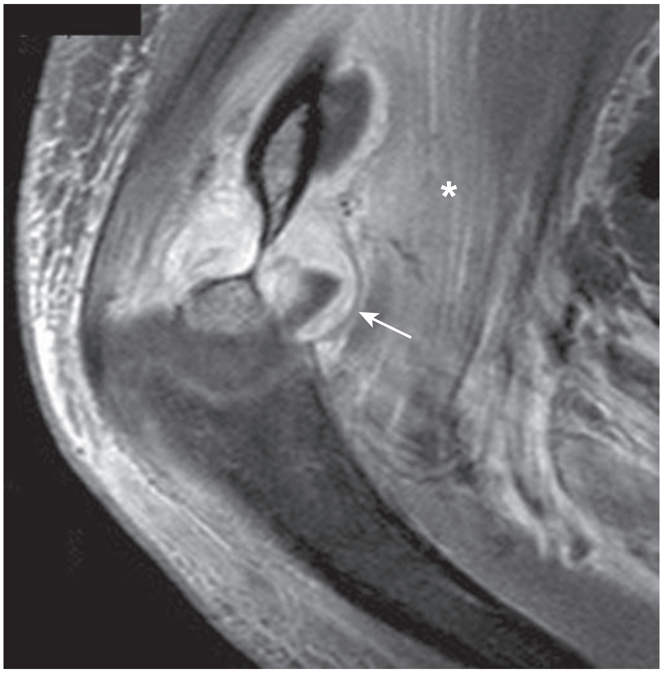


**Figure 137.33. Elbow septic arthritis and distal humeral osteomyelitis in an 11-year-old boy.** Sagittal T1-weighted, fat-saturated, postgadolinium MR image demonstrates thick synovial enhancement *(arrow)* and juxtasynovial myositis *(asterisk)*. Marrow hyperenhancement is also seen in the distal humerus.

including those with human immunodeficiency virus infection. *S. aureus* is the most commonly identified organism; it is isolated in 45% of cases in a U.S.-based study, followed by group A β-hemolytic streptococci (GABHS; 10%).[1] GABHS infections may occur in the setting of *Varicella* infection,[59] and multifocal pyomyositis may be seen as a complication of bacterial endocarditis. Secondary pyomyositis may also occur as the result of extension from adjacent osteomyelitis, particularly in the pelvis. Damaged muscle with some degree of underlying immune suppression and a source of bacteremia are the key predisposing elements.

Clinically, the gluteal muscles, thighs, and calves are more commonly affected than the upper extremities, trunk, and chest wall.[60] Approximately 25% of patients have a history of antecedent trauma. Usually, only a single muscle is involved. Early in the course of illness, patients experience low-grade fevers, general malaise, and dull, cramping pain.[61] The involved area lacks the cutaneous erythema usually evident with cellulitis, and it has a "woody" nonfluctuant feel. Fever usually occurs as infection advances. Infections of the pelvic musculature may clinically mimic osteomyelitis or septic arthritis by producing hip or groin pain. Infection of the piriformis muscle may irritate the adjacent sciatic nerve and produce pain that extends into the ipsilateral lower extremity.[62] Pyomyositis is usually accompanied by elevations in white blood cell count, erythrocyte sedimentation rate, and C-reactive protein level.

***Imaging.*** Early in the development of pyomyositis, the affected muscle is enlarged and edematous without a frank abscess. Without treatment, the process progresses to form an intramuscular abscess. US may be helpful in localizing relatively superficial sites of pyomyositis (Fig. 137.34).[63] Infections at deeper sites and infections that have not yet formed an intramuscular abscess are less readily detected with US.

MRI is the preferred modality for imaging of suspected pyomyositis, and it is particularly valuable in cases of pelvic involvement.[64,65] On MRI, the involved muscle appears enlarged and edematous with increased signal on T2-weighted and inversion recovery sequences. On T2-weighted images, the abscess is seen as high signal with a hypointense rim and less well-defined hyperintensity of the adjacent muscle (Fig. 137.35). Postgadolinium T1-weighted images best reveal the abscess, and the abscess wall densely enhances (see Fig. 137.34). Changes may result from associated cellulitis and include skin thickening, stranding of subcutaneous fat, and swelling of fascial planes; these findings are best seen on fat-saturated T2-weighted and inversion recovery images. A sympathetic effusion may be present if infection is near a joint.

***Treatment.*** Appropriate antibiotic therapy is usually curative for pyomyositis. More aggressive abscesses may require abscess drainage and debridement of muscle.[66]

## Necrotizing Fasciitis/Cellulitis

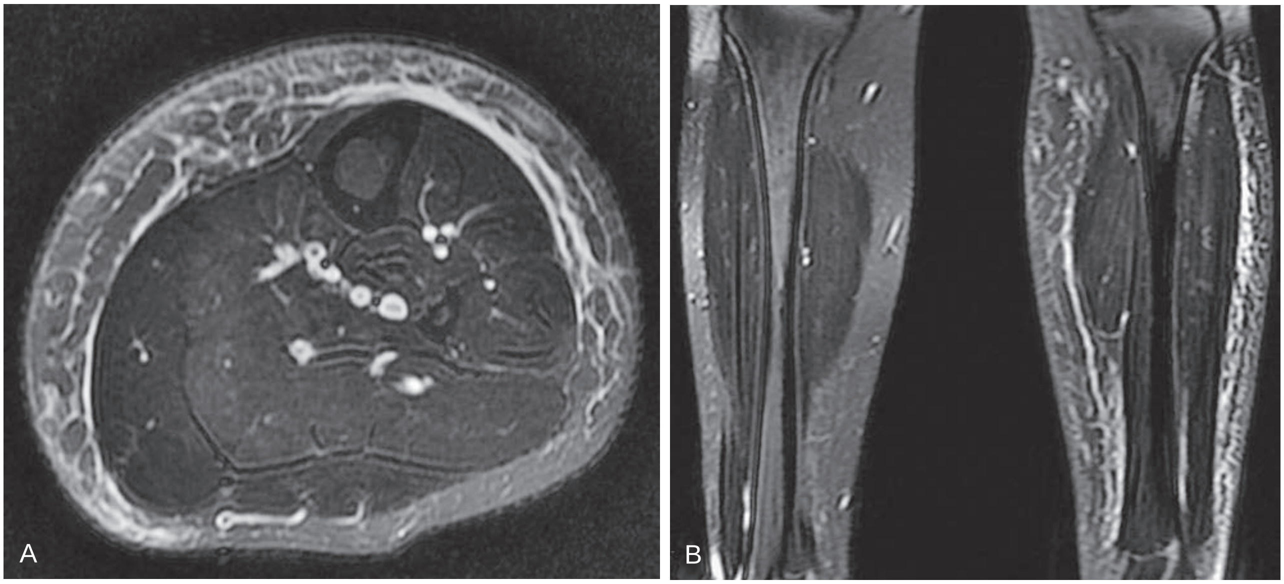
***Etiology, Pathophysiology, and Clinical Presentation.*** Necrotizing fasciitis is a rapidly progressive, sometimes fatal soft tissue infection that characteristically involves the deep fascia of the extremities and trunk.[61] The disease tends to affect the elderly and those with impaired immunity, but it can occur in immune-competent patients of any age. Underlying skin infection related to lesions such as furuncles, insect bites, and even minor trauma or surgery has been associated. Necrotizing fasciitis is most commonly a polymicrobial infection with both aerobic and anaerobic organisms. In children with chicken pox, secondary infection of vesicular skin lesions with *S. aureus* or GABHS has been linked to development of cellulitis and, less frequently, necrotizing fasciitis.[67]

The early clinical presentation of necrotizing fasciitis is nonspecific and may be accompanied by vague complaints of fever and malaise with rapid progression to sepsis and acute renal failure. Initial soft tissue findings are those of warmth and induration. A high index of suspicion is paramount for early diagnosis.

***Imaging.*** Pathologic changes and extent of necrotizing fasciitis and cellulitis are detected most sensitively on MRI with fat-suppressed, T2-weighted, STIR sequences, and postgadolinium, fat-suppressed, T1-weighted imaging (Fig. 137.36). Cellulitis is characterized by high T2 signal thickening and gadolinium enhancement with or without fluid collections in the subcutaneous tissue and superficial fascia (e-Fig. 137.37). Necrotizing fasciitis should be considered when these changes extend to the deep fascia. Patients with necrotizing fasciitis may have thick (>3 mm) fascial signal intensity or low signal intensity in the deep fascia on T2-weighted images, along with focal or diffuse nonenhancing portions of deep fascia and involvement of three or more compartments in one extremity.[68] Soft tissue gas appears as areas of signal absence with susceptibility artifact. To help guide therapy, it is important to distinguish by MRI whether necrotizing fasciitis is related to underlying osteomyelitis and/or septic arthritis versus infection confined to the muscles and fascia.

Edema of fascia and muscles is nonspecific on MRI and overlaps with that of other pathologic conditions, including dermatomyositis, pyomyositis, and lymphedema. Additionally, in the very early stages of necrotizing fasciitis, deep fascial involvement may be minimal or lacking. Although absence of deep fascial involvement on MRI is fairly reliable for exclusion of necrotizing fasciitis, ultimate patient management relies on a combination of imaging and clinical findings.

***Treatment.*** Cellulitis is amenable to medical therapy with intravenous antibiotics; necrotizing fasciitis is a life-threatening emergency that requires additional urgent surgical debridement of necrotic tissue.[69] Therefore distinction between these two entities is critical for patient management.



**e-Figure 137.37. Cellulitis.** This 16-year-old girl presented with left leg swelling, fever, and rash. Axial (A) and coronal (B) T2-weighted MR images show reticulated high signal in the subcutaneous fat and superficial fascia without deep involvement.

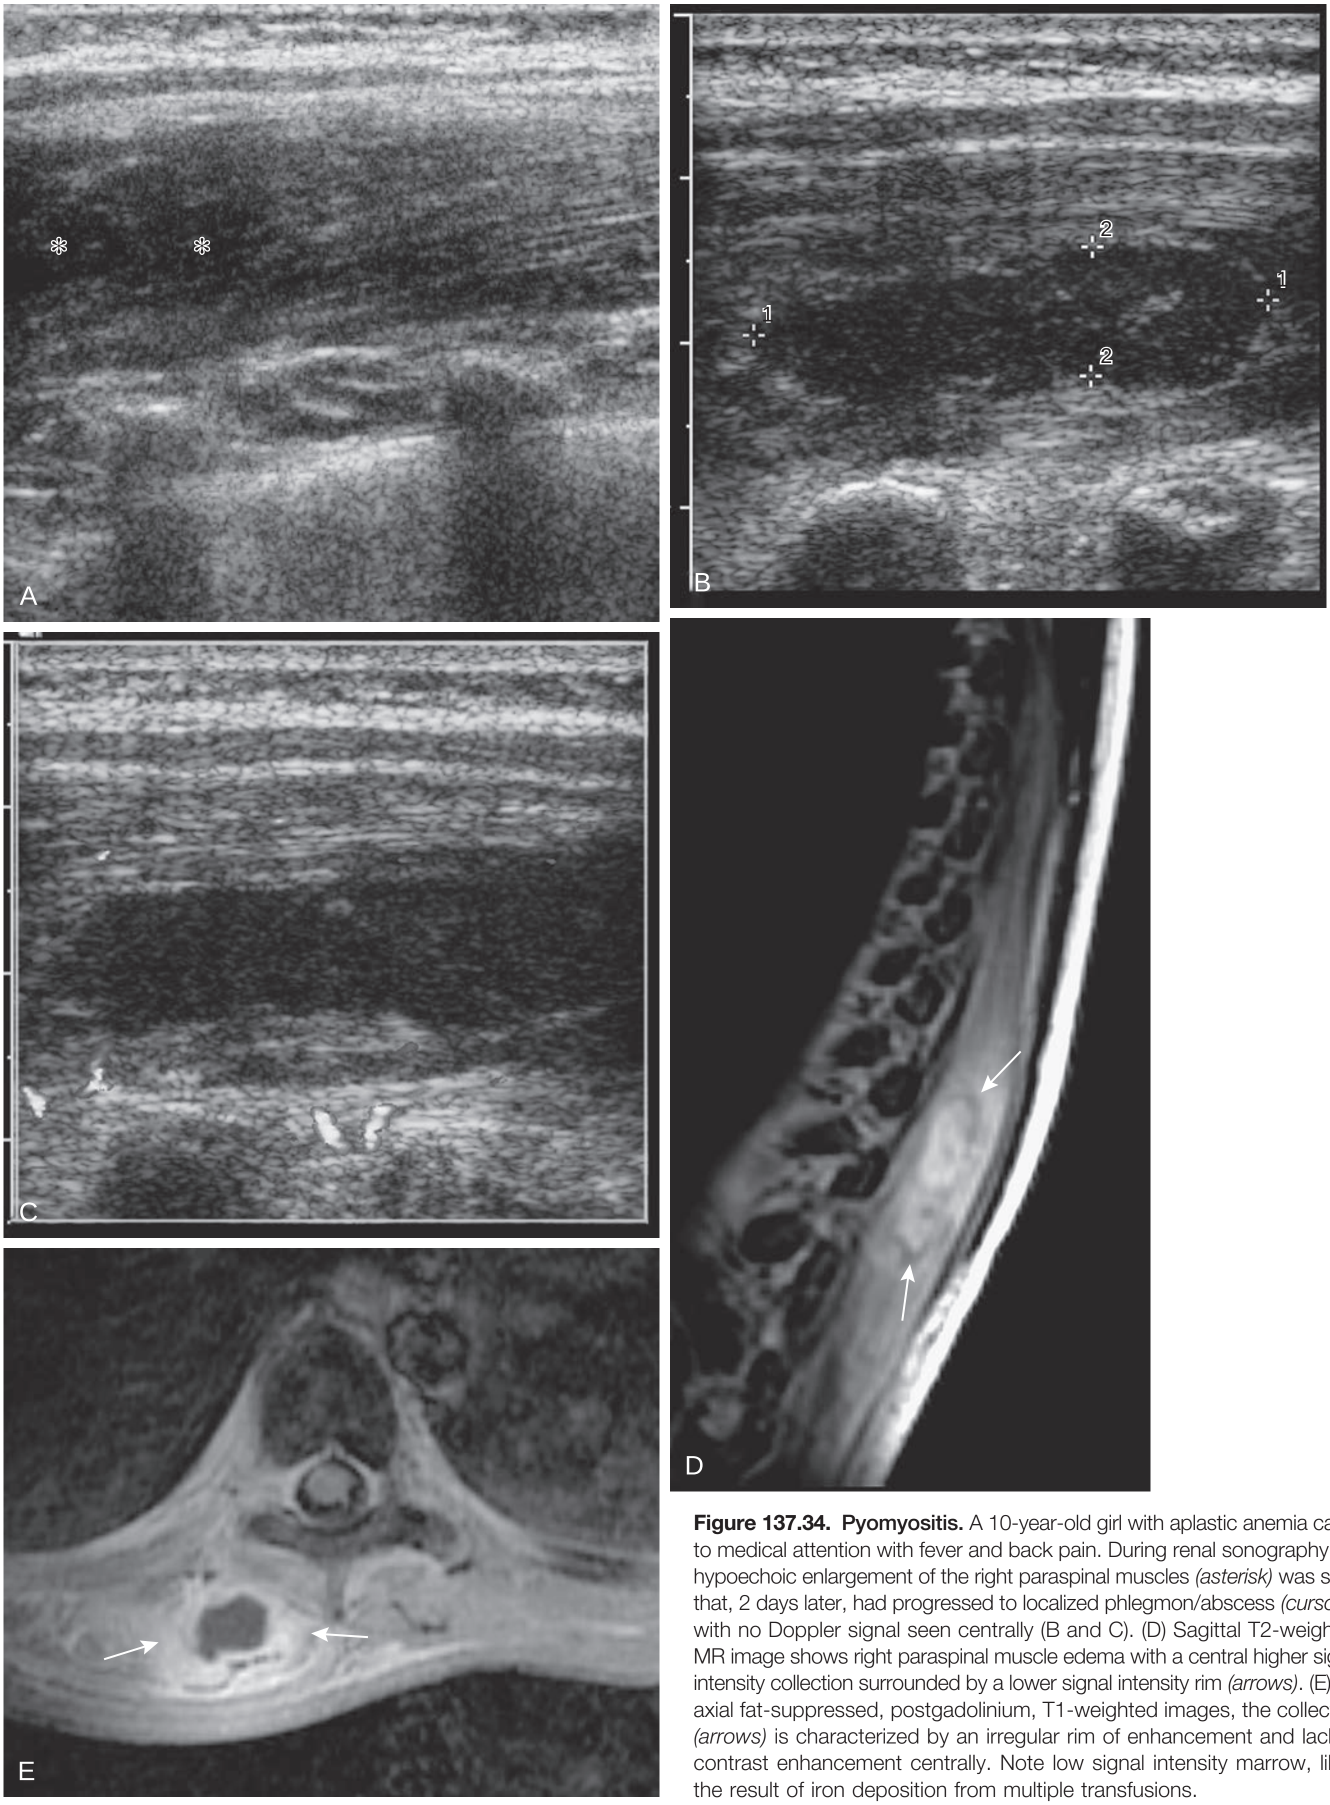


**Figure 137.34. Pyomyositis.** A 10-year-old girl with aplastic anemia came to medical attention with fever and back pain. During renal sonography (A), hypoechoic enlargement of the right paraspinal muscles *(asterisk)* was seen that, 2 days later, had progressed to localized phlegmon/abscess *(cursors)*, with no Doppler signal seen centrally (B and C). (D) Sagittal T2-weighted MR image shows right paraspinal muscle edema with a central higher signal intensity collection surrounded by a lower signal intensity rim *(arrows)*. (E) On axial fat-suppressed, postgadolinium, T1-weighted images, the collection *(arrows)* is characterized by an irregular rim of enhancement and lack of contrast enhancement centrally. Note low signal intensity marrow, likely the result of iron deposition from multiple transfusions.

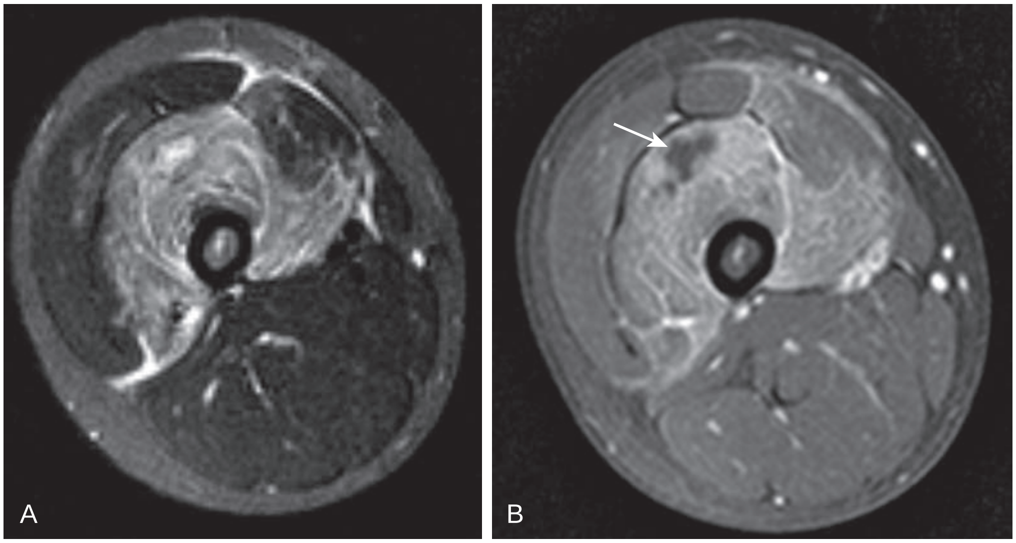

**Figure 137.35.** Pyomyositis and abscess in a 6-year-old girl. Pyomyositis and early abscess formation *(arrow)* in the quadriceps mechanism seen on axial STIR (A) and postgadolinium T1 fat-saturated (B) MR images.

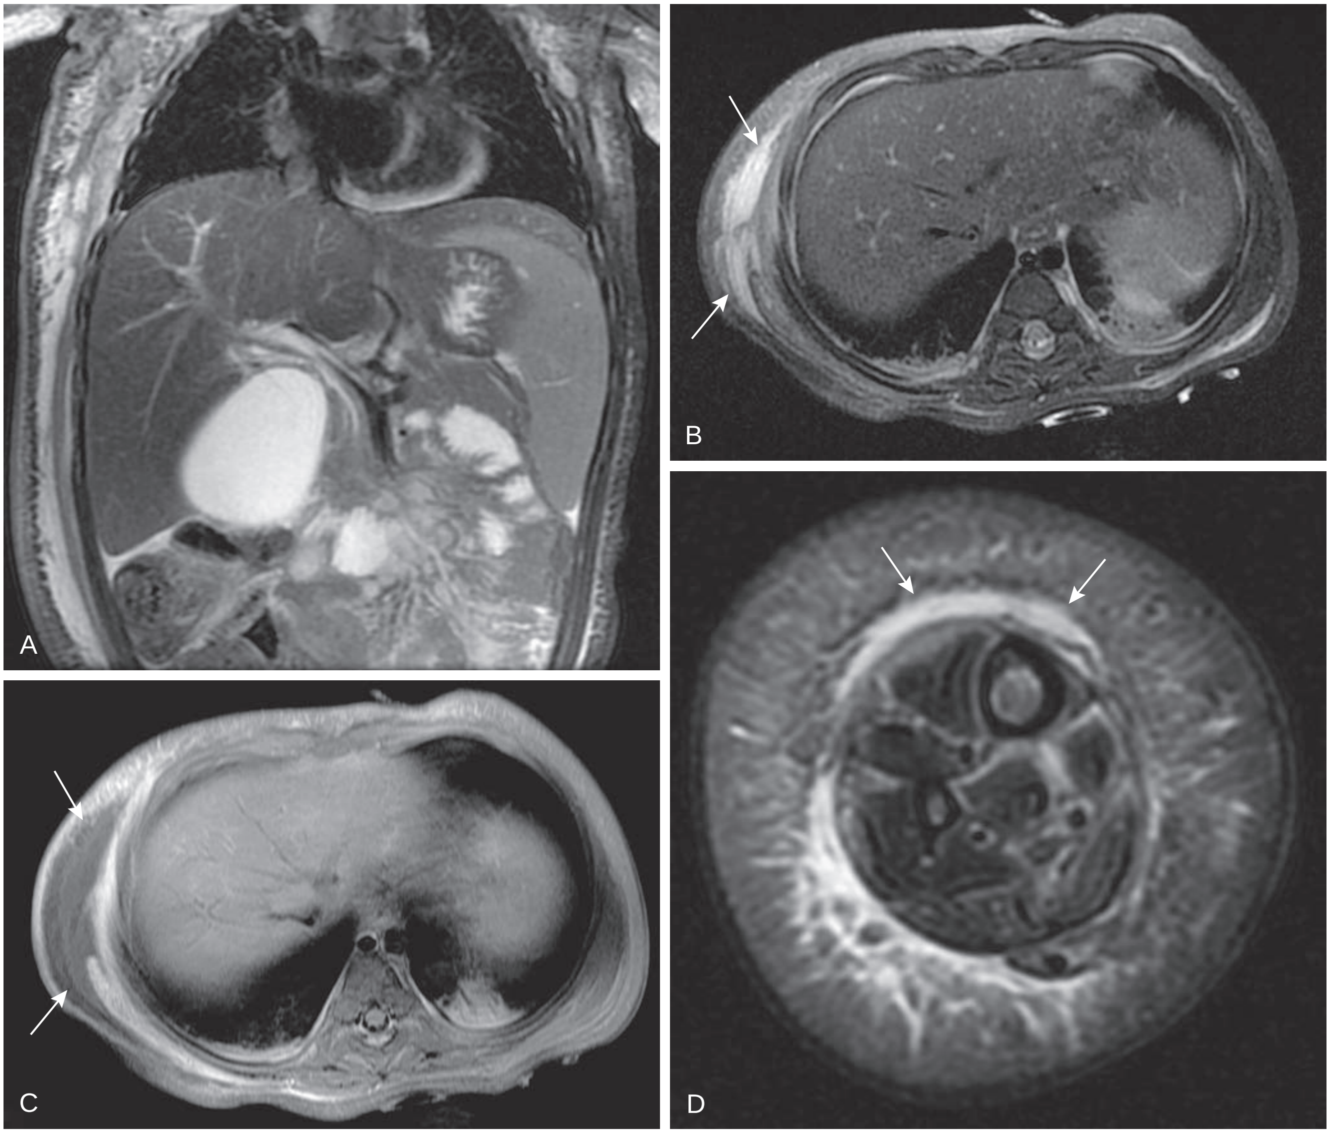

**Figure 137.36. Necrotizing fasciitis.** A 1-year-old girl with a 2-week history of progressive fever, leukocytosis, and swelling of the right side of the chest wall and right calf. Coronal (A) and axial (B) T2-weighted MR images show asymmetric high signal in the muscle and superficial and deep fascial layers of the right chest and abdominal wall *(arrows)*. Axial fat-suppressed T1-weighted image (C) after intravenous gadolinium administration shows enhancement of these areas with more superficial nonenhancing fluid lacking rim enhancement *(arrows)*. Similar changes *(arrows)* are seen in the right lower leg on axial T2-weighted (D) and postcontrast fat-suppressed T1-weighted images (E). Biopsy of both sites showed acute inflammation with coagulative necrosis. Cultures were negative, but dramatic clinical improvement was noted with intravenous antibiotic therapy.

*Continued*

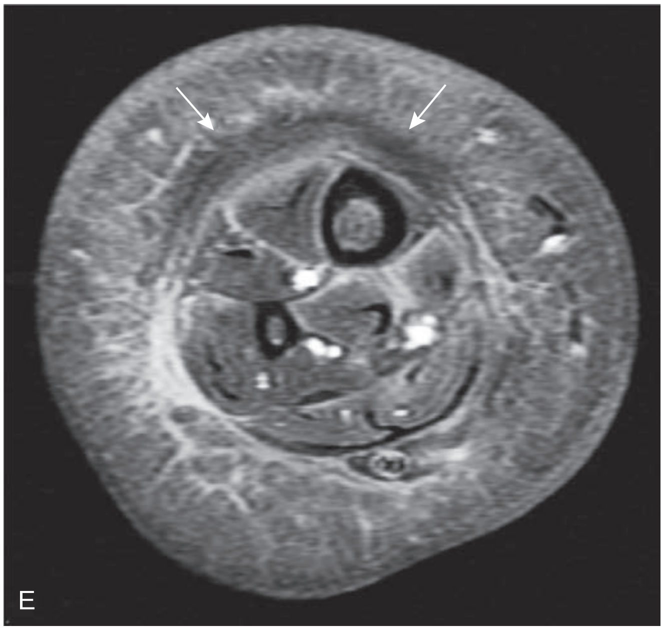

**Figure 137.36, cont'd.**

## KEY POINTS

- Radiographs should always be obtained before advanced imaging to rule out obvious alternative causes for symptoms, such as a fracture.
- When infection is a concern and symptoms are nonlocalizing, whole body MRI or bone scan can be performed. If symptoms are localizing, a focused MRI is recommended.
- When osteomyelitis is present, identify and measure all abscesses, their location, and whether there is secondary involvement of a nearby joint.
- US and MRI are not able to distinguish pyogenic and nonpyogenic joint effusions.

## Acknowledgment

This chapter includes material from Chapter 159, "The Soft Tissues," in a previous edition of this text, originally written by Kathleen H. Emery, MD.

## SOFT TISSUE TUMORS

### Overview

In general, clinical presentation and findings guide diagnostic imaging in the assessment of soft tissue neoplasms. In children with subtle masses, the primary objective of imaging is to confirm or exclude the presence of a mass. In children with obvious masses, imaging is performed to assess the local extent of the tumor, to provide a differential diagnosis, and to guide potential biopsy.

Most soft tissue tumors in children are benign.[1] When the mass is hard and fixed, conventional radiographs are often performed to determine whether an underlying bone lesion is present that is simulating, or is associated with, a soft tissue mass. Conventional radiographs may show secondary changes in the configuration of adjacent bones and may also reveal the presence of cortical bone erosion, periosteal reaction, and soft tissue calcifications. Occasionally, radiolucency indicates the presence of a fat-containing tumor.[1]

Superficial masses are often assessed by ultrasonography (US), a modality that is easily accessible, lacks ionizing radiation, and rarely requires sedation.[2] Color and spectral Doppler analysis can assess and characterize vascularity.

Nuclear medicine also plays a significant role in the assessment of soft tissue tumors. Many soft tissue sarcomas (STS) are detected by gallium-67 and thallium-201 scintigraphy.[3,4] Technetium-99m–methylene diphosphonate (99mTc-MDP) bone scintigraphy may be performed to identify local bone involvement and distant skeletal metastases. In addition, positron emission tomography (PET) and PET computed tomography (CT) are playing an increasing role in initial tumor assessment and evaluation of tumor response and recurrence.

With continuing advances in magnetic resonance imaging (MRI), the role of CT has become limited. CT offers similar but more detailed information than that provided by conventional radiographs. Two areas in which CT has a clear advantage over MRI are in the detection of calcification, such as in myositis ossificans, and when lesions are present along the anterior abdominal wall or chest, where artifact may significantly degrade MRI quality.[1] Also, CT of the lungs is usually performed to assess for metastatic disease.

MRI is the imaging study of choice for assessment of most soft tissue tumors. The superb soft tissue contrast and multiplanar images provide details on the tumor's extent and relationship to underlying anatomic structures.

Although MRI technology continues to evolve, the basic tenets of the MRI examination of a soft tissue tumor remain constant. First, quality images should cover the entire tumor, including its margins and important adjacent structures, and they should include any needle biopsy tracts that may have to be excised at the time of surgical resection. The area that contains the tumor should be imaged in at least two orthogonal planes. T1- and T2-weighted images should be obtained. Fat saturation is often added to confirm the presence of fat in a lesion and/or to highlight the presence of enhancement after intravenous gadolinium administration. Short-tau inversion recovery (STIR) sequences are also useful, because they inherently suppress signal from fat and do not require a homogeneous magnetic field. Gadolinium-enhanced T1-weighted images add information about tumor vascularity and are helpful in guiding percutaneous biopsy by differentiating viable tumor from areas of necrosis.[5] Cystic lesions may be identified by their lack of central enhancement.[6] MR angiography (MRA) is useful for characterizing tumor vascularity and for planning the optimal surgical approach when large vessels may be involved. Most soft tissue tumors have prolonged T1 and T2 signal characteristics.[7] The MRI signal characteristics of most soft tissue tumors are nonspecific and usually cannot predict histology nor can they differentiate between benign and malignant neoplasms. Biopsy is necessary for histologic diagnosis.

### Benign Soft Tissue Tumors

#### Desmoid Tumors

***Overview.*** Desmoid tumors, representing deep or aggressive fibromatosis, are rare mesenchymal neoplasms with a fibrotic texture.[8,9] Although distant metastases do not occur, these tumors are locally aggressive and can lead to significant morbidity and mortality. Desmoid tumors are slightly more common in females, with an incidence of 2 to 4 cases per million per year. The peak incidence is in the third and fourth decades of life.[10] When these tumors occur in younger patients, they tend to be more aggressive, with recurrence rates up to 87%.[11]

***Etiology.*** Desmoid tumors are classified into superficial and deep groups. Superficial tumors are usually small and slow growing, and deep lesions may occur in the abdomen or extraabdominally. In children, extraabdominal desmoid tumors are more common than the abdominal type. Most desmoid tumors in patients with Gardner syndrome are found in the abdomen. Extraabdominal desmoid tumors, also referred to as *aggressive fibromatosis*, are usually solitary and arise from the fascial sheaths and aponeuroses of striated muscle. In one series, head and neck, trunk, and extremity involvement was seen with approximately equal frequency.[12] Histologically, desmoid tumors consist of benign fibrous tissues that contain spindle cells and abundant collagen. Although they do not metastasize, desmoid tumors can infiltrate contiguous structures, including bone.

***Imaging.*** Desmoid tumors are variably echogenic on US, and their borders may be smooth or irregular. On contrast-enhanced CT, most appear more attenuated than striated muscle (Fig. 138.1). On MRI, these tumors may be nodular with infiltrative or well-defined margins. Tumors may be homogeneous or heterogeneous with varying signal characteristics. Some lesions are low signal on T1- and T2-weighted images, but more often tumors are heterogeneous and contain areas that are hyperintense to "fat" on T2-weighted images. On T1-weighted images, these masses contain areas that are hypointense, isointense, or slightly hyperintense when compared with muscle. This variability in signal reflects differences in the relative proportions of collagen, spindle cells, and mucopolysaccharides within the lesion (e-Fig. 138.2). On T2-weighted images, low signal generally reflects collagen, and high signal reflects a greater quantity of cellular tissue.[13] Tumors with high signal on T1-weighted images have been found to contain fat or myxoid material. Contrast enhancement may be

## Abstract:

There are a variety of musculoskeletal tumors, which occur in children. These include primary tumors of the bones and soft tissues and metastases. Imaging is essential in the detection these lesions, which may have characteristic features that allow for a definitive diagnosis without biopsy. Even when a definitive diagnosis cannot be made based upon imaging findings alone; imaging is essential to the workup and treatment planning of pediatric musculoskeletal tumors. This chapter reviews the radiographic, CT and MRI features of these tumors.

## Keywords:

**e-Figure 138.2. Desmoid tumor in a 17-year-old boy.** (A) T2-weighted fat-saturated axial MR image demonstrates hyperintense and hypointense components of the mass in the posterior thigh. Hyperintense areas likely represent cellular-dominant components of the mass, whereas hypointense areas likely represent colloid components. (B) T1-weighted postgadolinium coronal image demonstrates heterogeneous enhancement of the mass.

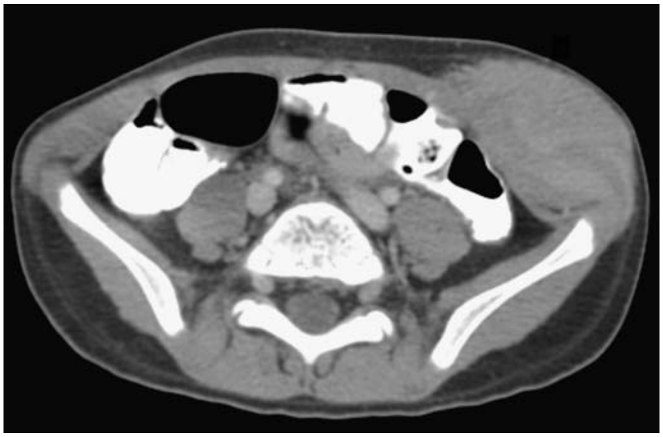

**Figure 138.1. Extraabdominal desmoid tumor (Gardner fibroma) in a 5-year-old girl.** Axial contrast-enhanced CT image shows a large lenticular-shaped mass originating in the anterior abdominal wall musculature.

homogeneous, heterogeneous, or absent and does not correlate with clinical outcome.[14]

A desmoid tumor may be prospectively suggested by the presence of areas of T2 hypointensity suggestive of collagen stroma within the mass, but biopsy is ultimately required for definitive diagnosis.

***Treatment.*** Stable asymptomatic desmoid tumors are often treated conservatively and observed for changes.[15] Symptomatic desmoids must be treated, and therapy often depends on anatomic location. If possible, surgical resection with wide margins is the treatment of choice.[10] However, recurrence is common (19%–77%) and is more frequent with extraabdominal desmoids (30%–50%) than with intraabdominal desmoids (15%–30%).[8,9,16] If surgery is not possible, systemic therapy should be considered. This is often the case when desmoids are associated with familial adenomatous polyposis or Gardner syndrome. These conditions increase the likelihood of postoperative complications such as hemorrhage, short-bowel syndrome, intestinal ischemia, obstruction, or fistula formation.[9,15] Nonsurgical treatment options include radiation and systemic therapy. Patients treated with chemotherapy have a lower incidence of tumor recurrence compared with those treated with radiation.[13]

## Infantile Myofibromatosis

Infantile myofibromatosis is the most common fibrous tumor of infancy. Tumors may involve skin, muscle, bone, or viscera and may be solitary (myofibroma) or multiple (myofibromatosis). Myofibromatosis occurs in children younger than 2 years of age. The prognosis of musculoskeletal lesions is excellent and spontaneous resolution usually occurs, although visceral involvement may portend a poorer prognosis. Lesions have a variable appearance on US and range from solid to anechoic centrally with a thick wall. On CT, myofibromas enhance to a lesser degree or similarly to muscle and often exhibit a peripheral rim of enhancement. On MRI, lesions are low signal on T1 weighting and usually high signal on T2 weighting. Some masses show decreased central signal on T2 weighting, likely due to collagen components. Enhancement of the fibrous and cellular components is seen with gadolinium administration (Fig. 138.3).[12,17–21] Osseous lesions tend to occur in the metaphysis and have a lytic appearance (Fig. 138.4).[20]

## Benign Peripheral Nerve Sheath Tumors

***Overview.*** Benign peripheral nerve sheath tumors are divided into schwannomas, also known as *neurinomas* and *neurilemomas*, and neurofibromas. Benign neurofibromas and, less commonly, schwannomas are frequently multiple and are associated with neurofibromatosis type 1 (NF1). However, both tumors may be solitary and may occur sporadically.

***Etiologies and Clinical Presentation.*** Schwannomas account for approximately 5% of all benign soft tissue neoplasms, and they are usually found as a solitary lesion in individuals between 20 and 50 years of age. Although they may occur virtually anywhere in the body, the head and neck, flexor surfaces of extremities (notably the ulnar and peroneal nerves), mediastinum, and retroperitoneum are the most commonly involved sites.[22] If the lesion is large, pain and neurologic symptoms may be clinical manifestations; otherwise, patients are usually asymptomatic.[23,24]

Neurofibromas may be localized, plexiform, or diffuse. The localized form accounts for 90% of cases and less often is associated with NF1, unlike the diffuse and plexiform subtypes.[22] *Localized neurofibromas* account for approximately 5% of all benign soft tissue tumors and are typically seen in younger patients between 20 and 30 years of age.[22] They often come to medical attention as a painless, slowly growing mass.[23]

Schwannomas and localized neurofibromas are similar histologically and are composed primarily of Schwann cells; therefore they exhibit similar imaging characteristics. Microscopic examination reveals a dense central core of Schwann cells surrounded by a peripheral zone of myxoid tissue. Peripheral nerve sheath tumors have a low incidence of malignant degeneration.[22]

***Imaging.*** A tumor can be suspected to have a neurogenic origin if it is located along the distribution of a peripheral nerve. Calcification in degenerating ("ancient") schwannomas may be visible radiographically; on bone scintigrams, these tumors have been observed to take up 99mTc-MDP.[25] Peripheral nerve sheath tumors may be accompanied by subtle atrophy of surrounding or distally innervated muscle. Most of these tumors are well-defined spherical or fusiform masses. On CT images, they tend to be hypoattenuated, possibly because of lipids in their Schwann cells, adipocytes, and perineural tissues.[26] On MRI, the bulk of the tumor shows low intensity on T1-weighted sequences and high intensity on T2-weighted sequences. Typically, the central zone consists of collagen and neurofibroma cells and is hypointense on T2-weighted images, lending a "target" appearance to the lesion that can also be seen on contrast-enhanced T1-weighted images; it is more easily appreciated when wide window settings are used to view the images. The presence of a target sign helps distinguish these benign tumors from their less well-organized malignant counterparts (Fig. 138.5).[27–30]

On MRI, differentiating a schwannoma from a neurofibroma can be difficult; however, schwannomas may contain more prominent areas of hemorrhage, cystic change, and necrosis with resultant heterogeneous signal intensities. In addition, neurofibromas intimately involve and are inseparable from the normal nerve. Schwannomas are eccentric to the nerve, which may be apparent on MRI in tumors that involve larger nerves. In smaller nerves, schwannomas may obliterate the nerve of origin and be indistinguishable from neurofibromas.[31]

*Plexiform neurofibromas* arise from the axis of a primary nerve and form tortuous, cordlike tumors along its axis. They are regarded as indicators of neurofibromatosis, even when they are the sole manifestation of the disease. Tumors tend to appear as lobulated, amorphous masses. Similar to solitary neurofibromas, these tumors are usually hyperintense on T2-weighted imaging and often have well-defined, central, tubular, hypointense structures, or they may form large masses that resemble a "bag of worms" on transverse images.[32]

*Diffuse neurofibromas* are uncommon and are often associated with NF1.[33] These lesions occur primarily in children and young adults and most commonly involve the head and neck regions. These ill-defined, infiltrative lesions tend to be located in the skin and subcutaneous tissues. They appear as linear or reticular strands

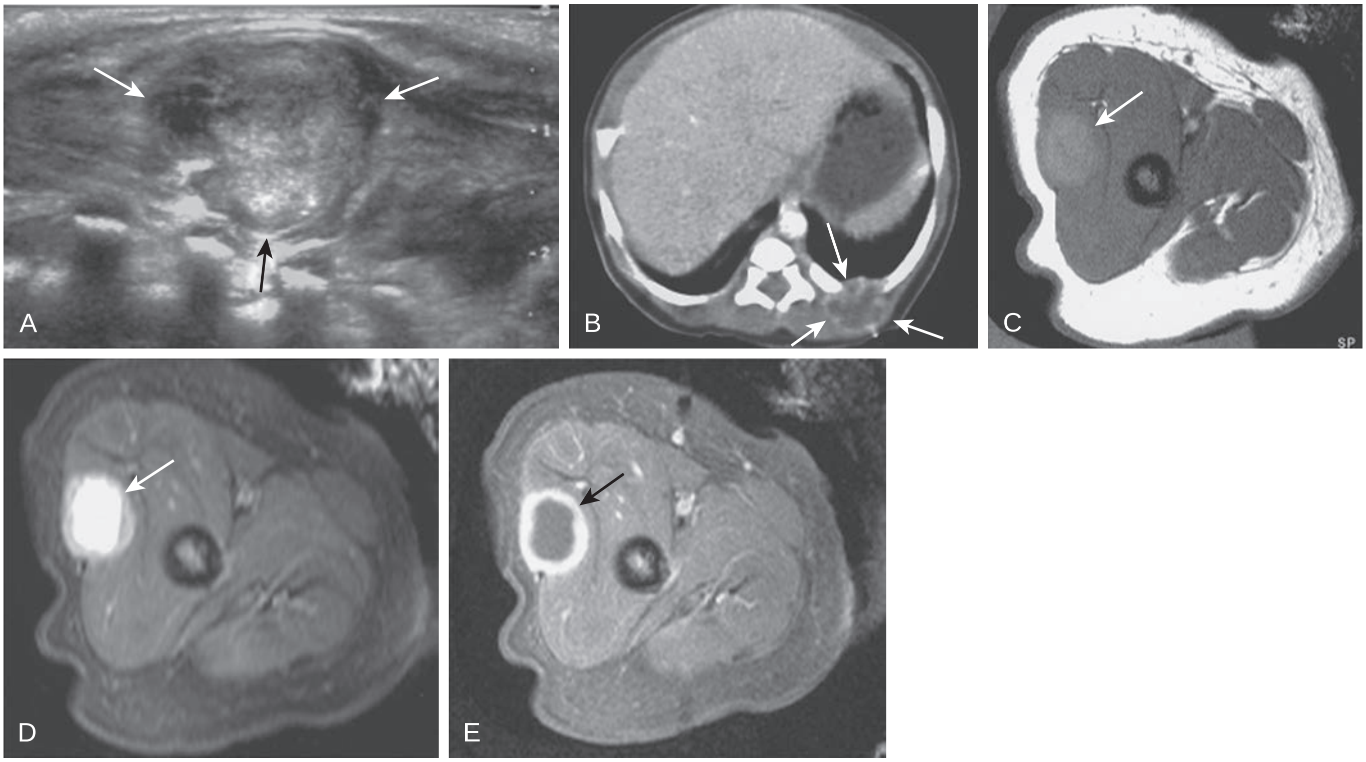

**Figure 138.3. Infantile myofibromatosis in a neonate.** (A) Ultrasound shows a solid, intramuscular subscapular mass *(arrows)*. (B) Axial contrast-enhanced CT image shows peripheral enhancement within the mass *(arrows)*. (C) Thigh lesion in the same patient shows hyperintense signal on T1-weighted MR imaging. (D) T2-weighted fat-saturated image demonstrates central increased signal intensity with a thick, irregular rind of soft tissue. (E) Postgadolinium T1-weighted fat-saturated images demonstrate enhancement of the rind of soft tissue and central areas of nonenhancement.

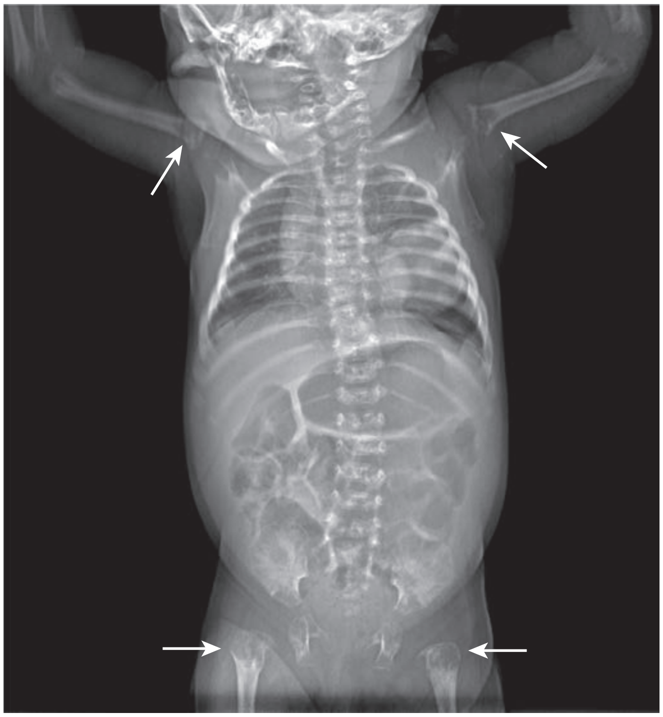

**Figure 138.4. Myofibromatosis.** Newborn girl with multifocal myofibromatosis with preferential involvement of metaphyses *(arrows)*.

of intermediate signal on T1-weighted and high signal intensity on T2-weighted images, with linear areas of enhancement after gadolinium administration.

## Benign Fatty Tumors

***Overview.*** The 2002 World Health Organization (WHO) Soft Tissue Tumor Classification includes nine types of benign fatty tumor: lipoma, lipomatosis, lipomatosis of nerve, lipoblastoma/lipoblastomatosis, angiolipoma, myolipoma of soft tissue, chondroid lipoma, spindle cell/pleomorphic lipoma, and hibernoma. Except for lipoblastoma, all of these tumors are more common in adults than in children.[24]

Lipoblastoma and lipoblastomatosis are benign mesenchymal tumors of immature fat that occur primarily in infants and young children, most often in boys younger than 8 years of age. The average age of patients at the time of presentation is 3.6 years.[34] Lipoblastomas are usually painless superficial tumors most commonly located in the extremities and the head and neck region, but they may also involve the trunk and deeper structures, such as the mediastinum, mesentery, and retroperitoneum. The tumor consists of lobules of immature adipose tissue with a variable amount of myxoid stroma separated by richly vascularized septa composed of connective tissue. The discrete form, *lipoblastoma*, is a well-circumscribed lesion that occurs in approximately 70% of cases and involves the superficial soft tissues. Lipoblastomas eventually evolve into mature lipomas. The term *lipoblastomatosis* refers to the diffuse type that often infiltrates adjacent deeper tissues, such as muscle, and has a tendency to recur locally[35]; spontaneous resolution has also been reported.[36,37]

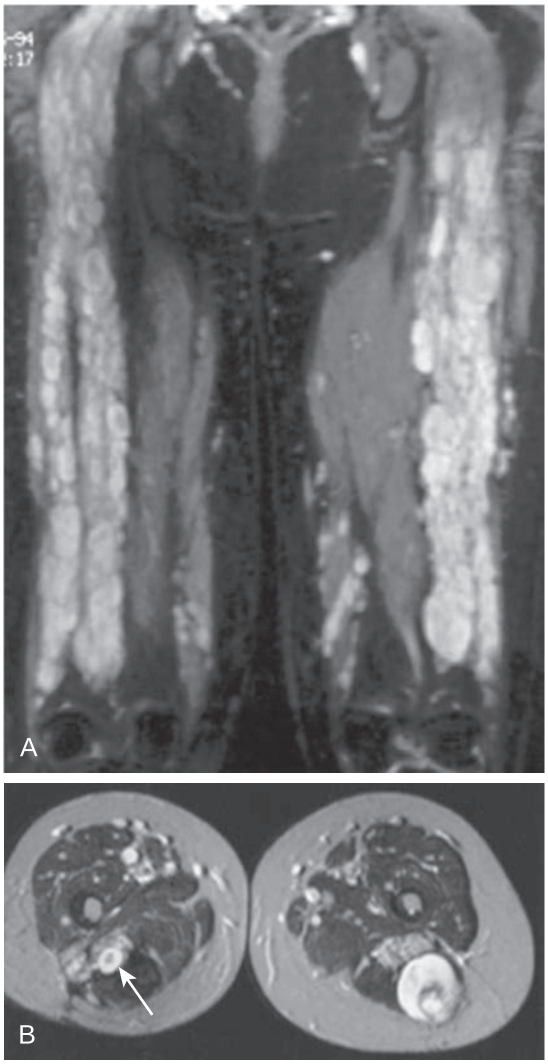

**Figure 138.5. Multiple neurofibromas and a malignant peripheral nerve sheath tumor in a young woman with NF-1.** (A) Coronal short-tau inversion recovery MR image of the thighs shows multiple plexiform neurofibromas distributed along the sciatic nerves. (B) Axial T2-weighted images show multiple, discrete, high-intensity neurofibromas. A characteristic target sign is evident *(arrow)*. The larger lesion in the posterior left thigh, which had shown recent growth, was a low-grade malignant peripheral nerve sheath tumor.

***Imaging.*** Imaging features reflect the amount of fatty tissue present. On US, hyperechoic fat can be clearly delineated from the myxoid component, and CT shows a similar combination of hypoattenuated fat and denser myxoid tissue. On MRI, the signal is often heterogeneous (e-Fig. 138.6) with lipomatous elements appearing hyperintense to muscle on T1-weighted images and isointense to subcutaneous fat on T2-weighted images; nonfatty tissues produce lower signal intensity than fat on T1-weighted images and are more intense than fat on T2-weighted images. In addition to low-signal myxoid components on T1 imaging, the fatty mass may contain low-signal fibrous septa that show contrast enhancement.[38–40]

The differential diagnosis includes lipoma; hibernoma, a rare tumor analogous to brown fat; and myxoid liposarcoma. However, liposarcoma is very rare in children younger than 10 years of age.[41] Thus a fat-containing tumor in a young child is much more likely to be a lipoblastoma.

***Treatment.*** The majority of fat-containing masses in children are benign. Although complete surgical resection is the treatment of choice for focal lesions,[34] subtotal resection may be considered, particularly when surgical resection may involve critical neurovascular structures, or when it may lead to significant cosmetic deformity.

## Malignant Soft Tissue Tumors

### Rhabdomyosarcoma

***Overview.*** The head and neck and genitourinary tract are the most frequent locations of rhabdomyosarcoma (RMS). About 20% of these tumors occur in the extremities. Most extremity RMS is of the alveolar or undifferentiated histologic types. The embryonal or botryoid types are found more often in the face, neck, and genitourinary system.[42] Prognosis is less favorable for patients with RMS of the extremities.[43] In the extremities, tumors tend to be deep and tend to spread along fascial planes and may cause erosion of adjacent bone.

***Etiologies, Pathophysiology, and Clinical Presentation.*** RMS contains a mixture of rhabdomyoblasts, which are recognized by their typical cross striations, and undifferentiated cells. These tumors are thought to arise from progenitor cells for striated muscle and can occur anywhere in the body, even in areas with no striated muscle. RMS accounts for more than 60% of STS in children younger than 5 years of age but only 25% of STS in those aged 15 to 19 years.[44]

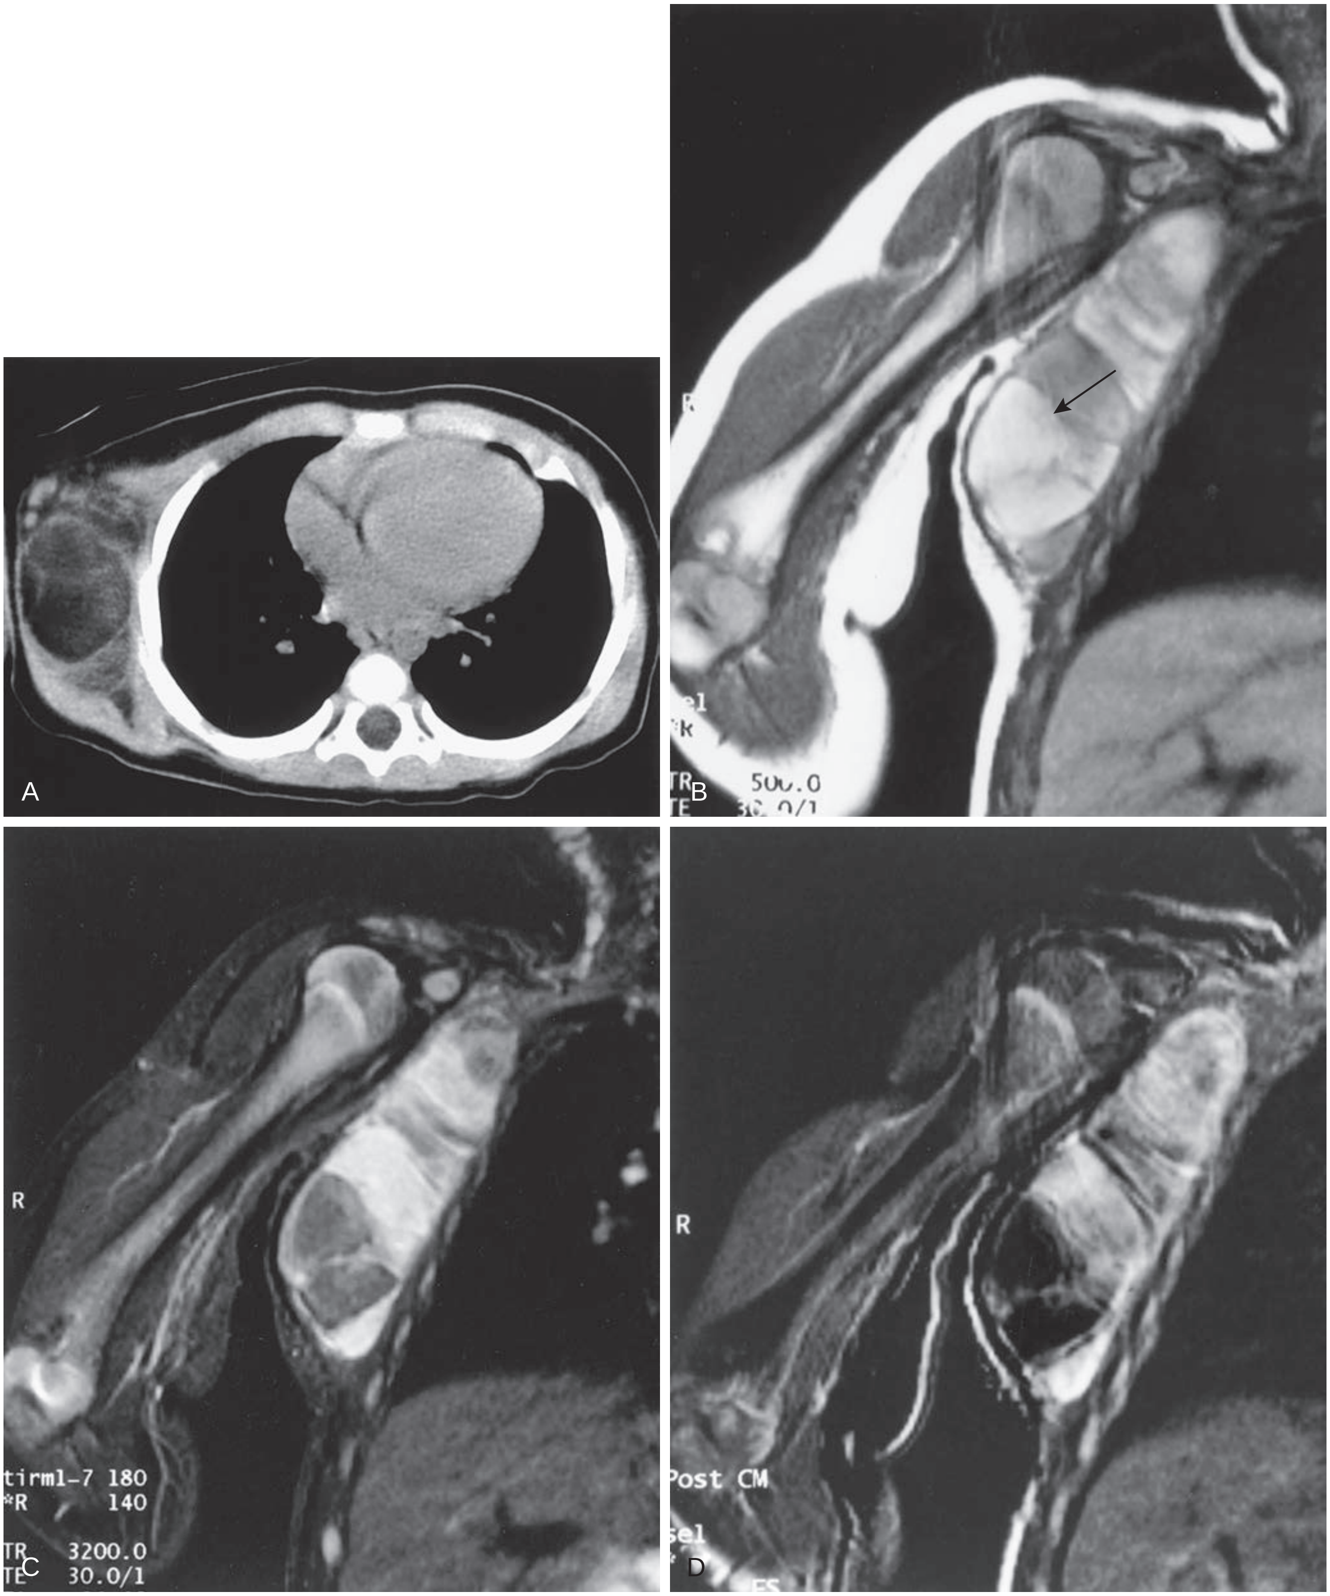
***Imaging.*** Imaging is usually nonspecific but is essential for staging and surgical management. MRI has superseded CT and US in this clinical setting, because it can define the anatomic location of the tumor (unicompartmental vs. multicompartmental), indicate its relationship to important nerves and blood vessels, and reveal local involvement of bone or lymph nodes. MRI characteristics are nonspecific, and most tumors are predominantly low signal on T1-weighted images, high signal on T2-weighted images, and demonstrate central tumoral enhancement (Fig. 138.7). Only 15% to 20% of patients have clinically detectable metastases at presentation. The lungs, bone marrow, and bone are the most common sites of distant metastases. Lymph nodes may also be involved. Bone metastases resemble those that occur with neuroblastoma; they have been reported even in the absence of detectable primary tumor.

***Treatment.*** Even if not clinically detectable, all patients are considered to have micrometastatic disease; this has resulted in the universal use of chemotherapy. The 5-year survival rate for children with RMS has improved from 55% in the 1970s to more than 70% currently.[45]

### Peripheral Primitive Neuroectodermal Tumor and Extraosseous Ewing Sarcoma

***Overview.*** Peripheral primitive neuroectodermal tumor (PPNET) and extraosseous Ewing sarcoma (EOES) are small round cell neoplasms that belong to the Ewing sarcoma family of tumors; they can arise in both soft tissue and bone. These neoplasms are related histogenetically and share a common cytogenetic characteristic, the translocation of bands 24 and 12 of the short arms of chromosomes 11 and 22. They are often indistinguishable histologically. Also known as *peripheral neuroepithelioma*, PPNETs have a higher degree of neural differentiation than is seen with Ewing sarcoma; thus these two tumors can be distinguished on the basis of immunohistochemical markers. This distinction is important, because disease-free survival is poorer for patients with PPNET than for those with EOES.[46,47]

***Etiologies, Pathophysiology, and Clinical Presentation.*** Both tumors occur most commonly in truncal and paravertebral soft tissues (50%–60% of cases) and in the extremities (25% of cases).



**e-Figure 138.6. Lipoblastoma in a 5-month-old.** (A) CT image of the chest of shows a low-attenuation mass in the right axilla. (B) Coronal T1-weighted MR image shows the inferior portion of the mass *(arrow)* is markedly hyperintense as a result of adipose tissue. The low signal in this portion of the mass shown in short-tau inversion recovery (C) and fat-suppressed contrast-enhanced T1-weighted (D) images is also characteristic of fat. Note exuberant enhancement of the superior half of the solid mass (D).

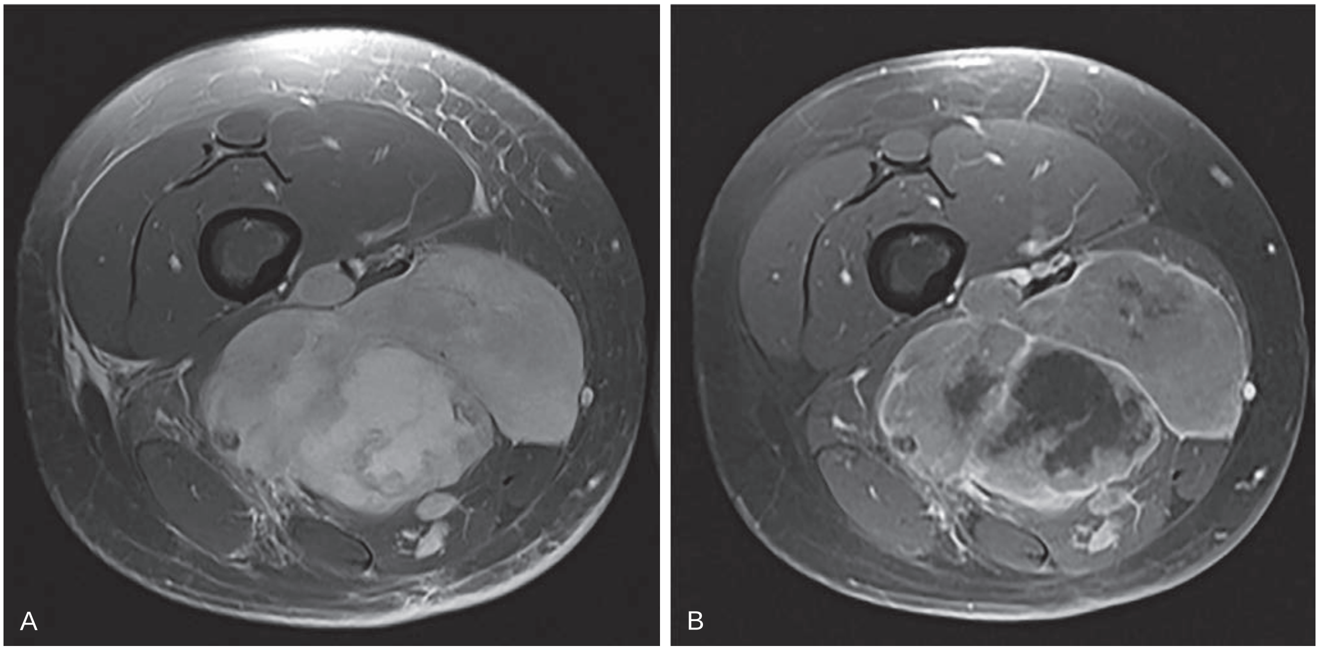


**Figure 138.7. Alveolar rhabdomyosarcoma of the thigh in an 16-year-old girl.** (A) T2-weighted fat-suppressed axial MR image demonstrates a multilobulated, hyperintense intramuscular mass. (B) Postgadolinium T1-weighted fat-suppressed axial MR image demonstrates predominantly diffuse tumoral enhancement of the mass with areas of necrosis.

PPNET occurs less commonly in the extremities than does EOES, and patients with EOES are generally younger. Askin tumors are thoracic PPNETs that involve the chest wall.[48] These tumors can be very large at the time of presentation and tend to be poorly circumscribed. They typically do not calcify but may erode adjacent bone.

***Imaging.*** On MRI, these tumors have a nonspecific imaging appearance. PPNET and EOES are typically isointense to muscle on T1-weighted images and inhomogeneously hyperintense on T2-weighted and STIR images; they show variable contrast enhancement. When these lesions outgrow their blood supply or, alternatively, when masses hemorrhage spontaneously or after minor trauma, cystic components may be seen; these lesions may superficially mimic a hematoma (Fig. 138.8). Postcontrast imaging is helpful in these circumstances to help identify solid soft tissue components and guide biopsy of viable tumor cells. Distant spread occurs to bone, lung, liver, and brain.[49,50]

***Treatment.*** Treatment is dictated by location and extent of disease and may involve surgery for localized disease with or without adjuvant/neoadjuvant chemoradiotherapy.[51]

## Synovial Sarcoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Synovial sarcomas predominantly occur in adults younger than 50 years of age, but they account for about 10% of pediatric STS. These tumors arise from undifferentiated mesenchymal cells, not from true synovial cells. A monophasic variety comprises spindle cells, and a biphasic variety consists of spindle cells and epithelial elements. Although synovial sarcomas often occur close to joints, tendons, and bursae, they are rarely intraarticular.[52] About 80% of synovial sarcomas occur in the extremities, and considerably more lower than upper extremity involvement has been noted. Synovial sarcomas may spread to regional lymph nodes, and the lungs are the most common sites of distant metastasis.[53]

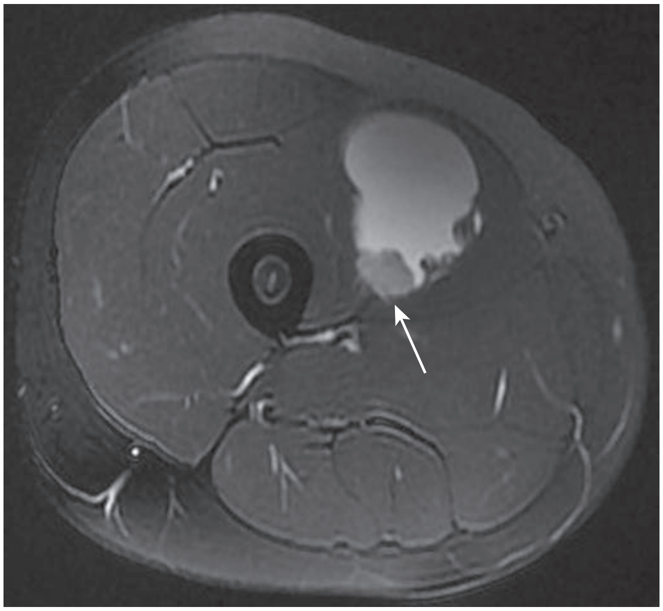
***Imaging.*** Radiographically visible calcifications are present in 30% of cases. On MRI, synovial sarcomas are often lobulated, well-defined, deep-seated lesions, although they may be infiltrative and can encase major blood vessels. Femoral vein invasion has been described, and erosion of the cortex of adjacent bones is present in up to 20% of patients.

MRI signal characteristics are nonspecific. Synovial sarcomas are usually isointense to muscle on T1-weighted images. Foci of high T1-weighted signal may be present, and fluid-fluid levels are caused by hemorrhage; tumors generally have heterogeneous signal with areas of high intensity on T2-weighted images (Fig. 138.9). In one large series, 35% of tumors showed a triple-signal pattern on T2-weighted images; these findings are consistent with high (fluid)-signal intensity, intermediate-signal intensity similar to that of fat, and low-signal intensity resembling that of fibrous tissue (Fig. 138.9B).[54] A multilocular appearance with fluid-fluid levels may be seen in 18% to 25% of these tumors. Some synovial sarcomas may appear predominately cystic (e-Fig. 138.10), particularly on T2-weighted images, which could be confused with a ganglion. Postcontrast images can help identify solid components. As a rule of thumb, a diagnosis of ganglion should only be considered when a fluid-filled neck can be seen extending from the lesion to a joint or tendon sheath, and no solid components lie within the lesion. Otherwise, a diagnosis of neoplasm should be favored, with biopsy recommended.[54–57]

***Treatment.*** The treatment of choice is surgery with or without adjuvant and neoadjuvant chemotherapy. A recent multicenter study of patients under 20 years of age with a minimum of 10 years of follow-up found that wide surgical resection is the most efficacious method of treatment. Presence of tumor in the trunk and high histologic grade were negative factors for recurrence-free and metastasis-free survival.[58]

## Malignant Peripheral Nerve Sheath Tumor

***Overview.*** *Malignant peripheral nerve sheath tumor* (MPNST) is the accepted name for a spindle cell sarcoma that arises from a nerve or a neurofibroma. In contrast to other STS of mesenchymal cell origin, MPNSTs are of neuroectodermal origin. The MPNST



**e-Figure 138.10. Synovial sarcoma in a 17-year-old girl.** T2-weighted fat-saturated axial MR image demonstrates a cystic mass with solid soft tissue elements posteriorly *(arrow)*.

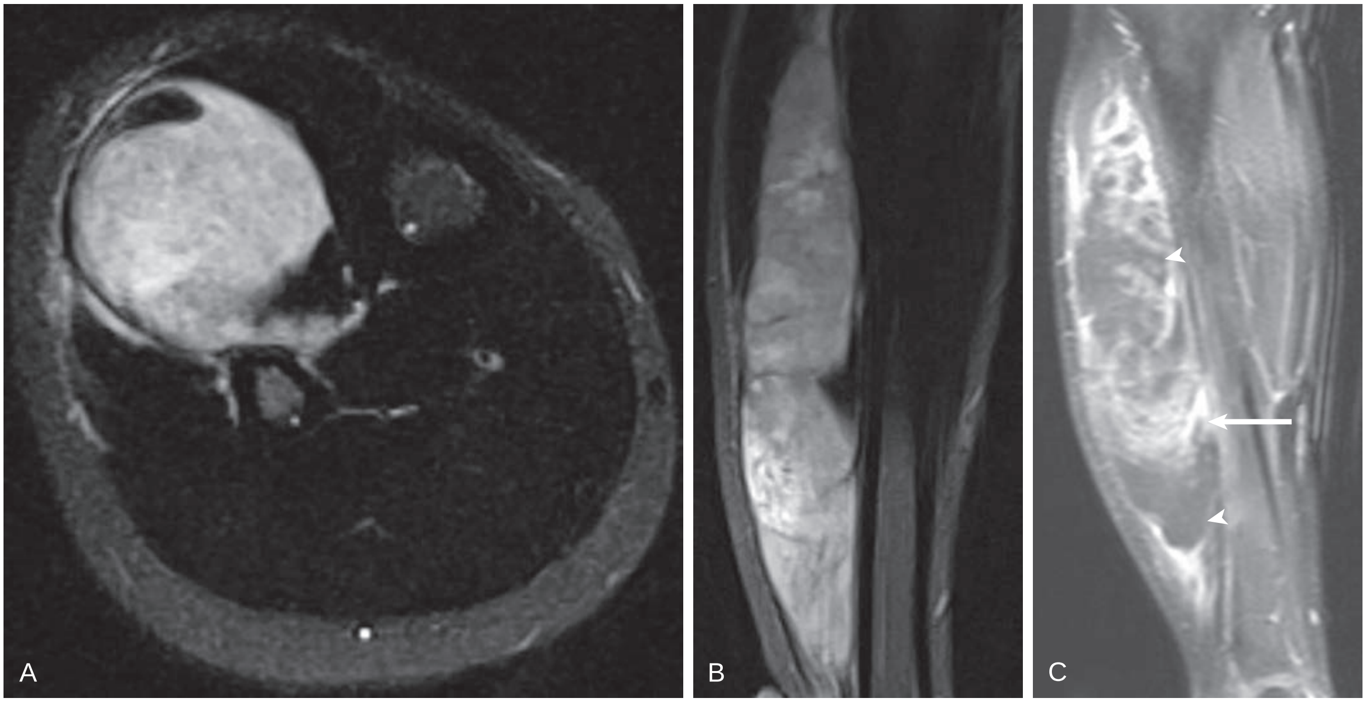


**Figure 138.8. Primitive neuroectodermal tumor in a 12-year-old boy.** Short-tau inversion recovery axial (A) and coronal (B) MR images demonstrate an extraosseous mass in the anterior leg with peritumoral edema. (C) Postgadolinium T1-weighted fat-saturated coronal MR image demonstrates cystic nonenhancing components of the tumor *(arrowheads)* and solid enhancing components *(arrow)*.

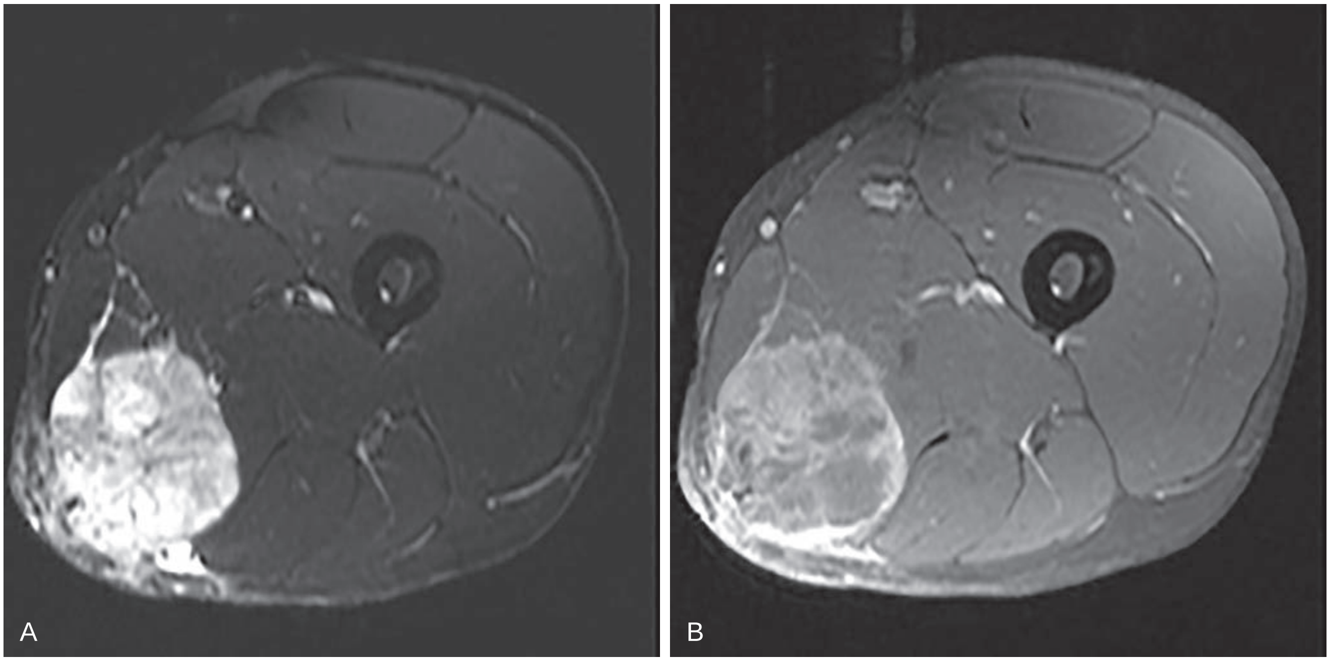

**Figure 138.9. Synovial sarcoma in a 16-year-old boy.** (A) Transverse STIR MR image shows a mixed intermediate and high signal intensity mass in the posterior thigh musculature and adjacent subcutaneous tissues. (B) A transverse T1-weighted fat-saturated MR image at the same level shows heterogeneous enhancement.

designation has replaced many formerly used terms, including *malignant schwannoma*, *neurofibrosarcoma*, *neurogenic sarcoma*, and *malignant neural neoplasm*. A variant of MPNST is the so-called triton tumor (named after a salamander) that contains neural and rhabdomyosarcomatous elements.[22]

***Etiologies, Pathophysiology, and Clinical Presentation.*** MPNST accounts for about 4% to 10% of STS and is the most common malignancy associated with NF1. Half of these tumors occur in patients with NF1; conversely, 2% to 29% of patients with NF1 develop MPNSTs—a much higher incidence than is seen in the general population. MPNST patients with NF1 are usually younger than those without associated NF1. Furthermore, in patients with NF1, MPNSTs tend to arise in preexisting benign neurofibromas; they are high-grade tumors that have a tendency to recur locally and metastasize. MPNSTs may also arise at previously irradiated sites.[31]

***Imaging.*** Similar to benign neurofibromas, MPNSTs are deep soft tissue lesions that are often associated with primary nerves, especially those of the thigh and lower extremities. CT and MRI appearance is nonspecific. Tumors may be well or poorly defined, homogeneous or inhomogeneous, and they occasionally erode bone. Malignant transformation of benign neurofibromas should be considered in patients in whom the mass is painful or enlarging, or when the typical target appearance of a benign neurofibroma is absent (see Fig. 138.5). Fluorodeoxyglucose (FDG) PET/CT may be helpful in detecting transformation of a neurofibroma to MPNST. A lesion with an SUVmax greater than or equal to 3.5, while nonspecific, raises concern for malignant transformation.[59]

***Treatment.*** Surgical resection with or without adjuvant and neoadjuvant chemoradiotherapy is used for treatment, depending on the tumor's location.

### Infantile Fibrosarcoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Infantile fibrosarcoma is an uncommon tumor that contains fibroblasts and myoblasts and occurs in young children, especially in the first 3 months of life.[60] This tumor is now considered a low-grade malignancy, in distinction from an adult-type fibrosarcoma that occurs in older children (10–15 years of age) and is more aggressive. Clinically, infantile fibrosarcomas present as enlarging, sometimes painful masses. Tumors often occur in the distal ends of the extremities and occasionally in the head, neck, and trunk. Because of their high degree of vascularization, they may be confused with hemangiomas on physical and imaging examinations.[61] These tumors may erode adjacent bone, and angiographic studies may reveal tumor vasculature.[62,63]

***Imaging.*** Because these masses are often present during fetal life, extensive remodeling of adjacent bones may occur (e-Fig. 138.11). MRI characteristics are nonspecific. Fibrosarcomas are usually isointense to muscle on T1-weighted images and are hyperintense on T2-weighted images. They may contain hypointense foci, which correlate with fibrosis.[64]

***Treatment.*** These tumors recur in up to 30% of cases, and metastases occur in about 5%.[65,66] Infantile fibrosarcoma has an excellent prognosis, with 5-year survival up to 84%.[67]

### Dermatofibrosarcoma Protuberans

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** *Dermatofibrosarcoma protuberans* is an intermediate-grade malignancy that involves the dermis. This tumor is most often seen in adults; it occurs rarely in children but may be seen at birth. It most commonly appears as a red-blue or pink plaque that grows slowly and may become nodular. A less common atrophic variant occurs as a depressed plaque. Lesions are typically fixed to the dermis but may extend into the underlying tissues. Lesions frequently recur locally, and metastasis occurs in 1% to 6% of patients; 75% of metastases occur in the lungs.[68,69]

***Imaging.*** MRI is useful for determining the extent of disease, especially with deep tumor invasion. MRI characteristics are nonspecific. On T1-weighted images, lesions are hypointense to fat and may be isointense, hyperintense, or slightly hypointense to muscle. On T2-weighted images, lesions are isointense or hyperintense to fat. Lesions can enhance after gadolinium administration. On MRI, these tumors may be confused with subcutaneous granuloma annulare, a benign localized inflammatory dermatosis that occurs in children.[70]

***Therapy.*** Treatment involves surgical resection with or without adjuvant and neoadjuvant chemoradiotherapy. One review found that the presence of metastasis had an overall decreased patient survival rate, and those with fibrosarcomatous change or acral location had a decreased disease-free interval despite wide local resection.[71]

### Malignant Fibrous Histiocytoma

The 2002 WHO Soft Tissue Tumor Classification has changed the designation of *malignant fibrous histiocytoma* (MFH). As a result, many lesions that had been regarded as MFH will be classified as other entities. MFH rarely occurs in children.[72-74]

## Disseminated Disease of Soft Tissues

### Lymphoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Muscle involvement by non-Hodgkin lymphoma (NHL) is usually due to metastatic spread via lymphatic and hematogenous routes; however, it may be the result of direct extension from primary bone lymphoma. Much less commonly, muscle lymphoma occurs as a primary extranodal tumor. The disease can cross compartmental boundaries, or it may invade subcutaneous tissues. Involvement of adjacent bone and bone marrow may occur. Primary T-cell lymphoma of the skin is referred to as *mycosis fungoides*. Typical findings include focal thickening caused by dermal and epidural infiltrates and lymphadenopathy in advanced-stage disease.[75]

***Imaging.*** Muscle involvement results in solitary or multiple masses detectable on CT, MRI, and FDG-PET. On CT, affected muscles appear diffusely enlarged with or without obliteration of normal fat planes. The tumor may be poorly defined, and its attenuation is equal to or slightly less than that of normal muscle on contrast-enhanced and noncontrast CT images. On MRI, masses are isointense or slightly hypointense to normal muscle on T1-weighted images; they are hyperintense on T2-weighted and STIR images, and enhance inhomogeneously (e-Fig. 138.12). Increased activity on FDG-PET scans correlates well with MRI findings.[76-78]

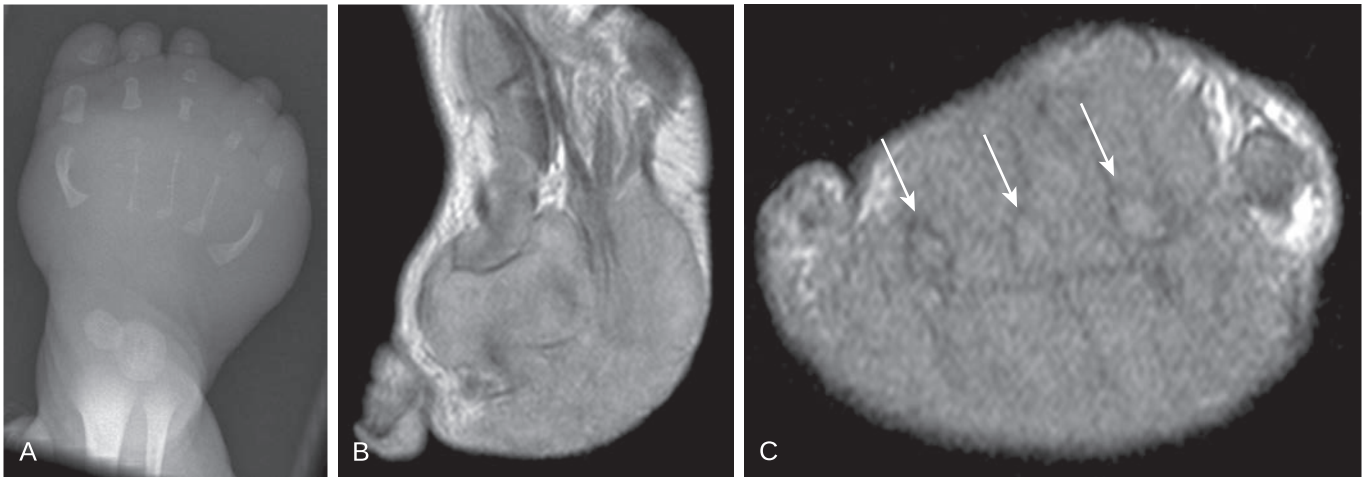
### Granulocytic Sarcoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** *Granulocytic sarcoma* is a rare solid tumor of primitive precursors of white blood cells and is also known as *chloroma* and *extramedullary myeloblastoma*. It occurs in patients with acute and chronic myelogenous leukemia and other myeloproliferative diseases. Children are more often affected than adults, and 60% of these tumors occur in children younger than 15 years of age.[79]

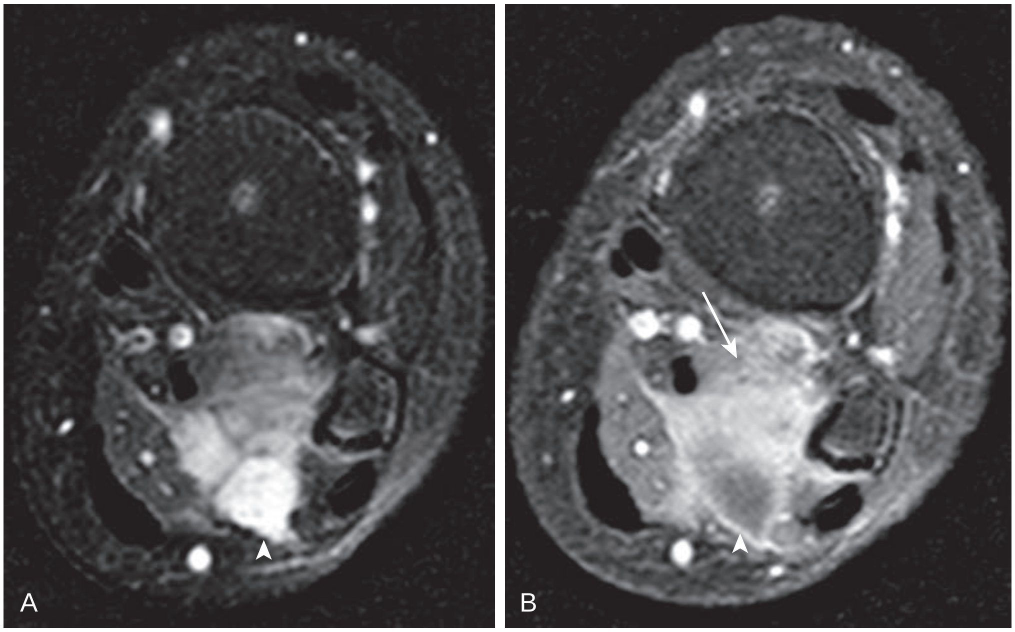
***Imaging.*** Chloromas may be solitary or multiple, and they can involve any part of the body, including the brain and muscles. Orbits and subcutaneous tissues, however, are the most common sites (see Chapter 7). These tumors are typically isoattenuating to slightly hyperattenuating to muscle on noncontrast CT and hyperattenuating to muscle on contrast CT. On MRI, lesions are typically isointense to muscle on T1-weighted images and hyperintense to muscle on T2-weighted images. Tumors usually enhance after gadolinium administration.[80–82]

### Metastases

Subcutaneous tissues and muscles may be involved in metastatic lesions. Neuroblastoma, in particular, may metastasize to the skin, subcutaneous tissue, or muscle (Fig. 138.13). Despite its large volume, muscle is not a frequent site for metastatic disease. On



**e-Figure 138.11. Infantile fibrosarcoma with rhabdoid elements in a 1-week-old boy.** (A) Anteroposterior radiograph of the foot demonstrates gracile metatarsal bones and a large soft tissue density mass. T1 sagittal (B) and T1 short-axis (C) MR images demonstrate a large multicompartment soft tissue mass enveloping metatarsal bones *(arrows)*.



**e-Figure 138.12. Extranodal non-Hodgkin lymphoma of calf muscle in a child.** (A) T2-weighted fat-saturated axial MR image shows multicompartment involvement of the soleus and popliteus muscle. (B) Posterior cystic components *(arrowhead)* do not enhance after contrast. Solid enhancing components are noted in the anterior aspect of the mass *(arrow)*.

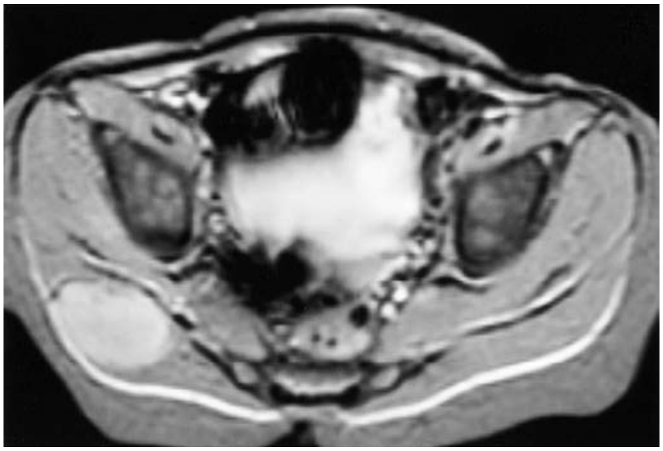


**Figure 138.13. Neuroblastoma metastasis.** Axial T2-weighted MR image of the pelvis of a 2-year-old girl with stage IV neuroblastoma shows a large metastasis in the right gluteal muscle.

CT, muscle metastases produce low-attenuation masses with loss of normal muscle planes. On MRI, metastases are similar in intensity to muscle on T1-weighted images and are hyperintense on T2-weighted images. Postcontrast images typically show enhancement with or without areas of necrosis.[83,84]

## BONE TUMORS

### Radiographic Evaluation of Bone Tumors

The initial mode of imaging of bone tumors is radiography. Radiographs serve to confirm the presence and site of a tumor, assist in the formulation of differential diagnoses, characterize the tumor, and guide in the selection of further imaging.[85,86] The decision to obtain radiographs is a clinical one, based on presentation, history, physical examination, and occasionally on laboratory tests. The differential diagnosis of a pediatric bone tumor can be narrowed down by asking a few simple questions.

#### How Old Is the Child?

Most bone tumors have a proclivity to occur within a certain age range. The differential diagnosis of a bone tumor in a 1-year-old infant is much different than that of a 16-year-old teenager or a 5-year-old child. Box 138.1 lists common pediatric bone tumors in accordance with the peak age at which they most commonly occur.[87–89]

#### What Is the Location of the Lesion? What Bone? What Part of the Bone?

Many bone tumors have a proclivity to affect certain bones within the skeleton or to occur at certain locations within a bone. Box 138.2 lists common pediatric bone tumors according to their preferred location in growing long bones. Lesions also vary in their centricity relative to the involved bone. Some tumors, such as a simple bone cyst, are central, whereas others are eccentric within bone (nonossifying fibroma) or juxtacortical (osteochondroma, periosteal osteosarcoma).[87,88,90]

#### Is the Lesion Unifocal or Multifocal?

Some lesions are always solitary, and others are usually multifocal. Some may be solitary or multifocal, although multifocal disease often implies a systemic disease or an underlying syndrome predisposing the patient to the development of a particular type of bone tumor. Box 138.3 lists common pediatric bone tumors that are multifocal.

**BOX 138.1** Pediatric Bone Tumors: Peak Age of Occurrence

**INFANT AND TODDLER (≤5 YEARS)**

Infantile myofibromatosis
Leukemia
Langerhans cell histiocytosis (multifocal)
Metastatic neuroblastoma
Osteofibrous dysplasia

**CHILD (5–10 YEARS)**

Ewing sarcoma of long bone
Langerhans cell histiocytosis (unifocal)

**ADOLESCENT (10–20 YEARS)**

Aneurysmal bone cyst
Chondroblastoma
Chondromyxoid fibroma
Ewing sarcoma of axial skeleton
Fibrous dysplasia
Osteochondroma
Leukemia (second peak)
Nonossifying fibroma/fibrous cortical defect
Osteoblastoma
Osteoid osteoma
Osteosarcoma
Periosteal chondroma
Primary lymphoma of bone
Simple bone cyst

**ADULT**

Adamantinoma
Enchondroma
Giant cell tumor (rare until physes fuse)
Parosteal osteosarcoma
Periosteal osteosarcoma

#### Is the Lesion Aggressive or Nonaggressive in Appearance?

In general, unlike malignant lesions, benign lesions have a nonaggressive radiographic appearance. However, exceptions are common, and some lesions may have both aggressive and nonaggressive features. Box 138.4 lists lesions covered in this chapter by their characteristic radiographic appearance—aggressive, nonaggressive, or indeterminate.

Radiographic features of a nonaggressive bone tumor are well-defined margins with a narrow zone of transition, particularly with sclerosis; expansion of bone contour from slow growth; smooth, single-layered periosteal new bone; and absence of an associated soft tissue mass. Radiographic features of an aggressive bone tumor are poorly defined margins with a wide zone of transition, permeative or "moth-eaten" bone destruction, frank destruction of bone without remodeling, aggressive forms of periosteal new bone, interrupted periosteal new bone, and the presence of an associated soft tissue mass. Aggressive forms of periosteal reaction include layering, or "onionskin," and "hair-on-end" periosteal new bone. Interrupted periosteal new bone may take the form of a Codman triangle, a sign of an aggressive process.[91]

By answering the aforementioned four questions, the radiologist can often narrow the differential and sometimes arrive at a single diagnosis. Most significant is the distinction between an aggressive and nonaggressive lesion; this is of major importance in guiding further imaging and initial therapy.

### BOX 138.2 Pediatric Bone Tumors: Location in Long Bones

**EPIPHYSIS**

- Chondroblastoma
- Giant cell tumor (after physeal fusion)
- Langerhans cell histiocytosis

**METAPHYSIS**

- Aneurysmal bone cyst
- Chondromyxoid fibroma
- Enchondroma
- Leukemia
- Metastases
- Nonossifying fibroma/fibrous cortical defect*
- Osteochondroma*
- Osteoid osteoma
- Osteosarcoma
- Parosteal osteosarcoma
- Simple bone cyst*

**DIAPHYSIS**

- Adamantinoma
- Ewing sarcoma/primitive neuroectodermal tumor
- Fibrous dysplasia
- Nonossifying fibroma/fibrous cortical defect (in older patients)*
- Osteochondroma (in older patients)*
- Osteofibrous dysplasia
- Osteoid osteoma
- Periosteal osteosarcoma
- Simple bone cyst (in older patients)*

*Osteochondromas, nonossifying fibromas/fibrous cortical defects, and simple bone cysts begin in the metaphyses. With maturation, these lesions may "migrate" into metadiaphysis and diaphysis.

### BOX 138.3 Pediatric Bone Tumors: Multifocal Lesions

- Brown tumors (hyperparathyroidism)
- Cystic angiomatosis/lymphangiomatosis
- Enchondroma (Ollier disease, Maffucci syndrome)
- Fibrous dysplasia (McCune–Albright syndrome)
- Infantile myofibromatosis
- Langerhans cell histiocytosis
- Leukemia
- Metastases (i.e., from neuroblastoma)
- Multifocal osteosarcoma
- Nonossifying fibromas/fibrous cortical defects
- Osteochondroma (oteochondromatosis)

### BOX 138.4 Pediatric Bone Tumors: Aggressive Versus Nonaggressive Radiographic Appearance*

**NONAGGRESSIVE**

- Aneurysmal bone cyst
- Chondroblastoma
- Chondromyxoid fibroma
- Enchondroma
- Fibrous dysplasia
- Nonossifying fibroma/fibrous cortical defect
- Osteoblastoma
- Osteoid osteoma
- Osteochondroma
- Simple bone cyst

**INDETERMINATE**

- Adamantinoma
- Desmoplastic fibroma
- Giant cell tumor
- Langerhans cell histiocytosis
- Osteofibrous dysplasia

**AGGRESSIVE**

- Ewing sarcoma/primitive neuroectodermal tumor
- Leukemia
- Lymphoma
- Metastases
- Osteoblastoma (aggressive form)
- Osteosarcoma

*Lesions are listed based on their most common radiographic presentations. With some lesions, variation from the norm is common.

Some benign bone tumors are adequately defined by radiography and do not require any further imaging for diagnosis or treatment. Most bone tumors, however, do require additional imaging; this may take the form of CT, MRI, scintigraphy, PET scanning, and rarely even US. The choice of imaging for a given tumor depends on the differential diagnostic considerations, possible treatment options, and whether the lesion is aggressive or nonaggressive. MRI is usually the preferred modality in the delineation of aggressive and suspected malignant lesions, and radiographs followed by MRI adequately define most bone lesions. As opposed to radiography, on MRI an aggressive lesion may have a well-defined margin, particularly with T1 weighting. Although MR is also very good at delineating nonaggressive and likely benign lesions, CT is better able to delineate ossified bone and thus occasionally may better define the characteristics and anatomy of some lesions. Image-guided biopsy has become a viable option to determine or confirm the diagnosis of many bone lesions. CT, US, fluoroscopy, and even MRI may be used for guidance.[92–96]

## Benign Bone Tumors

The vast majority of pediatric bone tumors are benign. It is important that radiologists recognize the typical benign tumors to avoid unnecessary diagnostic procedures. The differentiation of a nonaggressive lesion from an aggressive lesion will significantly affect the course of subsequent imaging evaluations, the approach to biopsy, and the preliminary choice of definitive treatment.

### Cartilaginous Tumors

#### Osteochondroma (Exostosis)

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Rather than a true tumor, osteochondromas are thought to be a developmental defect of growing bone in which an injury to the perichondrium causes bone growth in an aberrant direction. It is theorized that islets of cartilage from the physis are displaced along the metaphyseal surface and then grow. Osteochondromas occur in approximately 1% of the general population. Solitary osteochondroma is slightly more common in boys than girls. Growth ceases at skeletal maturity, and lesions are usually detected in the second decade of life as they grow. Most osteochondromas are asymptomatic and are discovered incidentally. However, a host of complications can occur (Box 138.5). When one of a pair of adjacent bones is affected, the osteochondroma can cause pressure deformity of the other bone. Symptomatic presentations of osteochondroma are usually due to irritation of adjacent muscles,

### BOX 138.5 Complications of Osteochondroma

**MUSCULOSKELETAL COMPLICATIONS**

Cosmetic and functional deformity
Pseudo-Madelung deformity
Radial head subluxation/dislocation
Coxa valga
Genu valga
Tibiotalar tilt
Leg-length discrepancy
Decreased range of motion
Impingement syndrome
Muscle/tendon irritation
Tenosynovitis
Snapping tendon
Tendon dislocation
Bursa formation
Synovial (osteo)chondromatosis
Synostosis
Pseudarthrosis
Short stature
Fracture

**VASCULAR COMPLICATIONS**

Displacement
Stenosis/occlusion
Claudication
Pseudoaneurysm
Venous compression/deep venous thrombosis/pulmonary embolism

**NEUROLOGIC COMPLICATIONS**

Peripheral nerve compression/entrapment
Cranial neuropathy
Spinal stenosis

**THORACIC COMPLICATIONS**

Hemothorax
Pneumothorax
Ruptured pericardium
Thoracic outlet syndrome
Dysphagia
Malignant transformation

tendons, nerves, or rarely blood vessels.[97,98] Pseudoaneurysm is a rare complication. A bursa may develop over an osteochondroma as a result of inflammation, and a pedunculated osteochondroma may fracture. Presentation with pain as a result of malignant transformation of a solitary osteochondroma in a child is extraordinarily rare.[99,100]

Osteochondromas develop in 6% to 12% of patients who received radiation at a young age. Latent periods vary from 3 to 16 years. Osteochondromas can occur even after low doses of radiation therapy and often occur in bones that were in the periphery of the radiation field. Multiple osteochondromas have been found in patients who received total-body irradiation as preparation for bone marrow transplantation at a young age. Sarcomatous degeneration of radiation-induced osteochondroma is very rare and of no greater incidence than with other osteochondromas.[101]

Patients with hereditary osteochondromatosis (hereditary multiple exostoses, diaphyseal aclasis) develop multiple osteochondromas throughout the skeleton. The disorder is autosomal dominant, and 10% of cases arise spontaneously. Patients have a mutation of the *EXT1* gene family that results in an error in regulation of normal chondrocyte proliferation and maturation.[102,103] In most patients, the disorder becomes manifest by 10 years of age. The multiplicity of lesions in these patients may lead to substantial deformity. Axial osteochondromas are frequently seen and may cause complications. Small lesions are common on the tubular bones of the hand. A pseudo-Madelung deformity of the wrist may occur because of forearm exostoses that cause ulnar shortening and angular deformity of the distal radius. Multiple metaphyseal lesions may interfere with normal modeling of the metaphyses.[104]

Malignant transformation of solitary osteochondromas, even those that are radiation induced, is exceedingly rare and probably occurs in fewer than 1% of patients.[101,105] However, the reported incidence of transformation to chondrosarcoma in patients with hereditary osteochondromatosis is 0.5% to 25%. Wide variation reflects patient selection biases; the actual incidence is probably less than 5%. Malignant transformation does not occur until well after skeletal maturity. Clinical and imaging findings suggestive of malignant transformation include an osteochondroma that grows or begins to produce symptoms after physeal closure, a cartilaginous cap greater than 1.5 to 2 cm thick in a skeletally mature patient, indistinct lesion margins, new lucency within an osteochondroma, and an associated soft tissue mass. Chondrosarcomas tend to arise at the periphery of an osteochondroma and are usually of low histologic grade.[106,107]

*Dysplasia epiphysealis hemimelica* (DEH), also known as *Trevor disease*, may be a manifestation of epiphyseal osteochondroma. Patients come to medical attention before 15 years of age, and 75% of patients are boys. Patients are seen initially with deformity, swelling, and pain. These patients form osteochondroma-like protuberances from the epiphyses. The lesions are usually confined to one side of the joint (medial more than lateral) and may occasionally involve contiguous joints in one extremity. The lower extremity (femur, tibia, talus) is usually affected, and the most commonly affected region is the ankle and hindfoot.[108]

*Subungual exostosis* is a broad-based irregular osteochondroma of the tuft of the finger under the nail bed. The lesion is most common in males in the second decade of life and most commonly affects the great toe. Unlike conventional osteochondroma, there is no medullary continuity of the exostosis with the underlying bone.[109,110]

***Imaging.*** On radiography, CT, and MRI, a hallmark of osteochondroma is continuity of the cortex and medullary space from the underlying bone into the lesion. On radiography, osteochondromas are most often found on the long-bone metaphyses, and 35% occur at the knee. Lesions in younger patients tend to be closer to the growth plates. Osteochondromas may also form on the pelvis, ribs, and scapulae; spinal lesions are rare. Underlying metaphyses are broadened as a result of disturbance of normal modeling. The shape of osteochondromas varies from sessile, plaquelike lesions (Fig. 138.14) to pedunculated lesions (Fig. 138.15) with a long stalk. The stalk of a pedunculated lesion is directed away from the adjacent joint. En face, osteochondromas may be mistaken for sclerotic intramedullary lesions.

CT nicely demonstrates the morphology of the lesions and usually confirms the diagnosis; however, MRI much better demonstrates the cartilaginous cap characteristic of the lesion (Fig. 138.16). On T2-weighted images and with other cartilage-sensitive sequences, the cartilaginous cap is seen as a well-defined, high-signal crescent that caps the osteochondroma. The role of MRI is not to define the presence or absence of malignancy but to identify pathologic fractures or overlying soft tissue impingement. Pedunculated osteochondromas tend to fracture and cause soft tissue impingement, whereas sessile osteochondromas tend to only cause soft tissue impingement.[111]

In DEH, radiographs show deformity with irregular enlargement of one side of the epiphysis (Fig. 138.17). MRI is necessary to define the abnormality in younger children, because the lesions may be predominantly cartilaginous.

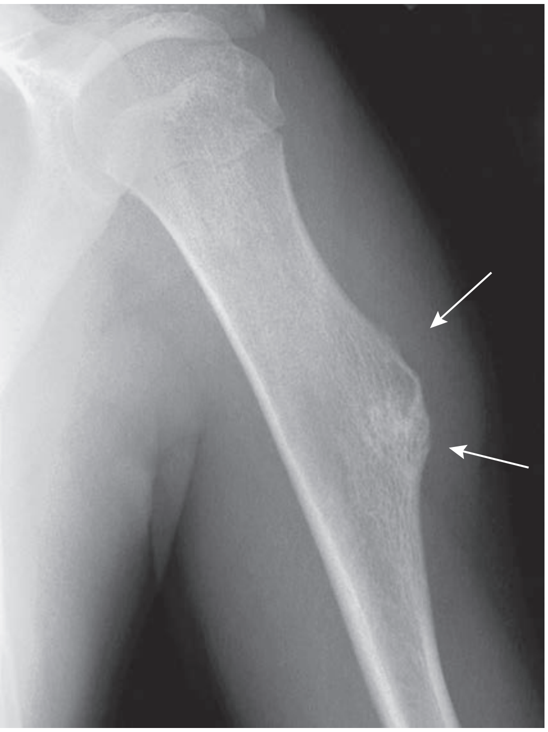

**Figure 138.14.** Sessile osteochondroma *(arrows)* of the proximal humeral diaphysis in a 16-year-old girl.

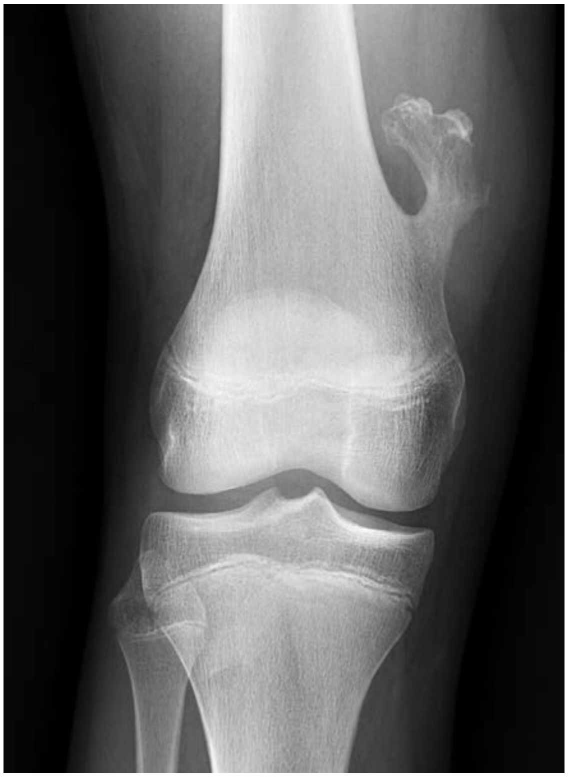

**Figure 138.15.** Pedunculated osteochondroma of the right distal femoral metaphysis in a 16-year-old boy.

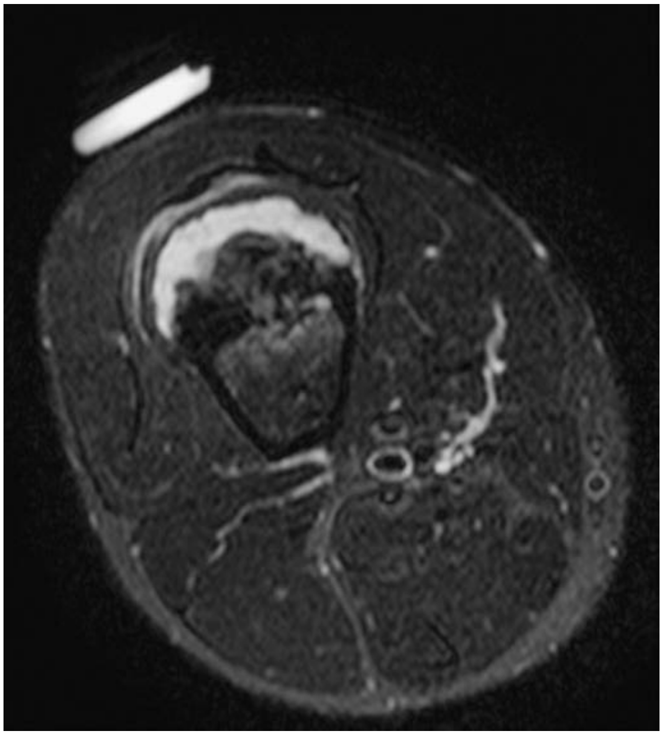

**Figure 138.16. Sessile osteochondroma in a 14-year-old boy.** T2-weighted MR image with fat saturation shows a broad, high-signal cartilaginous cap that covers the osteochondroma. Note the developing, overlying bursa. The anterior cortex under the cartilaginous cap is thickened. An external vitamin E marker was placed anteriorly over the palpable abnormality for localization.

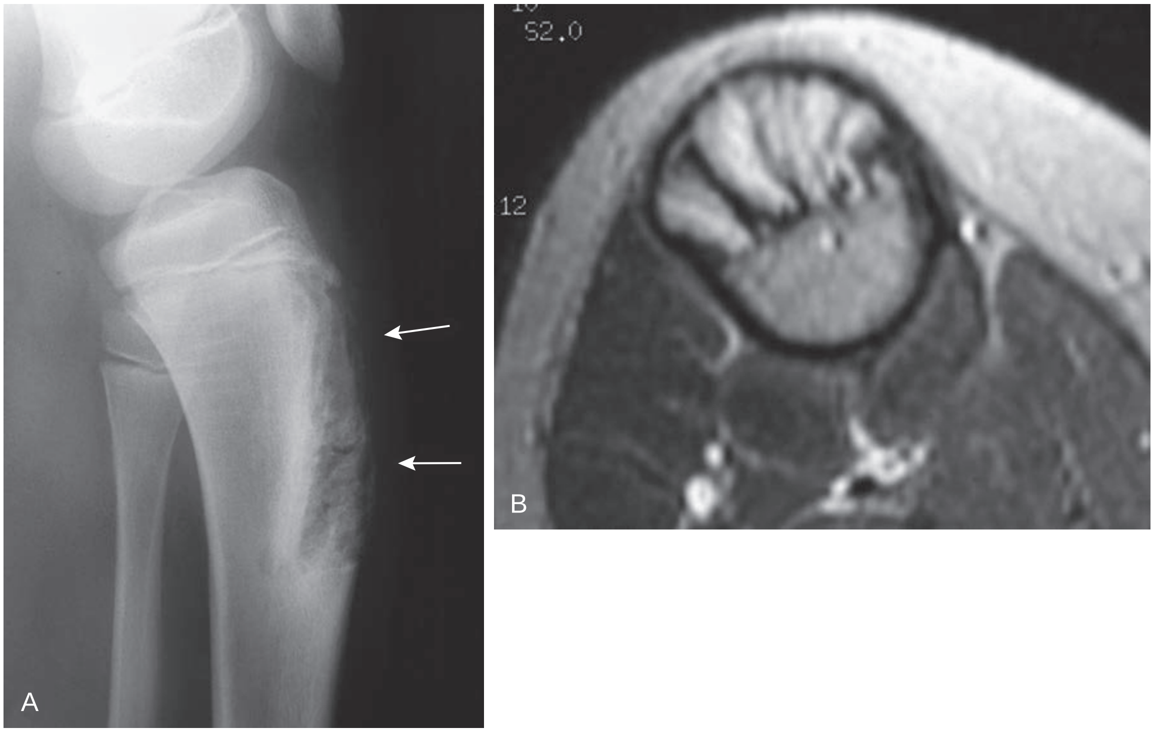
***Treatment.*** Osteochondromas are treated nonoperatively, unless soft tissue impingement is significant, or the lesion causes biomechanical alignment disorders. Treatment of epiphyseal osteochondromas are problematic, but nonarticular components may be resected. The articular components of epiphyseal osteochondromas usually are smooth, and the affected joint typically adapts over time.[112]

### Enchondroma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Enchondromas form owing to a failure of normal endochondral ossification adjacent to a physis. Tumors are composed of cartilage cells derived from the neighboring physis. Enchondromas are most frequently located in the small tubular bones of the hands and feet and in the metaphyses and metadiaphyses of the long bones. Enchondromas represent 80% of primary hand tumors in children and can form in any bone that forms in cartilage. Rib and vertebral lesions are uncommon. Enchondromas become more common with age, with a peak age for diagnosis in the third decade.

Enchondroma protuberans is an enchondroma variant that can resemble either a periosteal chondroma or a sessile osteochondroma (e-Fig. 138.18).[113] It has been described as an exophytic, exaggerated, eccentric from of enchondroma. This tumor arises in the medulla and expands eccentrically through the cortex so that the tumor eventually protrudes beyond it.[114] Rather than a cartilaginous cap, the tumor is covered by a thin layer of cortex and periosteum. This enchondroma variant most commonly occurs in the proximal humerus and in the hand.[115]

Ollier disease (enchondromatosis) is a nonheritable disorder of cartilage proliferation in which enchondromas involve multiple



**e-Figure 138.18. Enchondroma protuberans in an 11-year-old boy.** (A) Radiograph shows an ill-defined lucent lesion in the anterior cortex of the proximal tibia *(arrows)* abutting the physeal equivalent region of the tibial tuberosity. (B) Axial T2-weighted MR image shows a well-defined, high-signal lesion in the anterior tibial cortex and intramedullary space.

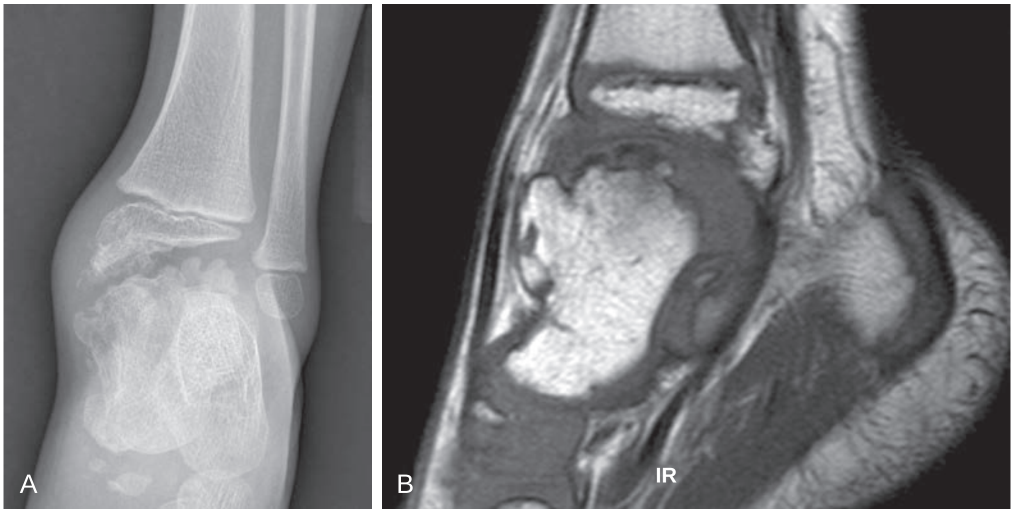


**Figure 138.17. Trevor disease (dysplasia epiphysealis hemimelica) in a 3-year-old boy.** (A) Radiography demonstrates “kissing” epiphyseal/epiphyseal equivalent osteochondromas at the level of the tibiotalar joint. (B) T1-weighted sagittal MR image shows marrow continuity with the osteochondromas.

bones. It is a mesodermal dysplasia and broader dyschondrogenesis that can affect any part of endochondrally formed bones, and it is more common in boys. Enchondromas form in any bone with a physis, although the hands may be disparately affected and may be grotesquely deformed. Enchondromas are bilateral but usually asymmetric in severity. Onset during infancy or early childhood may result in severe skeletal deformity. Enchondromas may interfere with growth plate function and may lead to limb shortening. The lesions of Ollier disease are expansile and lucent or trabeculated, usually with a shell of thin cortex. In the long bones, longitudinal lucent columns or streaks are characteristic.

Enchondromatosis accompanied by vascular malformations is known as *Maffucci syndrome*, which is also nonhereditary and a form of mesodermal dysplasia. The vascular malformations are predominantly venous but may be capillary and occasionally lymphatic. Calcified phleboliths may be demonstrated in the vascular soft tissue masses.

Malignant transformation is extremely rare with a solitary enchondroma, particularly in childhood. There is increased risk of malignant transformation in enchondromatosis, and Maffucci syndrome also carries an increased risk for extraskelatal malignancies.

*Metachondromatosis* is a very rare disorder that is a combination of enchondromatosis and osteochondromatosis.[116]

***Imaging.*** On radiography, as with other cartilaginous tumors, enchondromas exhibit a lobulated growth pattern that results in asymmetric expansion of the medullary cavity and endosteal scalloping (e-Fig. 138.19). The lesions may have characteristic channel-like lucencies that are perpendicular to the physis. Lesions are oval, well-circumscribed, and lucent with thin eggshell-like margins (Fig. 138.20). Focal, punctate calcifications may be evident on radiographs but are better appreciated with CT. The cartilaginous “ring and arc” pattern may be seen on CT. Margins of the lesion are sclerotic. The lesion may scallop the endosteum, erode cortex, and expand or distort the bone. Periosteal reaction is absent. The tumor is isointense with muscle on T1-weighted MRI and exhibits a heterogeneous, predominantly high T2-weighted signal. Signal intensity of the lesion parallels cartilage on all sequences. Enhancement with gadolinium varies; some lesions enhance peripherally, whereas others enhance more homogeneously. Adjacent bone marrow edema and enhancement are typically absent, but bone scans typically show increased activity.[117]

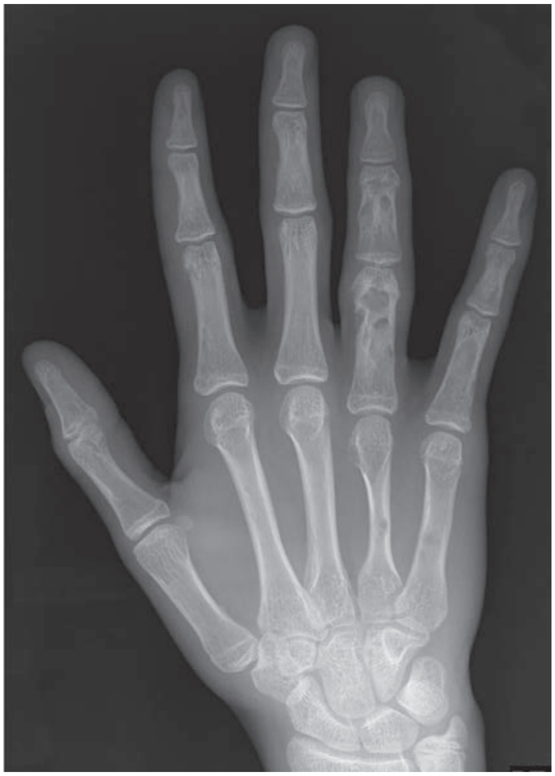

**Figure 138.20. Enchondromatosis in a 14-year-old boy.** Multiple, well-defined, lucent, expansile lesions are present in the metacarpals and phalanges of the ring and little fingers.

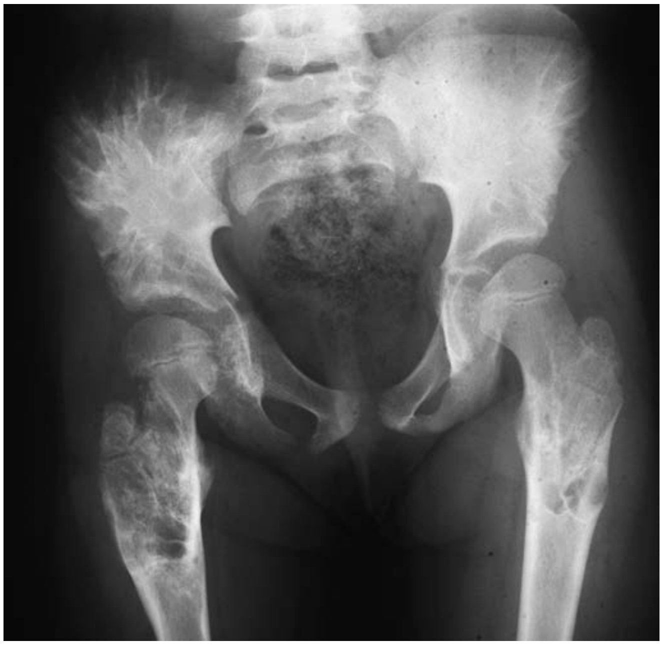
***Treatment.*** Enchondromas are managed nonoperatively and do not need to be longitudinally followed by imaging, unless new symptoms of pain or a pathologic fracture occur. These lesions do not have to be biopsied to confirm diagnosis.

### Periosteal (Juxtacortical) Chondroma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** This rare tumor is a surface variant of an enchondroma that arises from the periosteal surface of the cortex of the large and



**e-Figure 138.19. Enchondromatosis in an 8-year-old girl.** Multiple lesions are present within the proximal femurs and the iliac bones. The iliac lesions on the right are confluent and produce a radial pattern of tubular lytic channels. The proximal femoral diaphyses are mildly expanded with rim sclerosis, and speckled cartilaginous calcifications are present in some of the lesions.

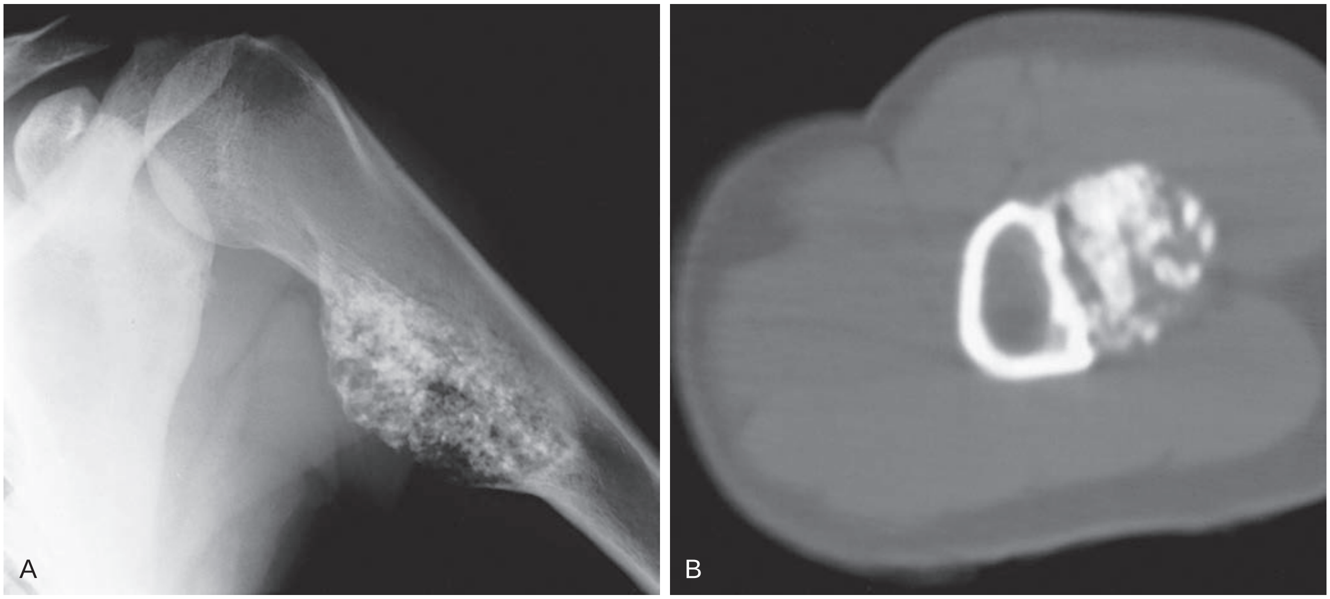


**Figure 138.22. Periosteal chondroma in a 19-year-old girl.** (A) Anteroposterior view of the humerus shows a broad-based tumor with a lobular mineralized matrix. (B) CT shows the superficial nature of the lesion, which is separated from the medullary cavity by cortical bone.

small tubular bones. One theory holds that the tumor is post-traumatic in origin, located under the periosteum and external to the cortex. Some tumors, such as within the femoral neck, are not covered with periosteum and are better labeled "juxtacortical." Periosteal chondroma most commonly occurs in the proximal humerus metaphysis, phalanges of the hands and feet, femur, and tibia. Patients are usually 10 to 30 years of age, and peak incidence is in the second decade of life; most come to medical attention with mild pain and swelling.[118] The lesion is more frequent in boys, and periosteal chondromas may be seen in patients with Ollier disease.

Periosteal chondroma does not have malignant potential, but biopsy may be advisable to distinguish it from periosteal osteosarcoma.

***Imaging.*** Radiographically, although periosteal chondroma may bear superficial similarity to a sessile osteochondroma, it is associated with sclerosis and external cortical scalloping, forming a periosteal shelf (e-Fig. 138.21). Focal calcifications of matrix within the lesion may be seen. Cross-sectional imaging delineates the underlying cortex and clearly distinguishes the lesion from a sessile osteochondroma. CT may show chondroid calcification (Fig. 138.22). MRI shows chondroid composition of the lesion, and peripheral enhancement is usually seen with gadolinium.[119] The tumor is usually 1 to 3 cm in size. A shell of reactive bone may be seen around the lesion, adjacent cortex is eroded or saucerized, and reactive bone sclerosis and buttressing is typically seen.

***Treatment.*** These benign lesions require biopsy to distinguish them from periosteal osteosarcomas. Lesions do not have to be followed by imaging after histologic diagnosis.

### Chondroblastoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Chondroblastoma, an uncommon tumor composed of primitive cartilage cells, usually occurs in the second decade of life. Roughly half occur before the physes close. The most specific feature of chondroblastoma is its location in the epiphysis of a long bone, most often the proximal humerus, distal femur, or proximal tibia. Chondroblastoma may also occur in epiphyseal equivalent regions such as apophyses, the patella, and carpal and tarsal bones. Larger lesions often may extend into an adjacent metaphysis, particularly in skeletally mature patients.[120] Up to 15% of chondroblastomas have a component of aneurysmal bone cyst (ABC). The tumor evokes a striking inflammatory response, which may help to distinguish it from other lesions.[121,122]

Included in the differential diagnoses for a lucent epiphyseal lesion in a child are chondroblastoma, osteomyelitis, and, after physeal closure, giant cell tumor (GCT).

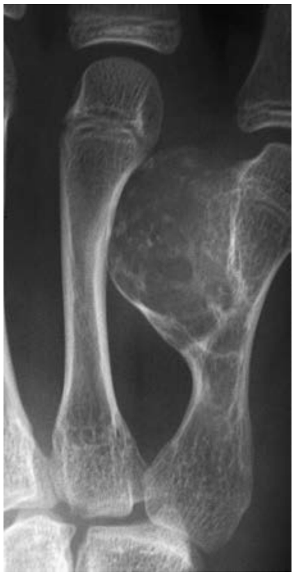
***Imaging.*** Radiographically, a chondroblastoma is seen as an eccentric, lucent, well-defined smooth or lobulated lesion with sclerotic borders within an epiphysis or epiphyseal equivalent (Fig. 138.23). The lesion may expand the bone, but the cortex is usually intact. Periosteal reaction distant from the lesion is another common feature suggestive of an accompanying inflammatory process.[123] Periosteal reaction on an adjacent metaphysis is seen in 30% to 50% of cases. Approximately one-third of chondroblastomas have a calcified chondroid matrix (see Fig. 138.23). This is better demonstrated by CT, which may also show cortical destruction. On MRI, chondroblastoma typically parallels cartilage signal intensity on all sequences. Signal intensity varies with the degree of calcification in the lesion. The rim of the tumor may have a lower intensity, and some foci give no signal because of calcification. Adjacent inflammatory changes consist of bone marrow and soft tissue edema and joint effusion and are usually prominent (see Fig. 138.23).[124,125]

Chondroblastomas superficially may mimic an epiphyseal Brodie abscess. MRI is useful in this circumstance. Both chondroblastomas and epiphyseal Brodie abscesses may demonstrate exuberant adjacent marrow and soft tissue edema, effusions, and reactive bone proliferation. However, on postcontrast imaging, chondroblastomas will demonstrate central enhancement, whereas Brodie abscesses will not.[126]

***Treatment.*** Chondroblastomas are treated with curettage and bone grafting. Approximately 20% of lesions recur. Otherwise, the prognosis is good. There are rare reports of metastatic chondroblastoma.

### Chondromyxoid Fibroma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Chondromyxoid fibroma (CMF) is a benign rare tumor that predominantly affects males in the second or third decade of life.



**e-Figure 138.21. Periosteal chondroma in a 13-year-old girl.** An expansile lesion originates at the surface of the metacarpal. Chondroid matrix is seen within the lesion, and the underlying cortex is externally scalloped.

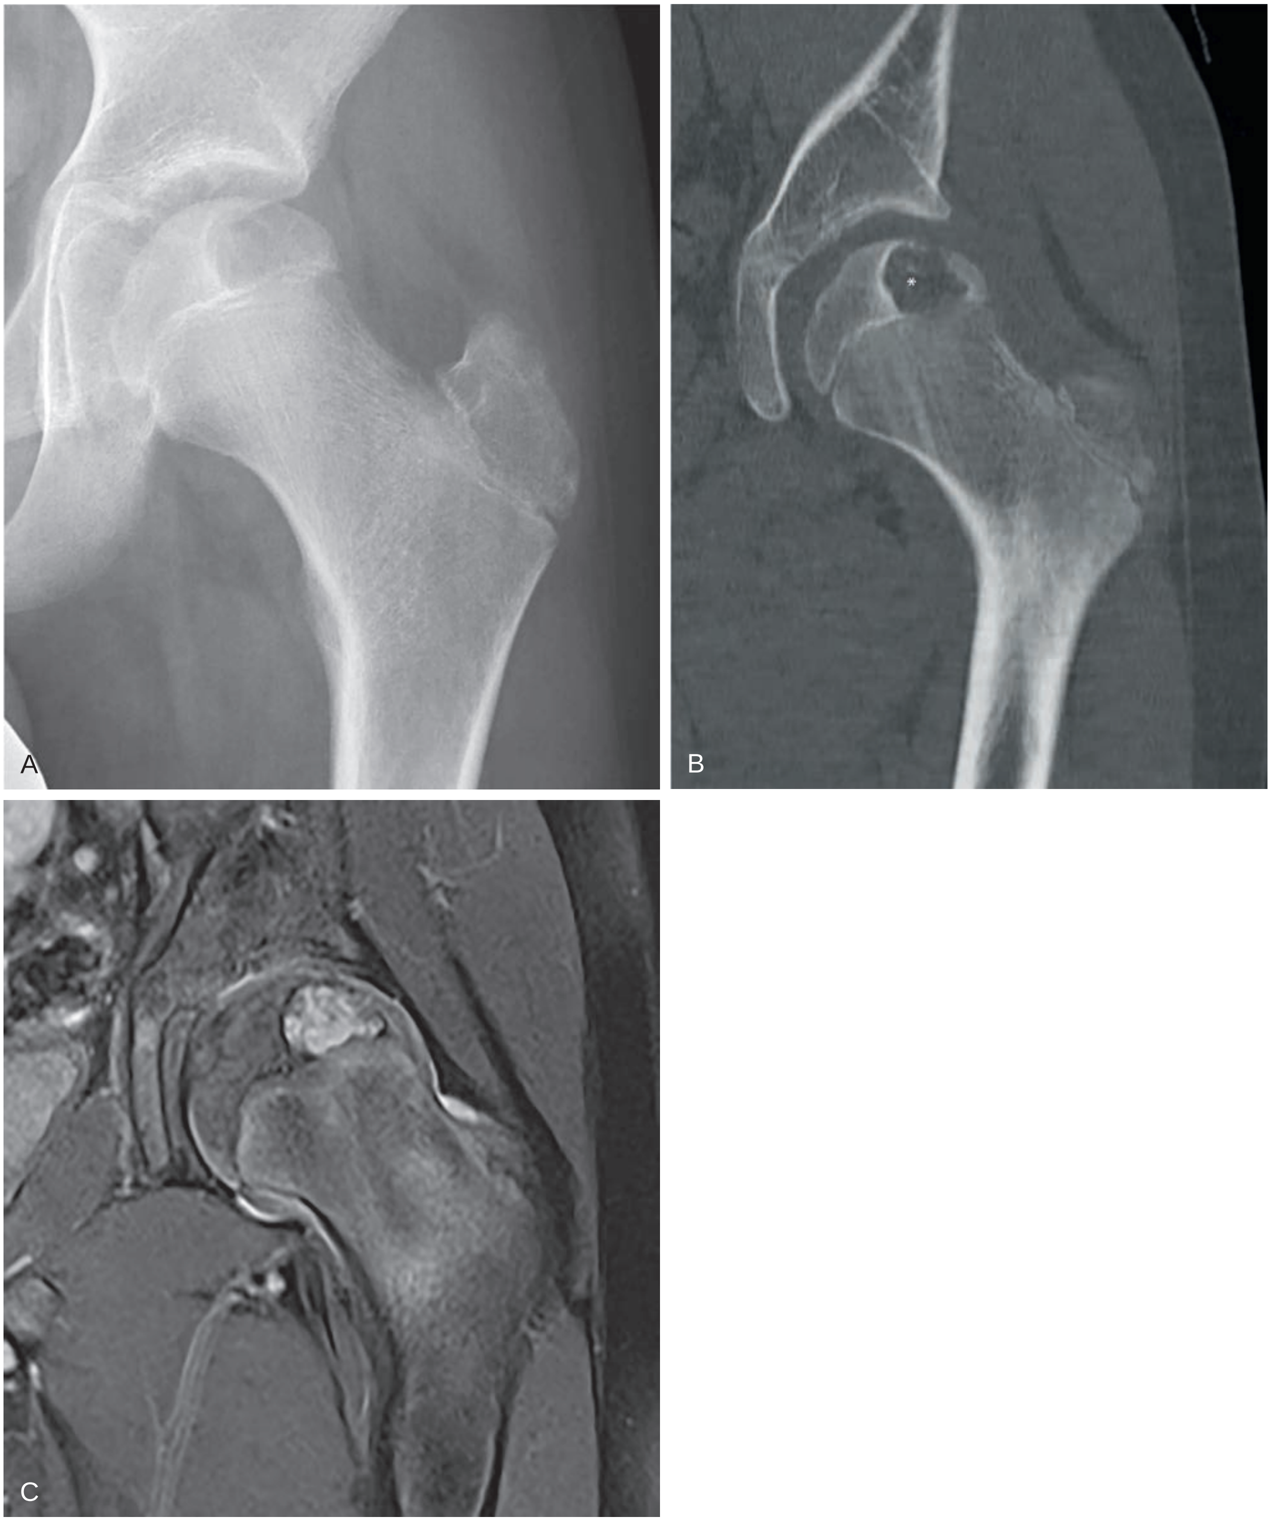


**Figure 138.23. Chondroblastoma in a 12-year-old boy.** (A) Radiograph shows a lucent lesion within the capital femoral epiphysis. (B) Coronal reformatted CT image shows a well-defined lesion with some calcified cartilaginous matrix *(asterisk)*. (C) Coronal STIR MR image shows the lesion to be of high signal intensity with regions of low signal representing chondroid matrix. Also note the adjacent marrow edema within the epiphysis and metaphysis.

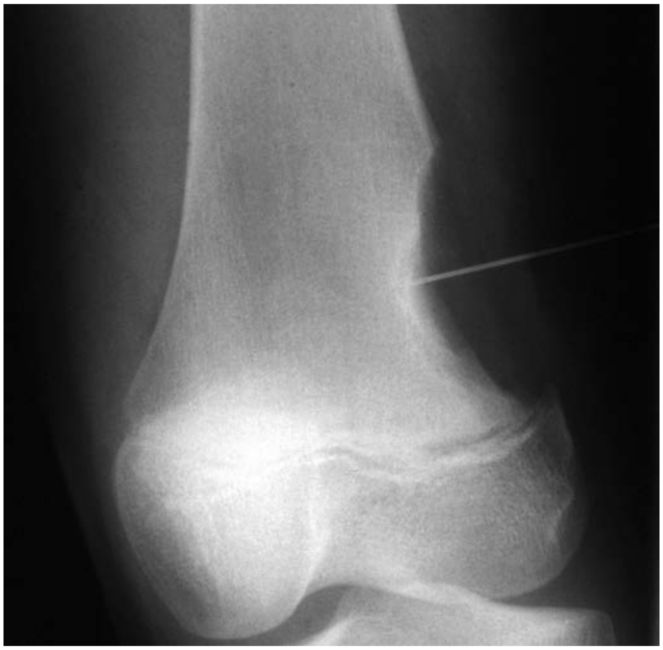

**Figure 138.24. Chondromyxoid fibroma in a 14-year-old boy.** The lesion has produced a well-defined scalloped defect in the distal femoral metaphysis. A biopsy needle is shown.

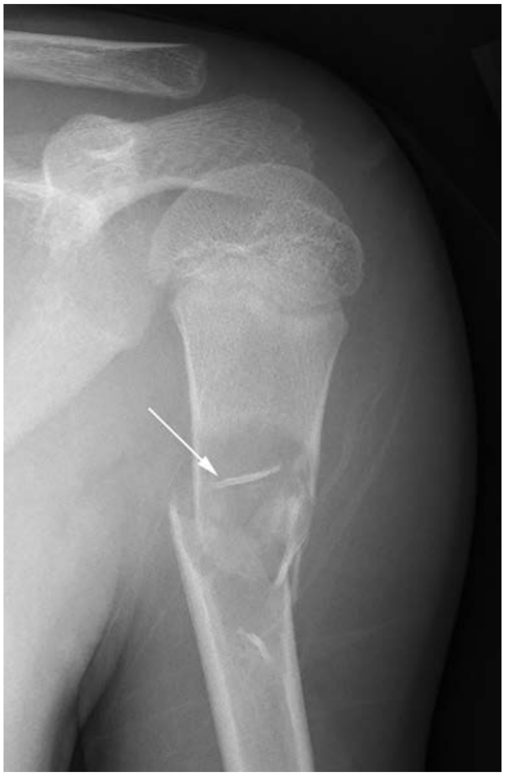

**Figure 138.25. Simple bone cyst with pathologic fracture in a 11-year-old boy.** The cyst has thinned and scalloped the overlying cortex. A fallen fragment is noted *(arrow)*.

Patients come to medical attention with pain. The lesion is a rubbery mix of fibrous, myxoid, and chondroid tissue. The most common site is the proximal tibia, but CMF may also arise within the ilium, other long bones at the knee, and tubular bones of the foot. The tumor is metaphyseal and often extends into metadiaphysis, but very rarely does it extend past a physis.[127,128]

***Imaging.*** On radiography, CMF has a characteristic but nonspecific appearance of a solitary, eccentric, lucent, well-defined lesion with sclerotic margins, which may show septations. In the short bones of the hands and feet, the lesion appears more central. The underlying cortex may be expanded, thinned, and occasionally absent. The lesion may appear bubbly, similar to an ABC.[129] Most lesions are elongated and oriented parallel to the long axis of the involved bone (Fig. 138.24). Matrix calcification and periosteal new bone formation usually do not occur. On MRI, CMF produces variable and often heterogeneous signal intensity depending on the composition of the lesion. In general, the lesion is of low signal on T1- and intermediate to high signal on T2-weighted imaging.[127]

***Treatment.*** Treatment of CMF is excision, and 25% of lesions recur. Multiple recurrences are common.

## Cysts

### Simple Bone Cyst

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** A simple bone cyst is also referred to as a *solitary cyst* or *unicameral bone cyst* (UBC), although the latter term is a misnomer, because these cysts are often septated. One theory holds that bone cysts arise because of a defect in endochondral bone formation or altered hemodynamics with venous occlusion that elevates intraosseous pressure and leads to cyst formation. Bone cysts have a membrane of loose vascular connective tissue and contain osteoclast-like giant cells and accumulations of fibrinoid material. The cyst space is usually filled with yellow, sometimes bloody fluid.

Cysts are more common in boys than girls by threefold, and 75% are seen in patients younger than 25 years of age; 25% are found incidentally. Bone cysts typically occur centrally in the metaphyses of the long bones and most commonly involve the proximal humerus (50%) and proximal femur (20%). Cysts have an "active phase," during which they increase in size and remain in close proximity to the physis. "Latent phase" cysts are found farther from the physis and usually do not continue to grow. Cysts may appear to "migrate" into the diaphysis, but actually it is the growth plate that migrates away from the cyst. In older patients, pelvic and calcaneal bone cysts become more common.[130]

Bone cysts are occasionally found in the calcanei of pediatric patients.[131] Often, these cysts are painless and are first detected by radiography of acute injuries to the feet. Calcaneal bone cysts are nearly always located near the base of the neck of the calcaneus. The thin, overlying lateral cortical wall of the calcaneus forms a well-defined bony border that allows differentiation from the "physiologic" pseudocystic radiolucent areas observed in the same region of normal bones.

Bone cysts are asymptomatic unless complicated by fracture; however, 75% of patients present with a pathologic fracture. Bone cysts are the most common cause of pathologic fracture in children.

***Imaging.*** On radiography, bone cysts have a central, medullary location within the metaphysis. Most cysts are less than 3 cm in diameter but may be much larger in the long axis. The cyst wall is well defined and sclerotic; the overlying cortex is thinned, and the lesion may be mildly expansile.[132] With fracture, a fragment of bone may be seen dependently within the cyst. This "fallen fragment" sign is considered pathognomonic for a simple bone cyst (Fig. 138.25). CT delineates the cyst and confirms a fallen fragment but is rarely necessary. In atypical cases, MRI may be performed to confirm the cystic nature of the lesion. The fluid contents are low signal on T1- and high signal on T2-weighted imaging. With contrast, the cyst lining enhances, but the contents do not (e-Fig. 138.26).[133] Increased areas of enhancement may be seen after pathologic fractures.

Occasionally, with preceding intralesional hemorrhage from fracture, fluid-fluid levels may be seen that represent settled, degraded blood products. When bone cysts heal after pathologic fracture, they may have multiple septations and fluid-fluid levels within them, and they may superficially mimic an ABC. As a general rule, if the lesion diameter is smaller than the thickest diameter of the affected bone, the lesion should be considered a complicated solitary bone cyst. If the lesion diameter is greater than the thickest diameter of the affected bone, an ABC should be considered.

***Treatment.*** Fractured cysts tend to heal spontaneously; however, larger cysts with or without fracture are usually treated with curettage and bone grafting. The prognosis is excellent, although 35% to 50% of bone cysts recur, in some cases multiple times. Treated cysts often have a complex appearance with mixed sclerosis and lucency, septations, and mild expansion and deformity of the involved bone. Premature growth plate closure may occur as a complication of treatment or pathologic fracture but not as a result of the cyst itself. Cyst aspiration with corticosteroid injection or sclerotherapy has also been used for treatment.

### Aneurysmal Bone Cyst

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Histologically an ABC is composed of anastomosing channels that contain blood and are variably lined with fibrous walls that contain red blood cells, hemosiderin granules, foreign body giant cells, and spicules of reactive bone. The etiology of an ABC is poorly understood and may be primary or secondary and/or reactive. A wide variety of lesions may act as the nidus for ABC development, and underlying lesions are pathologically identified in one third of cases. A large ABC may obscure the underlying lesion, or it may represent only a small component of a larger tumor. In lesions without an underlying tumor, the role of antecedent trauma and intraosseous or subperiosteal hemorrhage acting as a nidus has been proposed. ABC is slightly more common in girls. Whether primary or secondary, the lesion is most common in the first three decades of life, and it is rare in patients younger than 5 years. Patients usually come to medical attention with nonspecific pain and swelling, and 10% present with pathologic fracture.[134] ABC is most common in the metaphyses of long bones, the craniofacial bones, and the posterior elements of the spine. Long-bone lesions can be subclassified as either *intramedullary* or *juxtacortical* (cortical or subperiosteal). A subperiosteal ABC is rare and mimics other subperiosteal tumors and pathologies.[135–137]

An unusual solid variant of ABC has radiographic features similar to those of the typical ABC.[138,139] The solid variant lacks cavernous, blood-containing spaces and is characterized histologically by the solid elements—proliferating fibrous tissue, benign giant cells, and newly formed osteoid matrix. A third of these tumors are not "aneurysmal." The solid variant of ABCs is histologically indistinguishable from extragnathic giant cell (reparative) granuloma. It is most common in the second and third decade. The lesion favors the axial skeleton over appendicular locations, and the most common locations are in the craniofacial bones, small tubular bones of the hands and feet, and the femur.

***Imaging.*** On radiography, ABC appears as a lucent, expansile, "blowout" or "soap-bubble" lesion with thin, smooth, bony walls (e-Fig. 138.27 and Fig. 138.28). As previously mentioned, if the lesion diameter is greater than the widest part of the affected normal bone, an ABC should be considered (see e-Fig. 138.27). ABCs are multiloculated, and the cortex is usually intact but may be markedly thinned to the point of being undetectable on imaging, and periosteal new bone may be present. Both CT and MRI demonstrate fluid-fluid levels, which are characteristic of the lesion.[140,141] This finding is due to sedimentation of degraded blood products, especially methemoglobin, which has a much shorter T1 relaxation time than that of hemoglobin. Fluid-fluid levels may be single or multiple and may be seen as varying horizontal levels within separate loculations (see e-Fig. 138.27 and Fig. 138.28). If the loculations are very small, fluid-fluid levels may be less

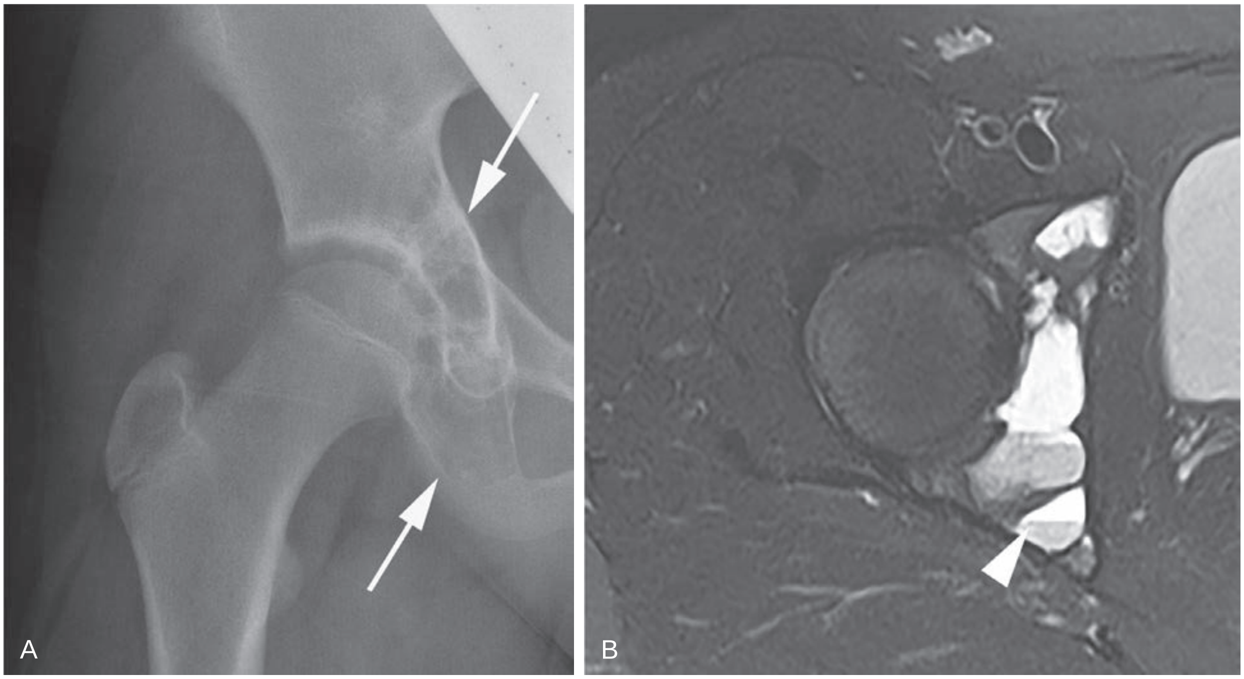

**Figure 138.28. Aneurysmal bone cyst in a 10-year-old girl.** (A) Radiograph of the hip shows an expansile, lucent lesion with a thin, bony shell *(arrows)*. (B) Axial STIR MR image shows several fluid-fluid levels *(arrowhead)* within the lesion.

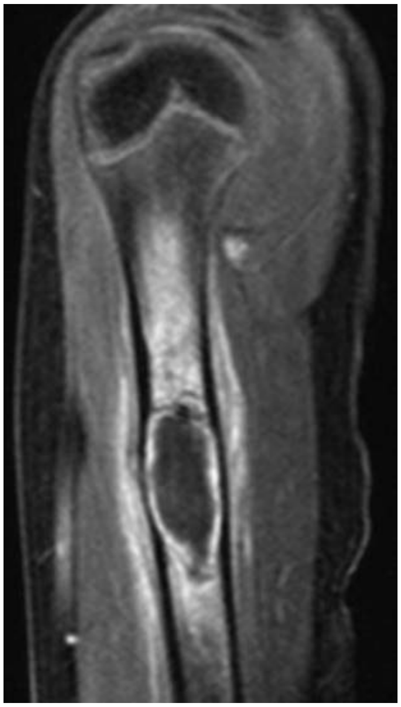
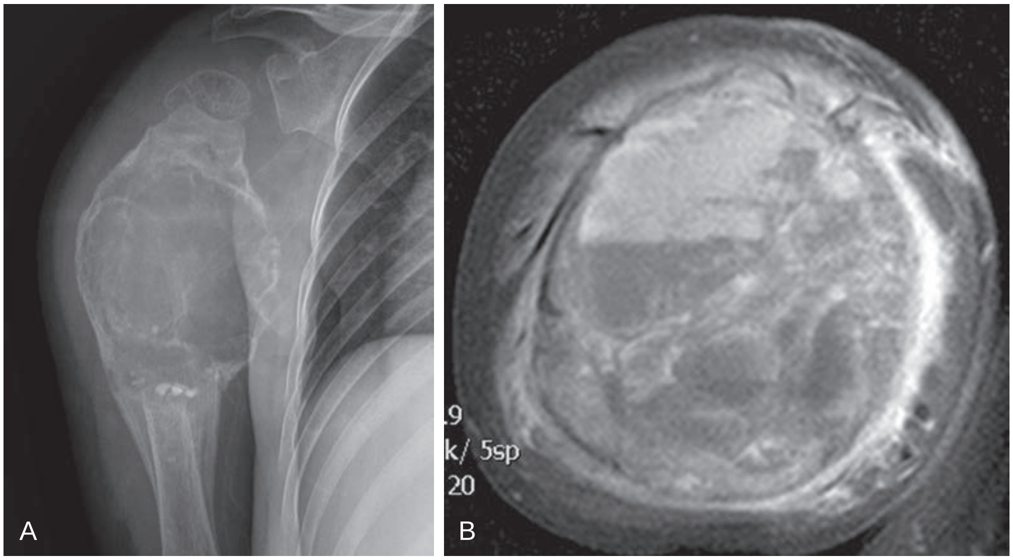


**e-Figure 138.26. Simple bone cyst in an 8-year-old boy.** Sagittal contrast-enhanced fat-saturated T1-weighted MR image shows a lesion that contains fluid with an enhancing rim. Enhancement is also seen in the adjacent marrow and soft tissues. The degree of enhancement is increased in this patient owing to a healing pathologic fracture through the lesion.



**e-Figure 138.27. Recurrent aneurysmal bone cyst (ABC) in a 4-year-old boy.** (A) Radiograph of the humerus shows a “blowout” lesion, whose width is wider than the widest part of normal bone. Note the bone graft material in the dependent components of this treated ABC. (B) T2-weighted fat-saturated axial MR image demonstrates multiple fluid-fluid levels.

apparent. The signal characteristics of the cyst contents are variable and are probably dependent on the relative age and concentration of the blood components. Abundant hemosiderin may produce foci of low signal, which may be diffuse throughout the lesion. Septal enhancement is seen on postcontrast images.

It may not be possible to differentiate primary and secondary ABCs. Secondary ABCs can occur with numerous benign and malignant bone lesions, including fibrous dysplasia, chondroblastoma, GCT, nonossifying fibroma, simple bone cyst, and osteosarcoma, particularly the telangiectatic variant.[142,143] Any solid component suggests an underlying tumor. Lesions composed of a greater percentage composition of fluid-fluid levels are more likely benign. Solid enhancing soft tissue components on MRI should raise suspicion for primary bone tumor causing a secondary ABC or a telangiectatic osteosarcoma. In such cases, MRI can direct biopsy to the solid components.

On MRI, solid ABCs demonstrate low signal on both T1 and T2 images because of fibrosis. The lesion enhances with gadolinium. The solid variant of ABC may occasionally produce osteoid that may be evident on radiographs or CT.

***Treatment.*** ABC is treated with curettage and bone grafting, although 20% of ABCs recur after grafting. Vascular embolization and percutaneous sclerotherapy have also been used.

### Giant Cell Tumor

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** GCT, also known as *osteoclastoma*, is an uncommon neoplasm that rarely occurs before skeletal maturity. Approximately 5% of cases are reported before skeletal maturity,[144] most in the second decade and rarely in the first decade of life.[145] The lesion is most common in the long bones, particularly the distal femur and proximal tibia; it is less common in the short bones of the hands and feet, and in children, it rarely occurs elsewhere.[146] In skeletally mature individuals, the lesion originates in the metaphysis and extends into the epiphysis, typically extending to the subarticular region. In skeletally immature patients, the lesion is almost uniformly metaphyseal and usually abuts the physis. Epiphyseal involvement is very rare before physeal closure, and multifocal GCT is very rare in children. Patients with GCT come to medical attention with pain and tenderness, swelling, and limited range of motion of the adjacent joint.[147]

***Imaging.*** On radiographs, GCT appears as a geographic, lytic lesion (Fig. 138.29). Margins vary from sclerotic to ill defined. Frequently, a relatively sharp but nonsclerotic margin is apparent. Periosteal new bone, expansion of bone, and pathologic fracture are common. The metaphyseal end of the lesion tends to be less well defined. No calcified or ossified matrix is seen.

MRI findings vary. In one large series, 56% of tumors were solid or solid with cystic change, and 44% were cystic.[144] Solid areas tend to have intermediate T1 and T2 signal. Hemosiderin from intratumoral hemorrhage may produce foci of low signal. Occasionally, a GCT may have a more aggressive appearance, with cortical penetration and soft tissue extension. Approximately 15% of GCTs have an associated component of ABC and appear more expansile.[148] The prognosis of GCT is excellent, although up to 25% of tumors recur locally. Malignant GCT and metastasizing GCT have rarely been reported in children. The pulmonary “implants” from GCT usually have self-limiting growth potential, but recurrence and disease progression is possible.[149]

***Treatment.*** For resectable GCTs, en bloc excision has a lower recurrence rate, approximately 20%, compared with intralesional curettage, which has an approximately 50% recurrence rate.[150]

## Fibrous Tumors

### Fibrous Cortical Defect and Nonossifying Fibroma (Fibroxanthoma)

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Fibrous cortical defect (FCD) and nonossifying fibroma (NOF) are extremely common tumors that occur in the metaphyses of the long bones of children. FCDs are essentially a normal variant and are found in up to 40% of children during development. FCD and NOF are histologically identical and are composed of highly cellular stroma with spindle-shaped fibroblasts, osteoclast-like multinucleated giant cells, and foam or xanthoma cells. Arbitrarily, lesions smaller than 2 cm are considered an FCD, and those larger than 2 cm are called NOFs. Lesions probably represent a developmental defect in the periosteum of cortical bone and are seen in the latter

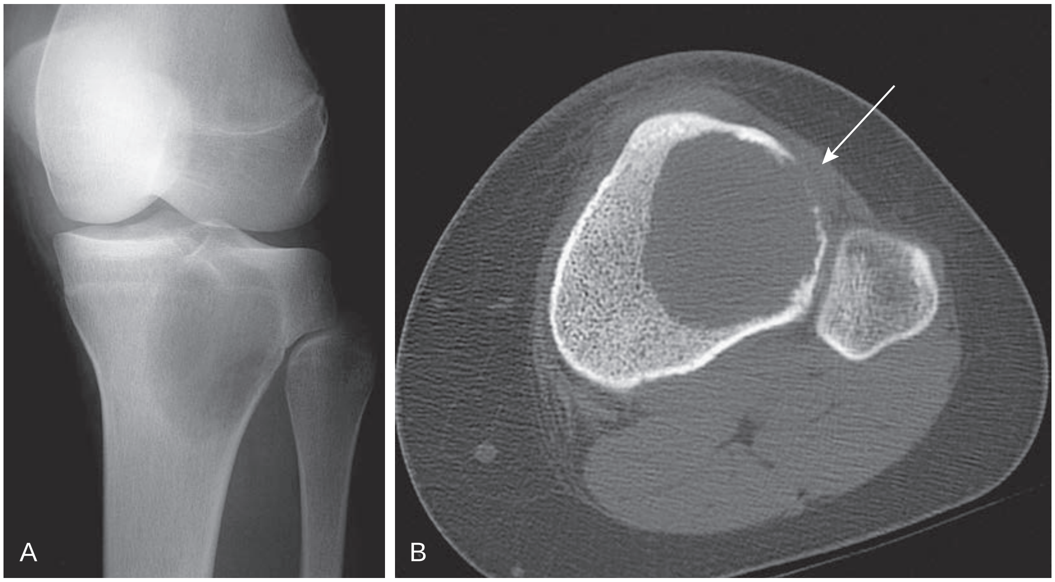


**Figure 138.29. Giant cell tumor in a 14-year-old girl.** (A) Radiograph shows a relatively well-defined lucent lesion in the proximal tibial metaphysis and epiphysis. The lesion does not have sclerotic margins and is near the articular surface but does not abut it. (B) Axial CT shows a large lucent lesion of the tibia. The lesion margins are well-defined but not sclerotic. The anterolateral cortex is destroyed *(arrow)*.

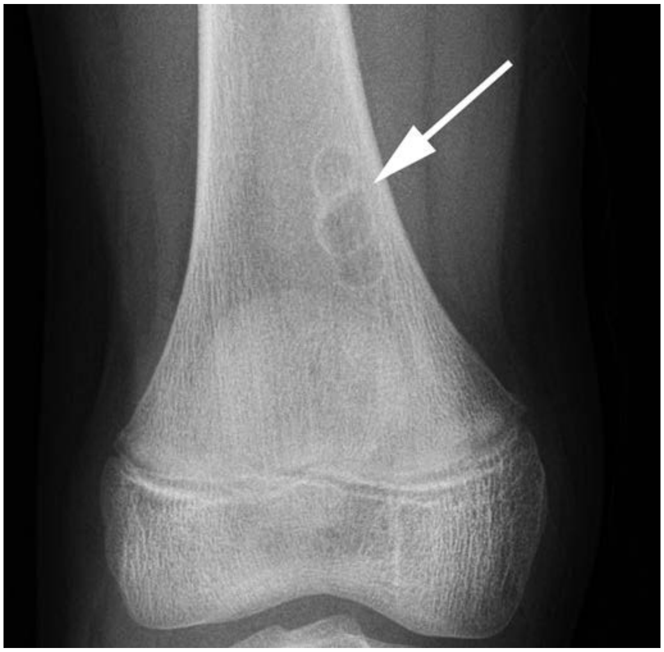

**Figure 138.30. Nonossifying fibroma in a 12-year-old boy.** The lesion is well-defined, with a “soap bubble” appearance and sclerotic margins *(arrow)*.

part of the first decade until shortly after skeletal maturation. The average time from diagnosis to spontaneous regression is 29 to 52 months; lesions become inactive after skeletal maturity, although rarely, an NOF may persist into adulthood.[151,152]

FCD and NOF are usually detected incidentally. The lesions are asymptomatic, with the exception of very large lesions, which may cause dull pain. Uncommonly, an NOF may be large enough to cause a pathologic fracture or lead to a stress fracture. FCD and NOF are most common in the metaphyses of the long bones of the lower extremity, especially at the knee. FCDs and the distal medial femoral avulsive irregularity are histologically similar.[153]

Multiple NOFs may be seen with neurofibromatosis. In Jaffe–Campanacci syndrome, disseminated NOFs are associated with cystic lesions of the jaw, café-au-lait skin lesions, and other anomalies but without neurofibromas. Some believe Jaffe–Campanacci syndrome is a *forme fruste* of neurofibromatosis.[154–157]

***Imaging.*** On radiography, FCDs are seen as small, well-defined, ovoid, cortically based lesions. NOFs are similar but larger (Fig. 138.30), more lobular, and multilocular with a characteristic “soap bubble” appearance. Usually, the lesions extend inward; however, the outer cortex may be thinned and bulging. In thinner bones, such as the fibula, the lesion may occupy the entire width of the bone. FCDs and NOFs originate in metaphysis near the growth plate and migrate into metadiaphysis and diaphysis with maturation. Their radiographic appearance is sufficiently specific that neither additional imaging nor biopsy is indicated.

The radiographic features of FCD and NOF are similar on CT. On MRI, lesions are well defined, lobular, and cortically based. Low signal is seen on T1, and T2 signal and enhancement with gadolinium varies with the stage of lesion development. Active, early lesions are high signal on T2-weighted imaging, and they enhance. Involuting lesions are low signal on T2 and do not enhance, and no peritumoral edema is seen.[158] Active, early lesions may also show uptake on bone scans and PET scans.[159]

***Treatment.*** The natural history is for involution to occur with progressive sclerosis of the lesion.

## Fibrous Dysplasia

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Although it is not a true neoplasm, fibrous dysplasia that involves a long bone may mimic a bone tumor or cyst, especially when it causes localized expansion of the bone and is monostotic.[160] Pathologically, fibro-osseous tissue replaces the normal medullary space. Fibrous dysplasia can be monostotic (70%–80% of cases) or polyostotic, and monomelic or polymelic. Fibrous dysplasia is more common in girls than in boys. Most patients with focal disease are adolescents or young adults, but patients are occasionally seen in the first decade of life. Any bone may be affected. The most common presentation is monostotic disease that affects craniofacial bones, especially the skull base; a long bone, most commonly the femur; or a rib. Lesions may involve metaphysis and diaphysis but spare the epiphysis before physeal fusion. Patients with solitary lesions come to medical attention with pain, edema, deformity, or pathologic or fatigue fracture. Patients with polyostotic disease are seen with similar signs and symptoms, but often at a younger age (i.e., first decade). Polyostotic disease predominates on one side, is often syndrome related, and may be suspected based on other clinical findings.[161,162]

In 2% to 3% of patients, fibrous dysplasia is associated with endocrine disorders, mostly of hypothalamic dysfunction. In McCune–Albright syndrome, female patients are seen with precocious puberty, cutaneous café-au-lait spots, and unilateral polyostotic fibrous dysplasia. Mazabraud syndrome, characterized by polyostotic fibrous dysplasia and intramuscular myxoma, is rare in children.[163]

***Imaging.*** Fibrous dysplasia in the long bones causes expansion of the medullary cavity, endosteal scalloping, coarse trabeculation, and sclerotic margins that form a “rind.” Bowing of the affected bone may occur. In the femur, the resulting deformity is called a *shepherd’s crook* (Fig. 138.31). Lesions may be central or eccentric. Because the radiographic opacity of a fibrous dysplasia lesion depends on the relative amount of dysplastic bone and fibrous material within the lesion, the appearance varies, from having the look of ground glass to appearing radiolucent. The ground-glass appearance is due to a matrix that contains a fine meshlike pattern of delicate bone spicules (Fig. 138.32). It is relatively specific for fibrous dysplasia but may be simulated by other lesions that replace the medullary trabeculae. Lucent lesions usually have a sclerotic margin, and small cartilaginous foci within the lesion may develop chondroid calcification (osteocartilaginous fibrous dysplasia). In addition, a single lesion or involved bone may demonstrate varying appearances within different areas. Active, early lesions tend to be radiolucent, whereas older lesions may be more sclerotic. No periosteal reaction is present unless there is a fracture. Similar findings are visible with CT.

On MRI, lesions are similar in signal intensity to muscle on T1-weighted imaging. On T2-weighted imaging, lesion signal intensity varies depending on the composition of the lesion; pure fibrous tissue is hypointense on T2. However, lesions of fibrous dysplasia are often hyperintense[164] because of the inhomogeneous nature of the lesion, which consists of spindle cells, trabeculae of immature woven bone with osteoid seams, and small cysts. Fluid-fluid levels have been reported,[165] but soft tissue extension is rare. Central or, less frequently, peripheral enhancement may occur with gadolinium, and lesion uptake on bone scans is variable and may even be normal.

***Treatment.*** Imaging findings often are diagnostic, biopsy is rarely necessary, and treatment is supportive. Surgical treatment is predicated on the presence or absence of pathologic fracture or impending biomechanical failure. Orthopedic implants are used to reinforce and stabilize affected bones.

## Osteofibrous Dysplasia

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Osteofibrous dysplasia (OFD), also known as *extragnathic*

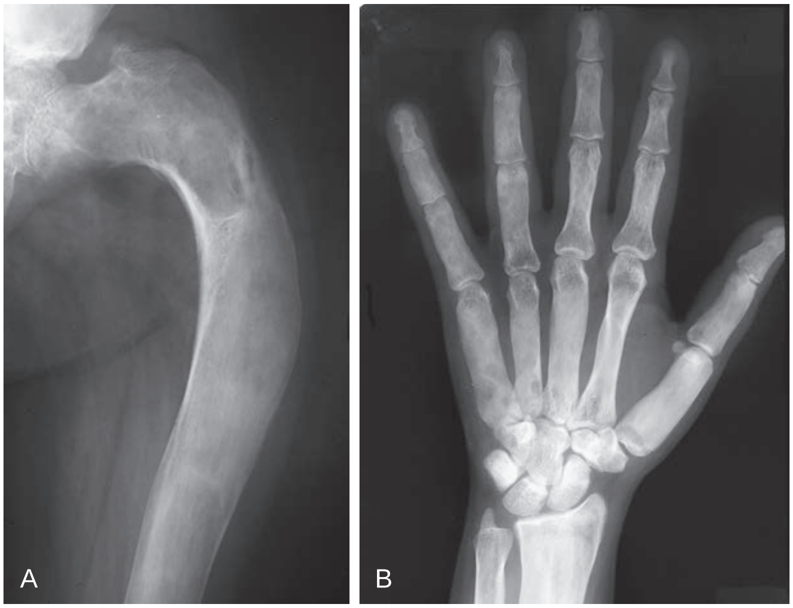

**Figure 138.31. Polyostotic fibrous dysplasia in a 22-year-old woman.** (A) The femur is expanded and bowed with a "shepherd's crook" deformity. The femoral trabeculae are replaced by "ground-glass" matrix. (B) Diffuse sclerosis is seen in the hand and wrist with mild expansion and indistinct transition from cortex to medullary space.

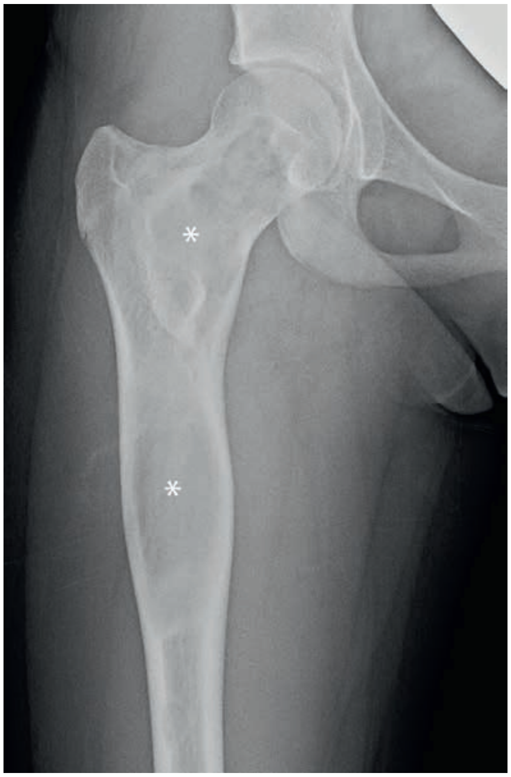

**Figure 138.32. Focal fibrous dysplasia in an 13-year-old girl.** The lesion has well-defined, sclerotic margins and a ground-glass matrix *(asterisks)*.

*ossifying fibroma* or *intracortical fibrous dysplasia*, is a proliferation of fibro-osseous tissue. OFD is usually sporadic, although autosomal-dominant inheritance has been reported.[166] Most cases occur during the first decade of life, and some tumors have been found in newborns.[167,168] OFD is a rare lesion that is usually confined to the diaphysis and metadiaphysis of the tibia but can also involve the fibula, sometimes synchronously in the same patient. Rarely, lesions may be multiple and bilateral. OFD is usually painless and characterized by deformity that can progress until physeal fusion occurs. Patients may come to medical attention with anterior bowing, and fracture or pseudoarthrosis may occur.

OFD is histologically similar to fibrous dysplasia in that it contains well-differentiated fibroblasts, collagen, and bony trabeculae. The main differentiating feature is the presence of active osteoblasts in OFD. Differentiated adamantinoma and adamantinoma are closely related to OFD, because they share similar histochemical properties.[169] Especially in the second decade, radiologic and even pathologic distinction between OFD, differentiated adamantinoma, and adamantinoma is difficult, although OFD tends to occur at a younger age than adamantinoma. This differentiation is discussed later in this chapter.

***Imaging.*** By radiography, OFD is an eccentric, lucent, solitary, or multiloculated lesion that involves the anterior cortex of the tibia (Fig. 138.33). The lesion may be rounded in appearance or ovoid and may be longitudinally oriented with the tibial shaft; it may be purely intraosseous, or it may have a minor extraosseous component. Involvement of the tibia is more commonly proximal, but distal lesions occur and may be complicated by pseudarthrosis. The cortex is expanded, and larger lesions will expand posteriorly and may replace the medullary cavity. Lesions appear lucent or ground glass and are associated with cortical thickening and anterior bowing of the bone. Cross-sectional imaging is very helpful in determining the lesion's intracortical location, an important feature in distinguishing OFD from fibrous dysplasia, which is intramedullary.

### Long-Bone Adamantinoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Long-bone adamantinomas are rare tumors in children, and patients are often seen initially with pain and anterior tibial bowing.[170] As opposed to OFD, adamantinoma is a low-grade malignancy. Up to 15% of affected patients die of metastatic disease. On the basis of clinical, radiologic, histologic, and histochemical characteristics, long-bone adamantinomas (unrelated to the jaw

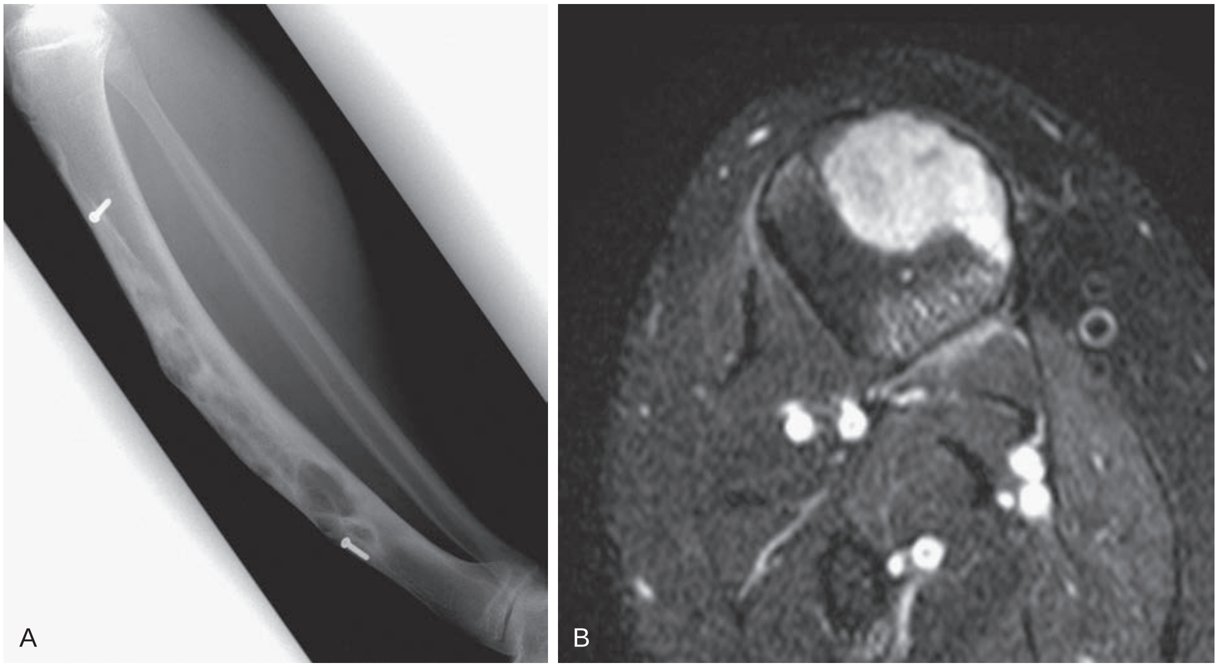

**Figure 138.33. Osteofibrous dysplasia in a 15-year-old boy.** Biopsies obtained several years prior had led to a diagnosis of adamantinoma, for which surgical excision with grafting had been performed (screws are related to the prior graft). Symptoms recurred. (A) Lateral radiograph shows anterior tibial bowing with mixed sclerosis and cystic lucencies centered anteriorly within the tibia. (B) Axial T2-weighted MR image with fat saturation shows homogeneous, high-signal soft tissue within the lesion. Percutaneous and excisional biopsies both showed osteofibrous dysplasia.

lesion previously referred to as an adamantinoma) have recently been divided into two groups: *classic* and *differentiated* (OFD-like). Both types involve the tibia, the fibula, or both bones. The classic form occurs almost exclusively in adults and is found in either the cortex or the medulla, but it can expand through the cortex and periosteum. The differentiated form is seen in children and young adults up to 20 years of age and has been reported in newborn infants. The tumor is limited to the bony cortex and has a radiographic appearance identical to that of OFD. Adamantinoma and OFD do have some pathologic distinctions. Epithelial and mesenchymal cells, which express immunoreactive cytokeratin and vimentin, are present in adamantinomas. Epithelial elements are absent in classic OFD and are minimal in differentiated adamantinoma.[171]

Clinical, radiologic, and pathologic distinction of adamantinoma from OFD is challenging. The concept of a differentiated form implies a continuum between OFD and adamantinoma and suggests that OFD may be a regressive phase of adamantinoma. Some well-documented cases in the literature support this contention. Czerniak and colleagues[172,173] suggested that patients with the differentiated type have a more favorable prognosis than those with classic adamantinoma—no differentiated tumors have been known to metastasize—and that long-bone adamantinoma could be included among the few neoplasms capable of spontaneous regression.

***Imaging.*** Radiographic findings of long-bone adamantinoma are similar to those of OFD. Variable features that might raise suspicion for adamantinoma are periosteal reaction, moth-eaten destruction, and soft tissue extension. MRI of adamantinoma is nonspecific. The T1- and T2-weighted signal characteristics are similar to those of other tumors. Soft tissue extension may also be evident.[169,174,175]

***Treatment.*** Treatment of adamantinoma is usually en bloc resection. Treatment for OFD and differentiated adamantinoma is much more conservative. If surgery is to be performed for OFD or differentiated adamantinoma, it should be performed after the child reaches puberty, and only if the disease is extensive and has caused deformity.[169]

### Langerhans Cell Histiocytosis

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** The cause of Langerhans cell histiocytosis (LCH) is unknown. Recent evidence of clonal proliferation of Langerhans cells suggests a neoplastic etiology. The unifying pathologic feature of LCH is in an inappropriate proliferation of Langerhans cells. Like the cells of monocyte-macrophage lineage, the Langerhans cell originates from CD34+ stem cells of the bone marrow. Immunohistochemical staining for S100 protein and CD1a antigen are used in making the diagnosis.[176,177]

Focal LCH is a relatively common pediatric bone tumor and represents a continuum of disease that ranges from a single, indolent, self-limiting osseous lesion to a fulminant disseminated disorder that involves multiple organs systems. Approximately 80% of patients with LCH have osseous involvement. In the past, patients with LCH pathology were divided into three diagnoses: *eosinophilic granuloma* referred to localized skeletal disease, usually a single lesion, and approximately 70% of patients fall into this category; children with *Hand–Schüller–Christian disease* had the triad of geographic bone lesions, proptosis, and diabetes insipidus—a triad rarely seen in an individual patient; and *Letterer–Siwe disease* referred to the fulminant, disseminated, often fatal multisystem form. Fewer than 10% of patients fall into this last category. It is now recognized that LCH is a spectrum of disease rather than these three distinct entities.[178,179]

LCH is more common in whites, is twice as common in boys, and is seen from the neonatal period into adulthood. Most patients are younger than 15 years at presentation, with a peak incidence from 1 to 5 years of age. Focal lesions tend to be found in children

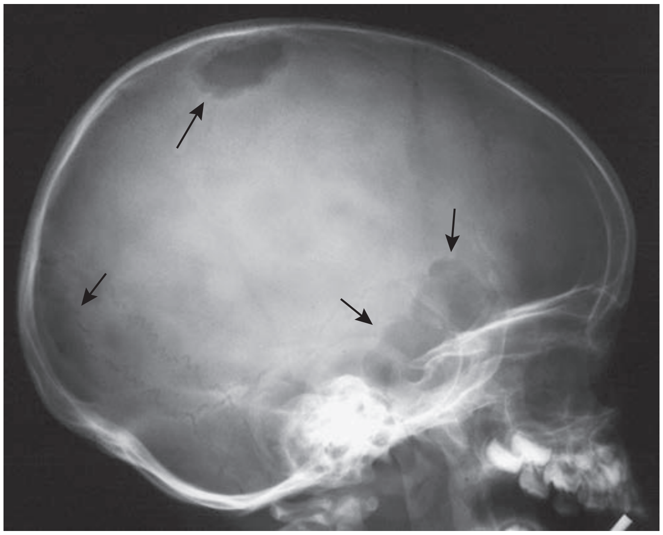

**Figure 138.34. Langerhans cell histiocytosis in a 2-year-old girl.** Lateral skull radiograph shows three lytic lesions in the skull. The lesion at the vertex has beveled edges.

who are slightly older, with an average age of 10 to 12 years. Multifocal and systemic disease is most common in infants and younger children. Fulminant life-threatening LCH is usually seen in the first two decades of life and is rare beyond 3 years of age. Disseminated disease may cause lymphadenopathy, hepatosplenomegaly, skin lesions (purpuric rash), diabetes insipidus, exophthalmos, thrombocytopenia, and anemia. Pulmonary involvement of LCH in children is seen almost always in the setting of disseminated disease, in which osseous lesions vary from relatively few to diffuse, confluent involvement.[180,181]

Solitary LCH lesions usually come to attention with local pain, tenderness, and an occasional palpable mass. Symptoms also relate to the involved bone; mastoid lesions may manifest as ear disease, and spinal lesions may show up as painful scoliosis or kyphosis. In addition, patients may have a low-grade fever, and elevated erythrocyte sedimentation rates and C-reactive protein levels.

The skull is the most frequent site of LCH, followed by the femur, mandible, pelvis, ribs, and spine; in addition, 70% of lesions occur in flat bones, and 30% occur in tubular bones (long bones, clavicle, hands, and feet). Lesions are usually located in the medulla. Primary lesions of the cortex are rare; however, the cortex is often secondarily affected by expansion of an intramedullary lesion. Long-bone lesions occur in the diaphysis or metaphysis, with rare involvement of the epiphysis. Rarely, lesions may cross an open growth plate. Multiple bone lesions occur in approximately 25% of patients.[182,183]

***Imaging.*** In the extremities, most LCH lesions are purely osteolytic with well-defined, minimally sclerotic borders. Many lesions are mildly expansile. Endosteal scalloping may be prominent and may progress to cortical disruption. Some lesions are permeative, and periosteal new bone formation may occur, giving them an aggressive appearance. Periosteal new bone may be in single or multiple layers. Although it is often said that LCH can have any radiographic appearance, lesions often have both aggressive and nonaggressive features. When such an indeterminate lesion is identified, LCH is high on the list of differential diagnoses.

Radiographically, LCH of the calvaria typically appears as a lytic bone lesion with a well-defined "punched out" appearance. Skull lesions appear geographic with beveled borders as a result of differential destruction of the inner and outer tables (Fig. 138.34). A so-called button sequestrum may be seen, and lesions of the maxilla and mandible produce "floating teeth" (e-Fig. 138.35). Vertebral lesions produce compression deformities, most commonly in the thoracic spine, followed by the lumbar and cervical regions. LCH often produces vertebra plana with marked loss of height of a single vertebral body (Fig. 138.36). With vertebral involvement, soft tissue extension into the spinal canal may be apparent and is best assessed by MRI. The height of affected vertebral segments tends to reconstitute after therapy. Involvement of the posterior elements may occur but is less common than vertebral body involvement.[184–186]

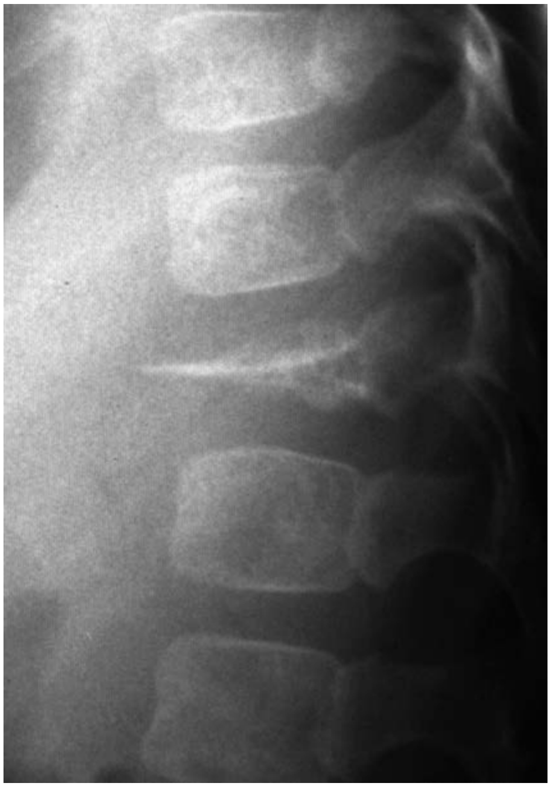

**Figure 138.36. Vertebra plana.** Lateral spine radiograph shows vertebra plana of a single vertebral body as a sequela of Langerhans cell histiocytosis in a 20-month-old girl.

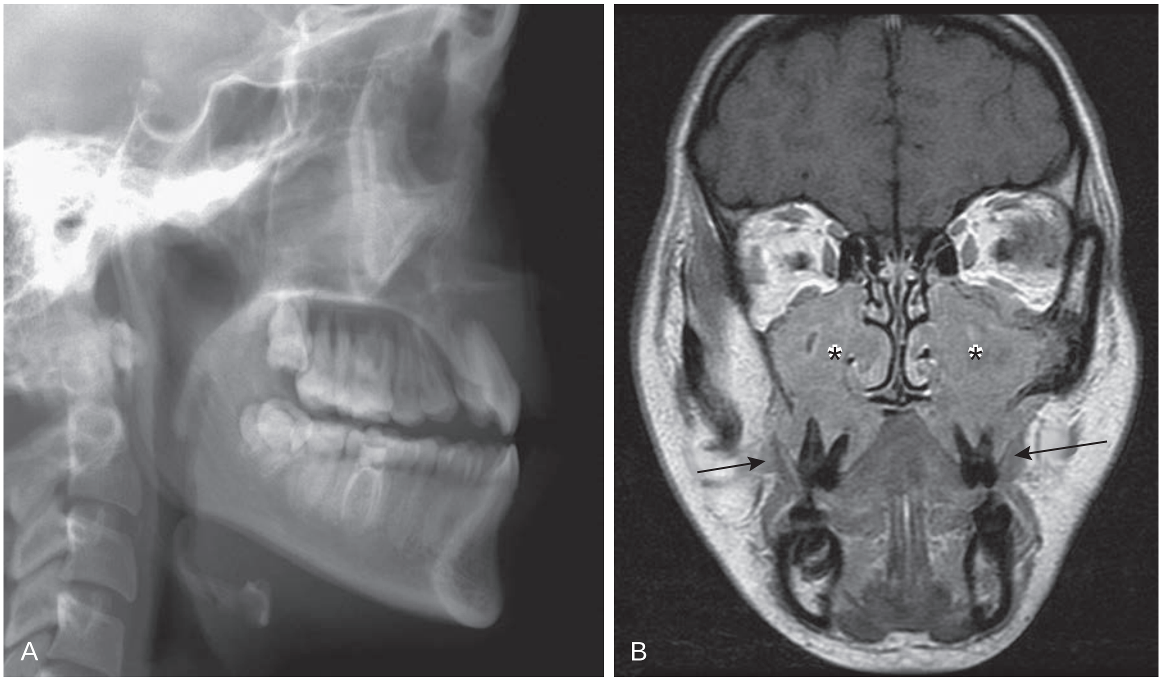
The imaging appearance of LCH depends on the stage and activity of the lesions. The natural history is for spontaneous involution of some lesions to occur. Even at the time of diagnosis, some lesions may be present that are already in a state of involution or quiescence. Involuting lesions will be less well defined and will show sclerosis. Both CT and MRI can be used for further delineation of osseous lesions. On CT, active lesions usually have a well-defined, nonsclerotic margin. A cortical break and soft tissue mass may be seen. MRI is preferred to CT, owing to the lack of ionizing radiation and superior tissue contrast. On MRI, active lesions are composed of soft tissue, which is low signal on T1- and high signal on T2-weighted imaging, which enhances relatively homogeneously (see e-Fig. 138.35). About half of the lesions will be hyperintense to muscle on T1-weighted images, and extensive bone marrow and soft tissue edema produces high signal on T2-weighted images and enhances (Fig. 138.37). LCH lesions that disrupt the cortex may produce a sizable soft tissue mass (seen in 30% of cases on MRI). Older, involuted, or involuting lesions appear as low signal on T1- and T2-weighted images. Also, a multiplicity of lesions is very suggestive of LCH, as opposed to many other entities that are usually unifocal. If LCH is a consideration, a radiographic skeletal survey may be beneficial in identifying other lesions. Often, the presenting lesion is not at the best site for biopsy, and other



**e-Figure 138.35. Langerhans cell histiocytosis in a 16-year-old girl.** Lateral radiograph (A) and coronal T1-weighted MR image with gadolinium show “floating” maxillary teeth with loss of the normal lamina dura (*arrows* in B). Enhancing soft tissue (*asterisks* in B) fills the maxillary sinuses and replaces the maxilla.

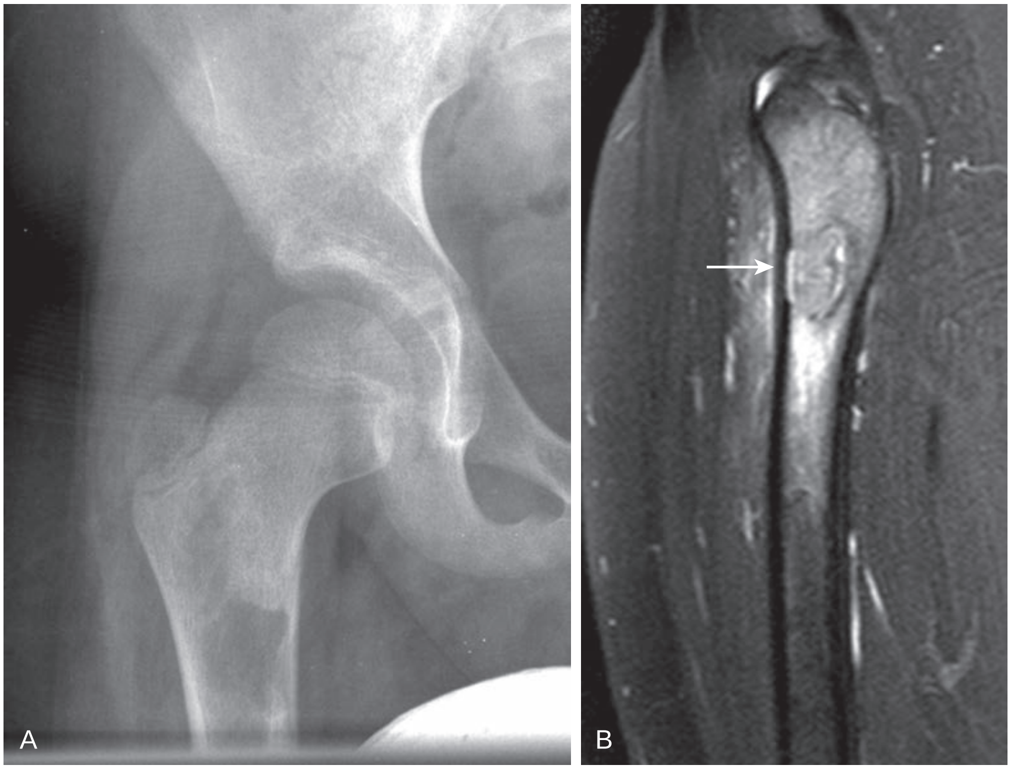


**Figure 138.37. Langerhans cell histiocytosis in an 8-year-old boy.** (A) Radiograph demonstrates a lytic lesion in the right subtrochanteric femur. (B) Short-tau inversion recovery sagittal MR image of the right femur demonstrates the primary mass *(arrow)* with extensive adjacent bone and soft tissue edema.

unsuspected sites may prove more suitable for tissue diagnosis. Because multiple skeletal lesions may coexist, skeletal imaging is necessary at the time of diagnosis and for purposes of follow-up. Some controversy exists about the relative accuracy of radiographic skeletal surveys and radionuclide bone scintigraphy, because up to 35% of lesions may be missed by bone scans.

Whole-body MRI may become an alternative method for identifying and following multifocal disease. PET scans have also shown utility in identifying sites of active disease and for following response to therapy.[187–189]

***Treatment.*** LCH localized to the skeleton carries a favorable prognosis. Recurrences are not uncommon. Solitary lesions are watched and usually involute spontaneously. More aggressive therapy may be occasionally warranted, depending on symptoms and lesion characteristics. Curettage and ablative techniques have been used, and children with multiple lesions and/or associated systemic disease are treated more aggressively with steroids and chemotherapy.[190] The disease is thus treated in a manner similar to that for a malignant process. The morbidity in children with systemic disease varies depending on the organs involved and the histologic pattern of disease. Children in whom organ function is unaffected and who respond well to initial therapy show a better long-term prognosis. Mortality of disseminated disease is approximately 10%.

## Osseous Tumors

### Osteoid Osteoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Osteoid osteoma is a common, benign tumor of bone that has a characteristic presentation and radiologic appearance. These tumors occur predominantly in boys, usually those in the second decade of life; however, it is not uncommon in both sexes from the first decade until the mid fourth decade, with a strong prevalence in whites. Pathologically, osteoid osteoma consists of a nidus that is usually surrounded by dense sclerotic bone. The nidus contains interlacing trabeculae at various stages of ossification within a stroma of loose, vascular connective tissue. Three types of osteoid osteoma are recognized: cortical (most common), cancellous or medullary, and subperiosteal (least common). The latter two types produce less sclerotic bone than cortical lesions, making radiologic diagnosis difficult. Osteoid osteomas can also be subdivided into *extraarticular* and *intraarticular* types. The incidence of medullary and subperiosteal types is higher at juxtaarticular and intraarticular locations.

Osteoid osteomas may develop in any bone. The single most common location of osteoid osteoma is the femur, and specifically, the femoral neck. The tibia is the next most frequent site. Osteoid osteomas occur less frequently in the upper extremities than in the lower extremities but frequently affect the tubular bones of the hands and feet. Osteoid osteomas most commonly affect the metaphysis or metadiaphysis, less commonly the diaphysis, and rarely the epiphysis. They are less common in flat bones and the spine, where they tend to affect the vertebral posterior arches. In such cases, patients usually are seen initially with painful scoliosis.[191] The classic presentation of osteoid osteoma is localized pain that is worse at night and relieved by nonsteroidal anti-inflammatory drugs (NSAIDs). Lesions near a joint may mimic arthritis.

***Imaging.*** Radiographically, the nidus may be purely radiolucent or may contain a dense center. The lucent nidus ranges from a few millimeters to 15 mm in diameter. With cortical osteoid osteomas, the nidus is encased by a broad zone of dense bone (Fig. 138.38).[192] Intraarticular osteoid osteomas tend to have little reactive bone or periosteal new bone formation. This type most frequently affects the hip, where it causes osteopenia and joint effusion.[193] Regardless of location, the nidus of an osteoma may be difficult to see on radiography.

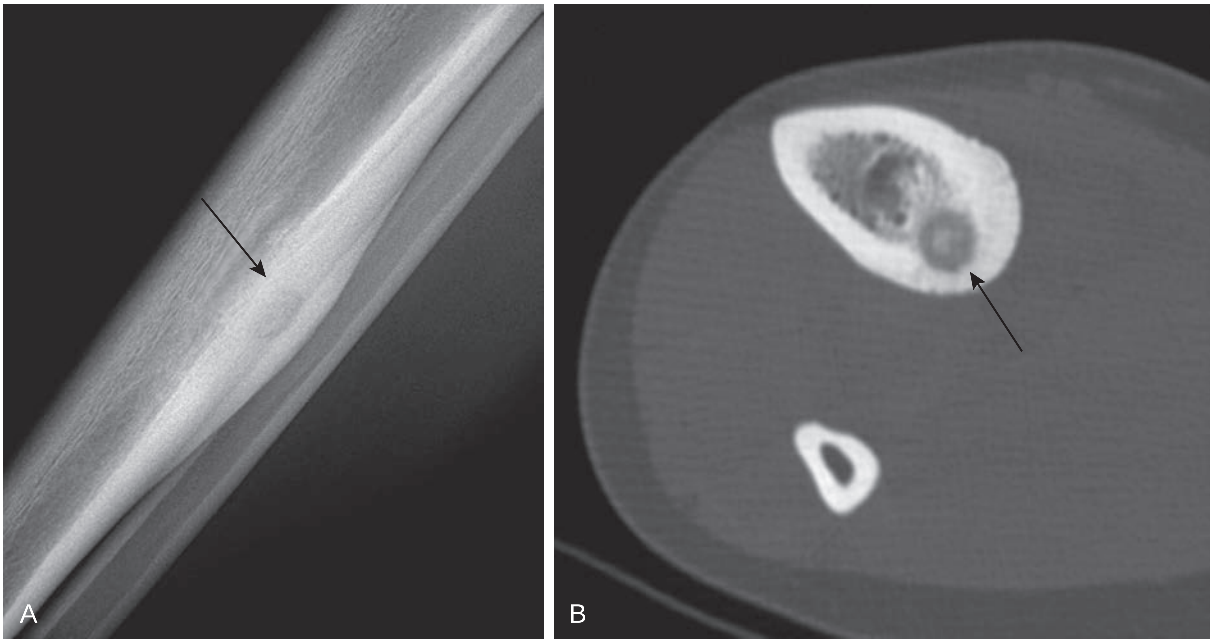

**Figure 138.38. Osteoid osteoma of the tibia in a 15-year-old girl.** (A) Radiograph shows cortical thickening posteriorly. The lucent nidus is faintly seen *(arrow)*. (B) CT better shows the nidus *(arrow)*. A small radiopaque sequestrum is present within the nidus.

CT is valuable in showing the lesion, confirming the diagnosis, and determining the anatomic location of the lesion before percutaneous therapy or surgical excision. The CT appearance of a lucent nidus with central sequestrum opacity and surrounding sclerosis is usually diagnostic of osteoid osteoma, particularly if the clinical presentation is classic (see Fig. 138.38). Intramedullary and subperiosteal lesions show less sclerosis. Subperiosteal osteoid osteomas lie on top of and may erode the cortex.[194] Also they may or may not have ossification within the nidus. Without the ossification, findings are less specific.

On MRI, low intensity may be seen on both T1 and T2 images, depending on the relative amount of ossification and fibrovascular tissue. Although there is no signal from the sclerotic bone, the inherent contrast resolution of MRI provides precise definition of potentially extensive reactive changes in the bone marrow and adjacent soft tissues. Osteoid osteoma may produce an intense inflammatory response within adjacent bone, joint, and soft tissues. If the nidus is not identified, a more aggressive process can be suggested.[195] Both the nidus and the adjacent inflamed tissues enhance with gadolinium.[196] However, if dynamic postcontrast images are obtained, the nidus will show peak enhancement in the early arterial phase with subsequent partial washout, while the reactive changes in the adjacent marrow will show slower, progressive enhancement.[197] The use of dynamic enhancement on MRI is even more important in atypical subperiosteal, juxtaarticular, and intraarticular locations.[198] Juxta- and intraarticular osteoid osteomas may produce reactive joint effusions and synovitis seen on MRI.

The chief imaging-based differential diagnoses for osteoid osteoma are stress fracture and osteomyelitis. Usually, clinical presentation and laboratory results point toward the correct diagnosis. Imaging findings of osteoid osteoma tend to be specific.

***Treatment.*** The traditional treatment for osteoid osteoma has been surgical excision, however, localization of the lesion and confirmation of excision may be challenging in the operating room. Therefore percutaneous methods of treatment have been developed, including excision with a large-bore needle or drill, cryoablation, and percutaneous radiofrequency ablation, which is now the preferred method of treatment.[199,200] Complex lesions or lesions located where percutaneous methods are contraindicated may still require surgical excision. Surgical or percutaneous methods are successful in approximately 90% of patients on the initial attempt.

### Osteoblastoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Osteoblastomas are closely related to osteoid osteomas and have in the past been considered a larger version of that tumor (giant osteoid osteoma). The two lesions are nearly identical histologically.[201] Osteoblastomas consists of numerous osteoblast-lined trabeculae that contain osteoid, however, these trabeculae are less organized than those in osteoid osteomas.[202] These tumors are often distinguished by size: tumors less than 1.5 cm in diameter are considered to be osteoid osteomas, whereas tumors larger than 1.5 cm are usually osteoblastomas.[203] The two types of tumors can also be distinguished by differences in clinical presentation, anatomic location, and imaging features. Osteoblastoma most commonly occurs in patients in the second and third decades of life,[204] and it is more common in boys. Osteoblastomas are not associated with a typical pattern of pain, and if painful, they do not typically respond to NSAIDs. Many osteoblastomas are found in the posterior elements of the vertebrae, where they can cause scoliosis and neurologic deficits. Nearly half of these tumors occur in the appendicular skeleton, primarily in the proximal femoral diaphysis and metaphysis. Tibial lesions are next most common. Long-bone lesions may be cortical or medullary in location. Another characteristic location for osteoblastoma is the neck of the talus, usually at its dorsal margin.

***Imaging.*** Osteoblastoma appears as three distinct radiologic variants: (1) an osteoid osteoma–like appearance, but larger; (2) an ABC-like appearance, most commonly in the spine; and (3) an aggressive appearance that mimics a malignancy, which is uncommon.[205] Osteoblastomas vary from 1.5 to 10 cm in size. Most are lytic with a well-defined sclerotic margin, but the tumor usually lacks the wide, dense rim of sclerosis typical of osteoid osteoma. Lesions in the spine are often expansile (Fig. 138.39). Adjacent sclerosis with spinal lesions may be minimal or absent. In the long bones, osteoblastomas appear radiologically as round or oval lucent, eccentric tumors within the medulla or cortex. Some sclerosis is

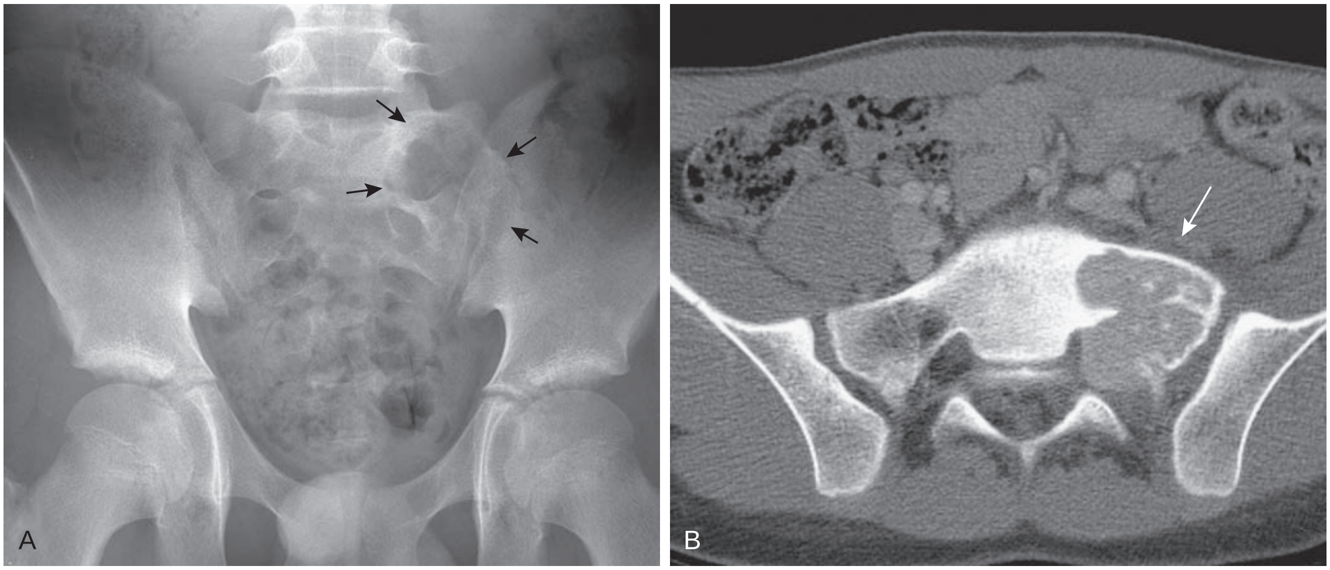

**Figure 138.39. Osteoblastoma of the sacrum in a 12-year-old boy.** A well-defined, lucent, expansile lesion *(arrows)* is seen within the left sacrum on radiography (A) and CT (B).

**TABLE 138.1** Differentiating Features of Osteosarcoma and Ewing Sarcoma

| Feature | Osteosarcoma | Ewing Sarcoma |
|---|---|---|
| Age range | 15-25 years | 0-25 years |
| Incidence | More common | Less common<br>Rare in nonwhites |
| Location | Metaphyses of long bones | Metadiaphysis of long bones<br>Axial, flat-bone involvement more common than osteosarcoma |
| Matrix | Usually “cloudlike” mineralization | Not mineralized or sclerotic |
| Periosteal reaction | “Sunburst”<br>Codman triangles | “Onionskin” |
| Metastases | Lung (80%)<br>Bone (20%) | Lung, rarely bone, marrow, lymph nodes |
| Other | Occasional multifocal disease<br>Association with retinoblastoma | 11 : 22 translocation<br>Radiation sensitive |

seen adjacent to the lesion, and mineralization of the matrix is frequently present. Periosteal reaction is common and is solid or layered. Talar lesions may expand into the soft tissues, and osteoporosis of the talus and other bones of the foot may be an associated finding. The calcified or ossified matrix of an osteoblastoma and the thin, bony outer shell are especially well visualized on CT images. Edema in the soft tissues or marrow may give high signal on T2-weighted MRI, but signal characteristics are not specific; osteoid within the lesion may cause areas of decreased signal, and bone scans may help in determining the location of a lesion. In addition, osteoblastomas are relatively vascular; hence angiography may reveal a dense capillary blush.

***Treatment.*** Treatment is by surgical excision or curettage. There is a moderate recurrence rate.

## Malignant Bone Tumors

Approximately 50% of all bone tumors in the pediatric age group are malignant; nearly two-thirds of these are osteosarcomas. Ewing sarcomas of bone comprise most of the remainder. Other types of osseous malignancies, such as chondrosarcoma, are extremely rare in children, although NHL occasionally occurs as a primary bone neoplasm. Osteosarcoma and Ewing sarcoma differ sufficiently, both in their clinical and imaging presentation, such that they can usually be distinguished from one another. Their characteristic features, discussed in this chapter, are summarized in Table 138.1.

### Osteosarcoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Osteosarcoma is the most common malignant primary bone tumor in the pediatric population. The peak incidence of osteosarcoma is in patients 15 to 25 years of age, but it has been described in a 19-month-old girl.[206] The tumors are slightly more common in males, and the long bones are affected in approximately 70% of cases. Most occur around the knee. The femur is the most common bone affected, followed by the tibia and then the humerus. The face, mandible, cranium, and axial skeleton are among the less commonly affected sites (Fig. 138.40). Most osteosarcomas are single, primary neoplasms that arise from the medullary cavity of the metaphyses of the long bones. The diaphyses alone are less commonly involved, which occurs in 2% to 11% of cases; an epiphyseal origin of osteosarcoma is extremely rare. Osteosarcomas can involve multiple skeletal sites synchronously, a condition known as *osteosarcomatosis.*[207,208] Extremely rare in children, extraskeletal osteosarcomas are found in various organs or in the soft tissues of the extremities of adults.[209,210]

Often referred to as *conventional osteosarcomas*, most are considered to be high grade because of their degree of cellular atypia and anaplasia. Other much less common categories of this tumor include well-differentiated medullary osteosarcoma, telangiectatic osteosarcoma, and surface osteosarcomas, including intracortical osteosarcoma and parosteal, periosteal, and high-grade surface

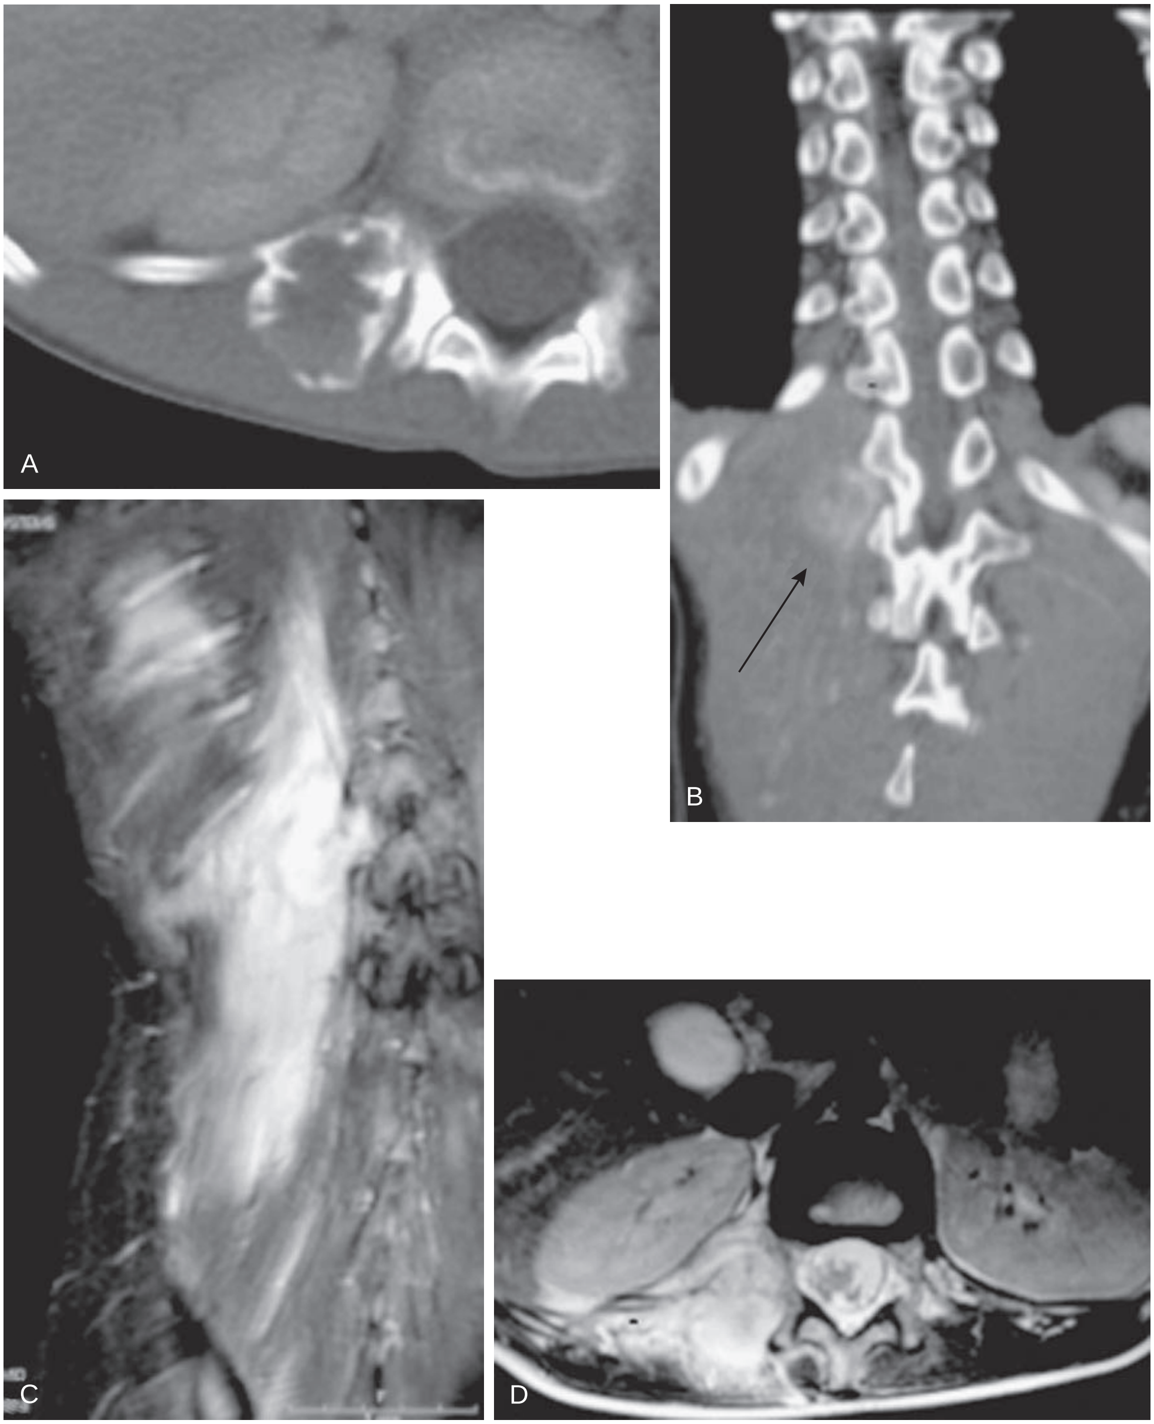

**Figure 138.40. Osteosarcoma of the spine in an 8-year-old girl.** (A) Axial contrast-enhanced CT through T12 after 10 weeks of chemotherapy shows a peripherally sclerotic expansile mass arising from the right costovertebral junction. Note disruption of the cortex posteriorly. (B) Coronal reconstruction shows the relationship of the mass *(arrow)* to the apex of the scoliosis. (C) Coronal short-tau inversion recovery MR image demonstrates massive edema in the paraspinal muscles in response to the osteosarcoma. (D) Axial contrast-enhanced fat saturated T1-weighted MR image demonstrates intense tumor enhancement and moderate enhancement of the surrounding paraspinous musculature.

osteosarcomas. Secondary osteosarcomas, which are rare in children, are usually associated with previous radiation therapy. Osteosarcoma can also arise in patients with inherited (usually bilateral) retinoblastoma who have a defect in a specific gene, or it can arise in patients who have undergone a spontaneous mutation of that gene. Although radiation therapy increases the incidence of osteosarcoma in these patients, secondary osteosarcoma may develop in sites remote from radiation fields. Osteosarcoma unassociated with other malignancies is occasionally familial and has been identified in siblings.

## Intramedullary Osteosarcoma

### Conventional Osteosarcoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Approximately 75% of osteosarcomas are the high-grade variant, and 75% of cases occur in patients between the ages of 15 and 25 years. The histologic hallmark of osteosarcoma is the presence of an osteoid matrix produced by sarcoma cells. In most cases, there is extensive immature bone formation. However, other tissues may predominate in the tumor matrix. The three main types of osteosarcoma, based on matrix type, are *osteoblastic*, *chondroblastic*, and *fibroblastic*. These tumors have differing mineral content.[210]

***Imaging.*** Radiography remains the primary method of diagnosis for conventional osteosarcoma. Other imaging methods are used mainly for staging purposes and to assist with surgical planning. Osteosarcoma typically manifests as a large, mixed sclerotic–lytic mass with a cloudlike matrix that involves the long-bone metaphyses. The tumors cause cortical erosion and destruction rather than expansion. Resultant periosteal new bone formation, often of the spiculated "sunburst" variety (Fig. 138.41), and periosteal elevation are often observed, frequently with Codman triangles (Fig. 138.42). However, conventional osteosarcomas are occasionally purely lytic and exhibit no periosteal reaction. Osteosarcomas with chondroblastic elements tend to be more lytic on radiography (see Fig. 138.42), and osteoblastic dominant osteosarcomas will demonstrate increased osteoid matrix (see Fig. 138.41).

CT is superior to radiographs for delineating osteoid matrix. Like radiographs, CT often underestimates the true extent of bone involvement (Fig. 138.43).

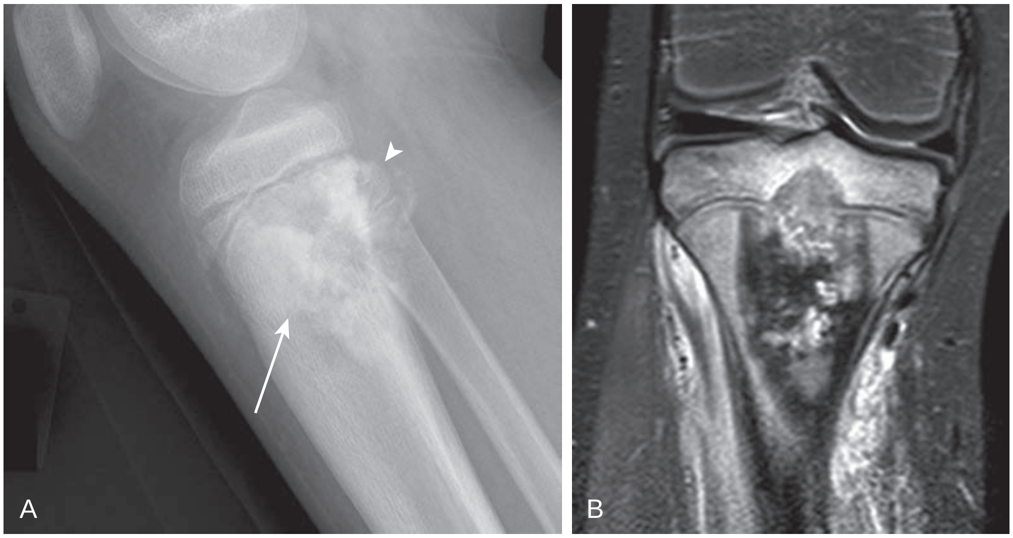

**Figure 138.41. Proximal tibial osteosarcoma in an 11-year-old boy.** (A) Radiograph demonstrates osteoblastic osteosarcoma with osteoid matrix *(arrow)* and "sunburst" periostitis *(arrowhead)*. (B) Corresponding short-tau inversion recovery coronal MR image shows low signal intensity throughout the majority of the mass, indicative of osteoid matrix. Note also the presence of transphyseal extension through the central physis.

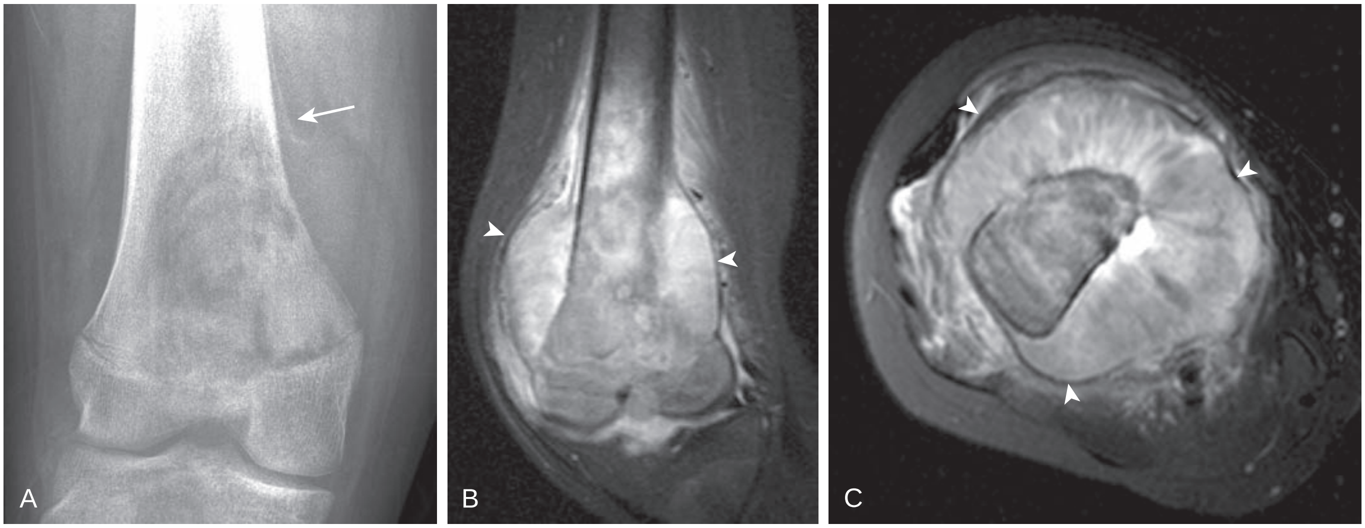

**Figure 138.42. Osteosarcoma in a 13-year-old girl.** (A) Radiograph demonstrates permeative lytic destruction in the distal femur metaphysis with aggressive periosteal reaction with a Codman triangle *(arrow)*. Short-tau inversion recovery coronal (B) and axial (C) MR image demonstrates distal femoral metaphyseal mass with transphyseal transgression into the epiphysis with a large extraosseous tumor component. Note the displaced periosteal envelope *(arrowheads)*.

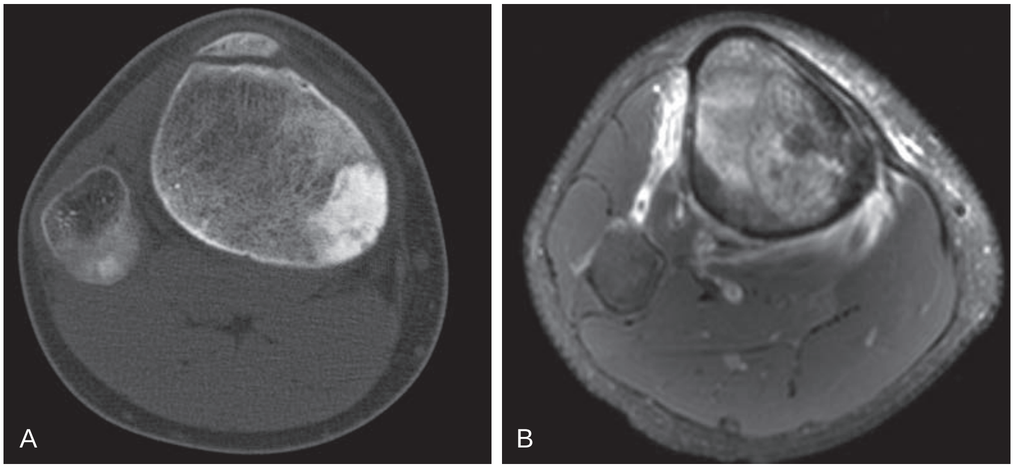

**Figure 138.43. Tibial osteosarcoma in a 14-year-old boy.** (A) Axial CT demonstrates intraosseous osteoblastic matrix replacing a portion of the medullary cavity. (B) Short-tau inversion recovery axial MR image through the same level demonstrates more extensive intramedullary involvement.

MRI is used to evaluate osteosarcoma. The longitudinal extent of marrow involvement, an important determinant of surgical therapy, is accurately shown as well-defined hypointense signal within hyperintense fatty marrow on T1-weighted images obtained in either coronal or sagittal planes. It is important to obtain a longitudinal T1-weighted image of the entire bone to measure intramedullary tumor length, to assess possible epiphyseal involvement (seen in as many as 80% of metaphyseal tumors), and to detect skip metastases that occur in a small percentage of cases. On T2-weighted images, the tumor-containing marrow can be either hyperintense or, if there is sufficient bone formation, hypointense to normal fat (see Fig. 138.41). The soft tissue component is usually of heterogeneous, mainly high-intensity signal that contrasts greatly with surrounding structures. STIR images are very sensitive to the water content of tumors and adjacent bone marrow edema, thus the intramedullary length of tumor extension may be overestimated on STIR sequences.[211] Contrast-enhanced T1-weighted images, preferably obtained with fat saturation, provide similar contrast and better signal-to-noise ratios than T2-weighted images. Furthermore, contrast-enhanced T1-weighted images are especially useful in determining the relationship between the tumor and the major blood vessels, in detecting joint involvement in the presence of effusion,[212] and in estimating the amount of necrosis within the tumor. Osteosarcoma is frequently accompanied by edema of the adjacent soft tissues that is hyperintense to muscle on T2-weighted STIR images and contrast-enhanced T1-weighted images. This edema can be localized to the tumor periphery, or it can involve whole muscle groups, as in the case of larger tumors. The latter finding has been associated with a poor prognosis.[213]

Between 10% and 20% of patients with osteosarcoma have metastases at the time of diagnosis, mainly to the lungs; therefore chest CT is essential in the search for pulmonary lesions at presentation. Like the primary tumor, these metastases can be calcified and therefore difficult to distinguish from calcified granulomas. Pleural-based lung metastases can also produce pneumothorax, hemothorax, or malignant pleural effusion. Such findings may be the first sign of pulmonary metastases at the time of diagnosis or at follow-up. Bone metastases are much less frequent, but radionuclide bone scans are justified to detect these lesions and to assess the extent of the primary tumor.

### Telangiectatic Osteosarcoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Telangiectatic osteosarcoma comprises about 2% of all osteosarcomas. Like conventional osteosarcomas, telangiectatic osteosarcoma tends to occur in the long bones adjacent to the knee and is seen more frequently in boys than in girls. These tumors contain little osteoid and do not form bone but rather are composed of single or multiple cavities that contain blood or necrotic tumor with septa of anaplastic cells.[214,215] Telangiectatic osteosarcomas by definition are composed of approximately 90% cystic components before treatment.[216]

***Imaging.*** Radiographically, telangiectatic osteosarcomas tend to be lytic and expand rather than destroy the cortex; they may also be associated with a soft tissue mass. Except for the presence of malignant cells that are often at the periphery of the cavity, the pathologic appearance of telangiectatic osteosarcoma mimics that of an ABC. Indeed, on MRI, the appearance of telangiectatic osteosarcoma and ABC may be identical; both may have single or multiple fluid-fluid levels produced by blood products of differing ages that are best demonstrated on T2-weighted images.[217] Telangiectatic osteosarcomas are characterized by enhancing soft tissue in the periphery and septations of the tumor, features absent in ABCs.[218] Biopsy of the soft tissue component is necessary to differentiate telangiectatic osteosarcoma from an ABC. The prognosis of patients with telangiectatic osteosarcoma is similar to those with conventional osteosarcoma.

### Surface Osteosarcomas

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** Surface osteosarcomas are classified by histologic grade as low-, intermediate-, and high-grade lesions.[219] *Parosteal osteosarcoma* is more common in girls than in boys, tends to occur after skeletal maturity has been achieved, and is of low histologic grade. *Periosteal osteosarcoma* probably arises from the deep layers of periosteum or the outer cortex and is classified as an intermediate-grade osteosarcoma; most periosteal osteosarcomas are chondroblastic,[220] and they may be mistaken for a chondrosarcoma by pathologists unfamiliar with pediatric orthopedic oncology. *High-grade surface osteosarcomas* comprise dedifferentiated parosteal osteosarcoma and high-grade surface osteosarcoma. The origin of high-grade surface osteosarcoma is controversial; histologically, it is difficult to differentiate from the much more common, conventional, intramedullary high-grade osteosarcomas.

Patients with parosteal osteosarcoma generally have an excellent prognosis, although this may be affected adversely by ingrowth into the medullary cavity. Parosteal osteosarcomas are composed of extensive osteoid tissue with a fibrous stroma and form a lobulated, ossified, juxtacortical mass. Patients with periosteal and high-grade surface osteosarcomas have similar prognoses

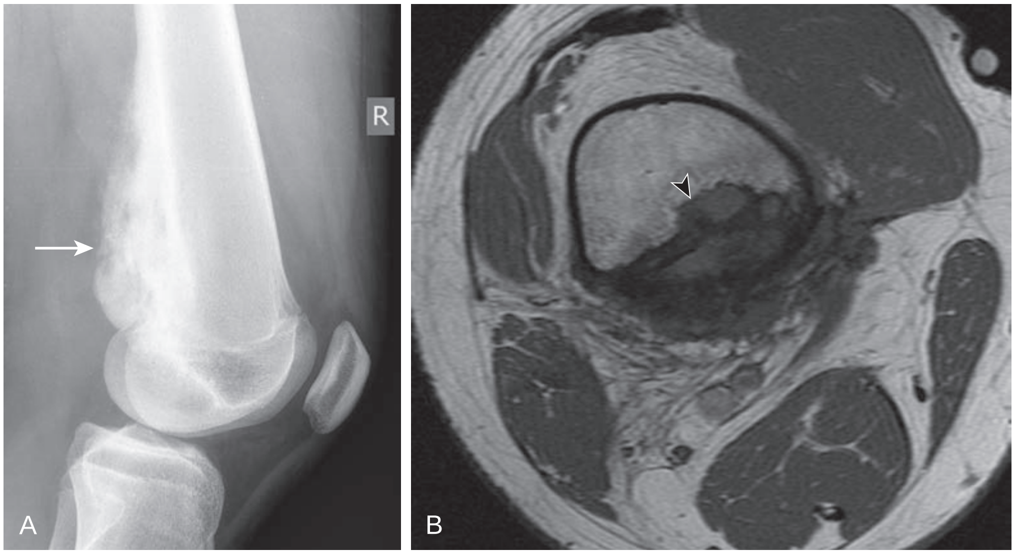

**Figure 138.44. Parosteal osteosarcoma in a 14-year-old boy.** (A) Lateral radiograph demonstrates a surface-based osteoblastic mass in the distal femur *(arrow)*. (B) T1-weighted axial MR image through the distal femur demonstrates the surface-based mass with intramedullary extension *(arrowhead)*.

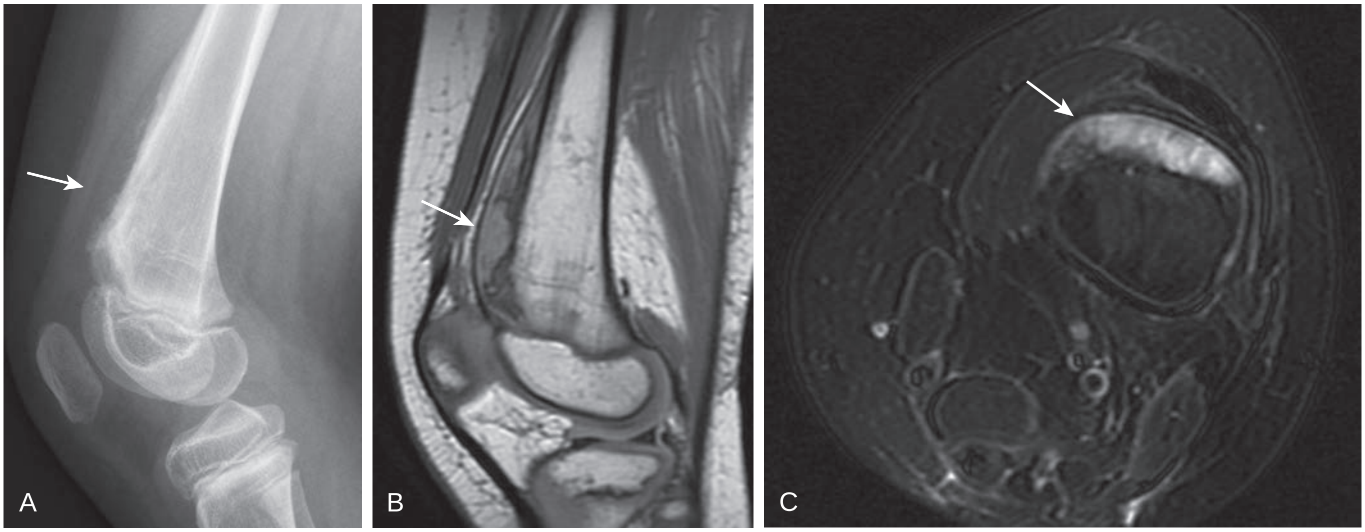

**Figure 138.45. Periosteal osteosarcoma in an 11-year-old boy.** (A) Lateral radiograph demonstrates aggressive, perpendicularly oriented periosteal reaction with little to no matrix *(arrow)*. (B) Sagittal proton-density MR image demonstrates an intermediate signal lesion. (C) On T2-weighted fat-saturated axial MRI, it is hyperintense and surface based, indicative of its chondroblastic composition *(arrow)*.

compared with those with conventional, intramedullary high-grade osteosarcomas.

***Imaging.*** Parosteal osteosarcomas are very osteoblastic and are slow growing. They demonstrate mature periosteal ossification and most commonly occur in the posterior aspect of the distal femur (Fig. 138.44). Early lesions may have a radiologic cleavage plane between the cortex and the tumor. Superficially, parosteal osteosarcoma may mimic a sessile osteochondroma. MRI is used to define the degree of intramedullary extension, if present, and adjacent neurovascular and muscle involvement.

Periosteal osteosarcomas also arise from the surface and may have adjacent intramedullary marrow edema, but true invasion is rare.[220] Because these lesions are invariably chondroblastic, they often have little to no matrix on radiography and are hyperintense on fluid-sensitive sequences (Fig. 138.45). Superficially, these lesions may mimic a juxtacortical chondroma.

***Treatment.*** Osteosarcomas are not radiosensitive. Thus treatment consists of preoperative chemotherapy; extirpation of resectable lesions, usually by limb-sparing surgery; and postoperative chemotherapy. MRI serves as a surgical road map to define the presence or absence of neurovascular involvement, physeal and epiphyseal extension, and joint involvement. If the physis is spared, physeal-sparing surgery can be attempted with an intercalary graft. When the epiphysis is involved, morbidity is higher, and a joint prosthesis is necessary.

Prognosis is influenced by response to initial chemotherapy, which is evaluated postoperatively by histologic estimation of necrosis within the treated tumor. Little change in tumor size is expected, even in tumors that respond well to chemotherapy. Imaging methods of assessing the effects of therapy include thallium-201 scintigraphy and dynamic contrast-enhanced MRI. Although PET and PET-CT appear to be useful in both staging and monitoring response, experience is currently limited in its use for osteosarcoma and other bone tumors. Long-term follow-up of osteosarcoma and other malignant bone tumors in children is essential.[221,222]

Bone scintigraphy and chest CT should be performed periodically after treatment, especially within the 2 years after therapy: 80% of relapses occur in the lung only, and 20% occur in the skeleton. Local or distant lymph node involvement is extremely rare.

### Ewing Sarcoma

***Overview, Etiologies, Pathophysiology, and Clinical Presentation.*** In 1921 James Ewing described a radium-sensitive bone tumor, which he called an *endothelioma*, that consisted of sheets of small polyhedral cells of probable endothelial origin.[223] Although the origin of this undifferentiated tumor has been debated since its initial description, what we now know as *Ewing sarcoma* has proved to be a distinct entity with characteristic histologic, radiologic, and cytogenetic features. The Ewing family of tumors includes Ewing sarcoma of bone, EOES, and primitive neuroectodermal tumor (PNET), also known as *peripheral neuroepithelioma*. PNETs exhibit neural differentiation and may arise from either bone or soft tissues. The Ewing family of tumors shares a distinctive cytogenetic feature: reciprocal translocation of chromosome bands q24 and q12 of chromosomes 11 and 22. This same translocation is also found in Askin tumor of the thorax.[224-226]

In younger patients, Ewing sarcoma of bone occurs less frequently than osteosarcoma, with 2.9 cases per million diagnosed in patients younger than 20 years of age. Most cases are detected in patients between 10 and 25 years of age (median 15 years). Like osteosarcoma, Ewing sarcoma occurs slightly more often in boys and is much more common in whites. Fever, leukocytosis, and elevation of the erythrocyte sedimentation rate may accompany these neoplasms. More than 50% of Ewing sarcomas involve a single long bone. Flat bones are more commonly involved than osteosarcoma, particularly the pelvis, but also other flat bones such as the ribs, clavicle, and scapula. Within long bones, the metaphysis and diaphysis are the usual locations. Ewing sarcoma involving the bones of the hands and feet, often initially misdiagnosed as an infection, is rare. Most Ewing sarcomas appear to arise from the medullary cavity. Multifocal osseous involvement at the time of diagnosis is rare.[226-228]

***Imaging.*** The typical radiographic appearance of Ewing sarcoma in the long bones is that of a permeative lesion with a lamellar "onionskin" periosteal reaction (Fig. 138.46). However, nearly 40% of these tumors display diffuse sclerosis, sometimes with a mixed lytic–sclerotic pattern. The sclerosis correlates histologically with the presence of dead bone.[229] Because Ewing sarcomas do not ossify, soft tissue extension is often poorly detected by radiographs but is almost always apparent on CT or MRI (Fig. 138.47). Indeed, the soft tissue masses tend to be disproportionately large in comparison to the amount of bone destruction, and they are especially extensive in Ewing sarcoma of the pelvis (Fig. 138.48). Cortical permeation and destruction may be visible on CT or MRI. However, these tumors can permeate Haversian canals and can grow into the soft tissues without causing large areas of cortical loss. Extensive marrow involvement is particularly well shown as nonspecific low signal, isointense to muscle on T1-weighted images. Ewing sarcomas found in the medullary cavity display intermediate to high signal intensity on T2-weighted images. Rarely, Ewing sarcoma can arise from the surface of the bone rather than from the medullary cavity. In this periosteal or subperiosteal location, Ewing sarcoma resembles other surface malignancies, such as periosteal osteosarcoma with periosteal elevation and Codman triangles.[230] The affected cortex is typically excavated or saucerized,[231] and cross-sectional imaging is required to exclude medullary involvement. Patients with this form of Ewing sarcoma are thought to have a relatively favorable prognosis.

***Treatment.*** With appropriate multimodal therapy, the long-term survival rate of patients with nonmetastatic medullary Ewing sarcoma approaches that of patients with osteosarcoma (about 65%). In some series, tumor volume has been shown to influence prognosis. Survival of patients with pelvic tumors may be somewhat shortened and is much reduced in patients with metastatic disease. As many as 25% of patients with Ewing sarcoma have detectable metastases at the time of diagnosis; most of these are found in the lung, therefore chest CT is necessary for disease staging. Local and regional lymph node involvement may rarely occur, and metastases in bone or bone marrow are less frequent, although skip metastases have been reported.[232]

In addition to MRI of the primary tumor, bone scintigraphy, thoracic CT scanning, and bone marrow examination should be performed to detect possible disseminated disease. Early experience indicates that PET and PET-CT are useful for detection of metastatic sites of disease and for monitoring therapeutic response. Most Ewing sarcomas respond well to initial chemotherapy; increased bony sclerosis develops, and the soft tissue mass disappears.

Percentage change in size of the soft tissue mass appears to be an important prognostic indicator.[233] T2-weighted MRI may show an increase in intensity of the treated medullary component because of serous atrophy, with increased interstitial fluid of the yellow marrow and replacement of cytoplasmic lipid with serous material.

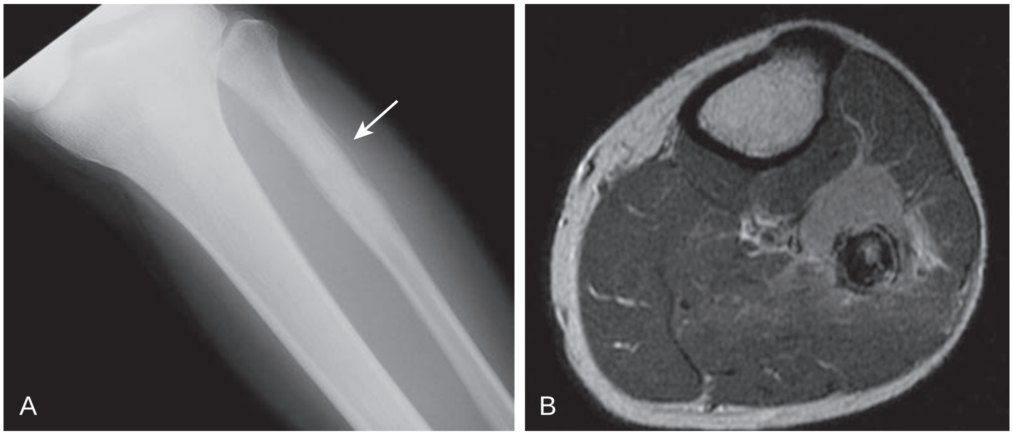

**Figure 138.46. Ewing sarcoma of the fibula in a 17-year-old.** (A) Anteroposterior radiograph of the leg demonstrates aggressive "onionskin" periostitis of the proximal fibula *(arrow)*. (B) T1-weighted axial postcontrast MR image demonstrates a large extraosseous mass that arises from the fibula with cortical destruction.

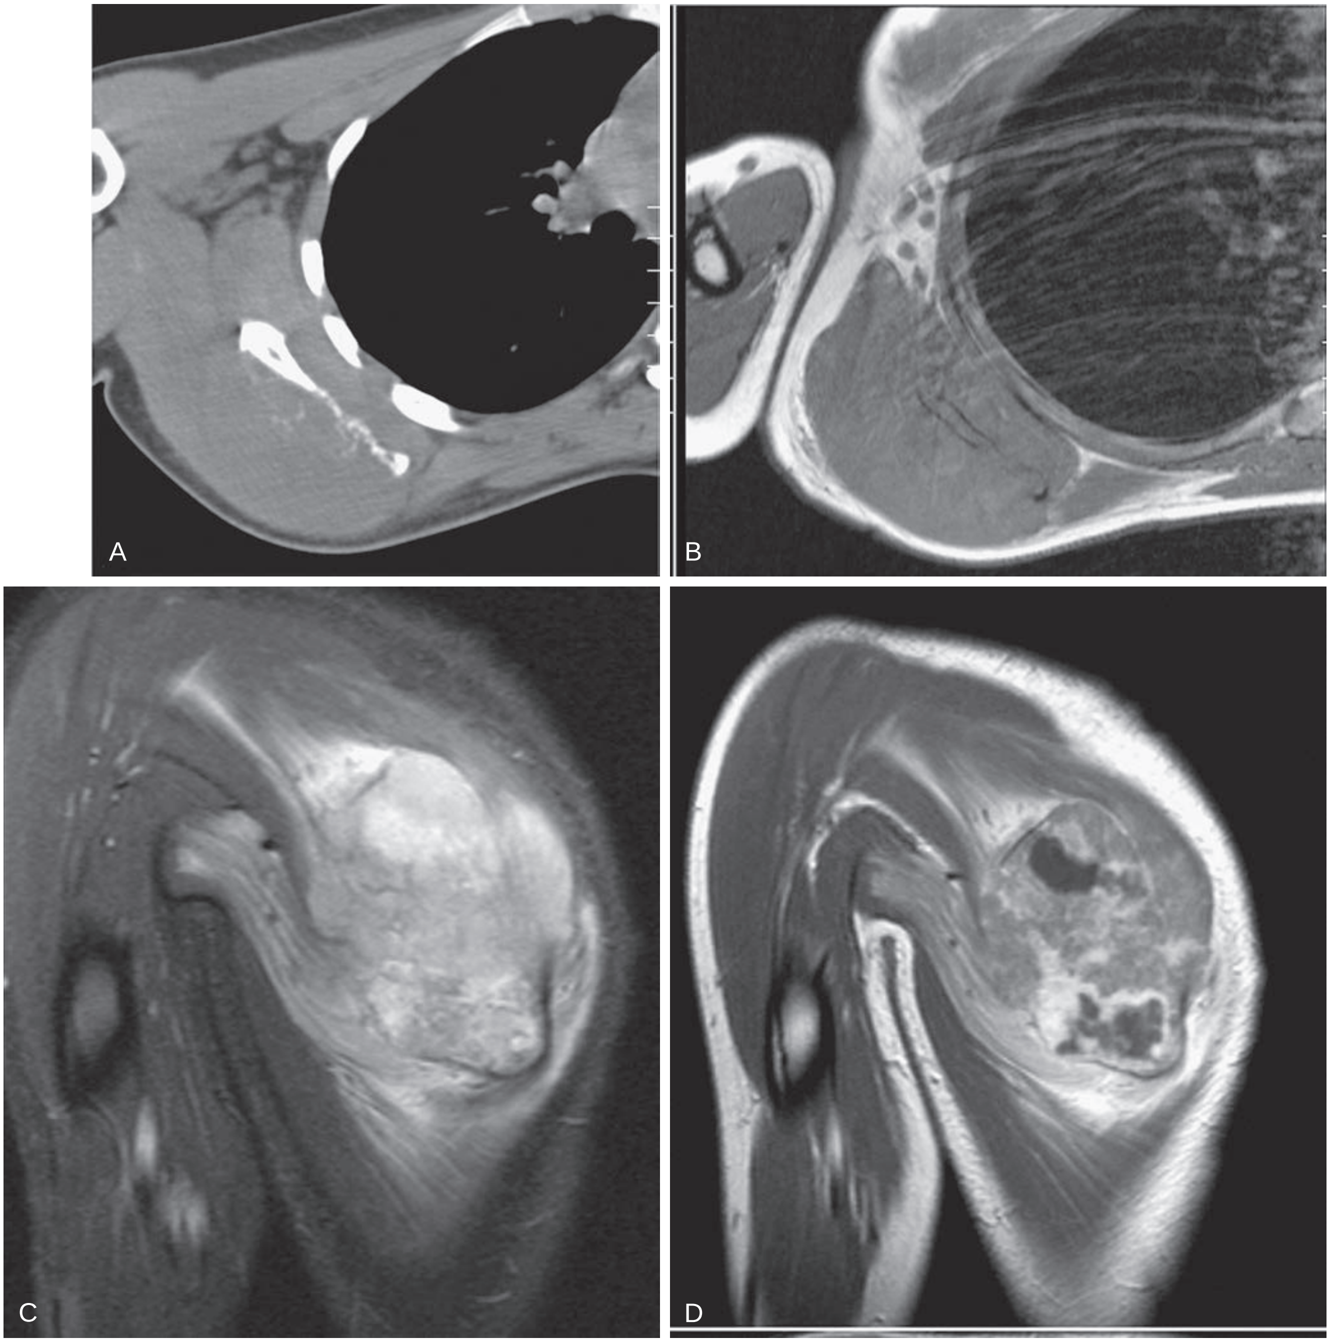

**Figure 138.47. Ewing sarcoma of the right scapula in a 16-year-old girl.** (A) Axial CT image shows a permeative pattern to the scapula with subtle dystrophic calcifications within the soft tissue mass. (B) T1 axial MR image shows marrow replacement and cortical destruction by the mass. (C) Short-tau inversion recovery sagittal MR image demonstrates a large heterogeneous mass with cortical destruction and intramuscular invasion. (D) T1 postcontrast MR image demonstrates heterogeneous central tumoral enhancement with areas of nonenhancement consistent with tumoral necrosis.

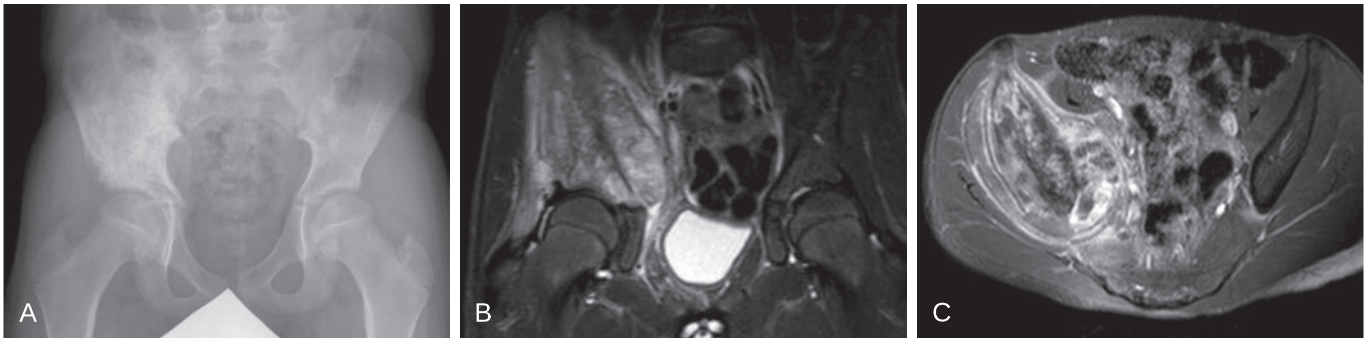

**Figure 138.48. Ewing sarcoma of the right iliac bone in an 11-year-old girl.** (A) Frontal radiograph of the pelvis demonstrates a mixed lytic and sclerotic lesion of the right iliac bone. (B) Short-tau inversion recovery coronal MR image demonstrates a right iliac mass with extraosseous extension. (C) Postcontrast T1-weighted axial MR image demonstrates heterogeneous enhancement of the mass, as it better delineates both extraperitoneal extension and posterior extension into the pelvic abductor muscles.

High T2-weighted signal intensity caused by radiation-induced inflammatory reactions may also be observed in those patients treated with radiation therapy.[234–237]

The surgical approach to resection of Ewing sarcoma is similar to osteosarcoma.

### KEY POINTS

- MRI features highly suggestive of soft tissue malignancy are neurovascular encasement, adjacent bone or joint involvement, and marrow abnormality.
- Fat-containing soft tissue masses in a child younger than 3 years of age is likely benign.
- In general, osteosarcoma has a predilection for the metaphysis, and Ewing sarcoma, for the diaphysis and flat bones.
- ABCs may be primary or secondary to another benign or malignant lesion.

# 139 Metabolic Bone Disease

Lauren W. Averill and Richard M. Shore

Skeletal ossification and mineralization are influenced by many metabolic factors, with sometimes arbitrary distinctions between metabolic bone disorders, endocrine bone disorders, and inherited skeletal dysplasias. Accurate diagnosis is essential because many of these disorders require specific therapy for both their skeletal and extraskeletal effects.

## ABNORMALITIES OF MINERALIZATION

### Bone Mineral Physiology

In the process of bone formation, osteoblasts produce organic bone matrix (osteoid), which then must be mineralized with deposition of hydroxyapatite crystals.[1–4] Mineralization of cartilage and osteoid requires sufficient levels of circulating calcium and phosphate as reflected in an adequate calcium x phosphate product. Mineralization also requires alkaline phosphatase to hydrolyze pyrophosphate, which otherwise would inhibit crystal formation.[5] Hence deficient mineralization of cartilage and osteoid may be due to either an insufficient calcium x phosphate product as in rickets and osteomalacia, or alkaline phosphatase deficiency as in hypophosphatasia.

Rickets is a complex disorder of the growth plate that involves not only deficient mineralization of cartilage and osteoid but also disruption of endochondral ossification, leading to the accumulation of excessive cartilage. This phenomenon results from failure of hypertrophic chondrocytes to undergo normal apoptosis, which is now believed to be caused by hypophosphatemia as the common metabolic pathway of all forms of rickets.[6] Osteomalacia is a pure disorder of insufficient mineralization of osteoid at sites other than the physes, hence at either sites of bone turnover or intramembranous bone formation.

Forms of rickets due to insufficient calcium (calcipenic rickets) mostly result from abnormalities of vitamin D, whose major function is maintenance of a sufficient calcium x phosphate product. Vitamin D may be synthesized in the skin from 7-dehydrocholesterol upon exposure to sunlight containing ultraviolet B radiation (290–315 nm), or it may be provided in the diet, although natural dietary sources of vitamin D are quite limited. Vitamin D then undergoes 25-hydroxylation in the liver followed by 1-α-hydroxylation in the kidney to produce 1,25$(OH)_2$-vitamin D, which is the active form of vitamin D (calcitriol). The most important biologic function of calcitriol is facilitation of gastrointestinal absorption of calcium by inducing transcription of the gene for calcium-binding protein. Calcitriol synthesis by 1-α-hydroxylase is promoted by parathyroid hormone (PTH) in response to hypocalcemia.

Rickets also may result from a variety of disorders that cause renal tubular phosphate wasting (phosphopenic rickets). Renal tubular phosphate handling is regulated by PTH and by a variety of other factors, most of which are produced in bone by osteocytes.[7–12] The most important of these is fibroblast growth factor 23 (FGF23), which causes renal tubular phosphate wasting by downregulating the sodium-phosphate cotransporter that facilitates phosphate reabsorption. Additionally, FGF23 downregulates 1-α-hydroxylase, leading to diminished calcitriol.

### Nutritional (Vitamin D–Deficiency) Rickets

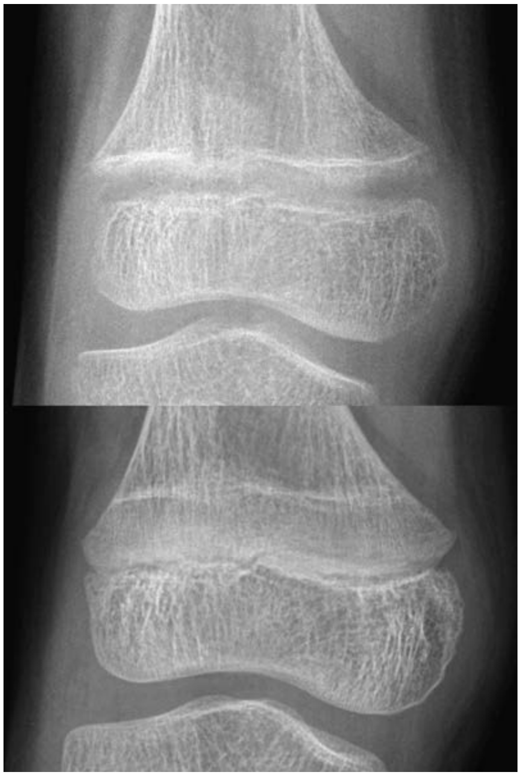
***Etiology.*** Both inadequate exposure to sunlight and insufficient dietary intake of vitamin D must be present for rickets to occur.[1–3,13,14] The first and most severe epidemic of rickets occurred during the industrial revolution as a result of urbanization and diminished exposure to sunlight from smog and the practice of staying indoors. This epidemic largely ended with food fortification after the discovery of vitamin D synthesis. However, rickets then became more prevalent in the United States during the mid-1990s with increased breast-feeding in the African American and Hispanic populations, because breast milk provides relatively little vitamin D. Less commonly, nutritional rickets may result from insufficient calcium intake.[15]

Because 25(OH)D readily crosses the placenta, infants born to vitamin D–replete mothers have sufficient stores, and thus nutritional rickets usually is not apparent before 3 to 6 months of age. Only if the mother is extremely deficient in vitamin D will nutritional rickets be seen in the newborn period.[15a]

Clinical manifestations of rickets include failure to thrive, short stature, bowing deformities, and predisposition to fractures. However, fractures do not occur in the absence of classic radiographic findings of rickets. Furthermore, the fractures that do occur in cases of severe rickets do not resemble those of child abuse.[15b] In addition, prominence of anterior rib ends causing a “rachitic rosary” and craniotabes (a softening of the skull bones) may be seen. Weakness is a clinical feature of rickets, correlating with the presence of vitamin D receptors in skeletal muscle.[16]

***Imaging.*** The features of rickets are most pronounced in regions of greatest bone growth, particularly the distal radius and ulna, distal femur, proximal tibia, proximal humerus, and anterior rib ends. An insufficient calcium x phosphate product causes decreased mineralization of the zone of provisional calcification and lack of normal chondrocytic terminal differentiation. As a result, the initial radiographic finding is rarefaction of the normally sharply defined zone of provisional calcification on the metaphyseal side of the growth plate so that metaphyseal bone fades gradually into the lucent physeal and epiphyseal cartilage (Fig. 139.1 and e-Fig. 139.2). There is loss of definition of the Laval-Jeantet collar, a short cylindric segment of the metaphysis adjacent to the growth plate that is an indicator of the most recently formed bone in young infants.[17] Deficient chondrocyte terminal differentiation and apoptosis causes accumulation of disorganized cartilage in the metaphysis in addition to nonmineralized osteoid, leading to widening of the distance between the epiphysis and metaphysis, metaphyseal fraying, and metaphyseal concavity (cupping). Metaphyseal concavity varies by site, being most pronounced in the distal radius and ulna (see Fig. 139.1). However, distal ulnar metaphyseal concavity with no other abnormality may be a normal finding. Metaphyseal findings that may be recognized on chest radiographs include involvement of the proximal humeral metaphyses and rib ends, producing the rachitic rosary (Fig. 139.3) of bulbous rib ends felt on physical examination.

Long bone shaft findings lag behind those in the metaphysis. In rickets due to vitamin D abnormality, PTH rises in an attempt



**e-Figure 139.2. Vitamin D deficiency rickets.** A less severe case than shown in Fig. 139.1. At 9½ years of age *(top),* distal femoral physeal widening and metaphyseal fraying is noted that resolved several months later after treatment *(bottom)*.

to restore a normal serum calcium concentration, producing secondary hyperparathyroidism (HPTH) with subperiosteal bone resorption, intracortical tunneling, and overall demineralization (Fig. 139.4). With ongoing bone remodeling, as nonmineralized osteoid replaces mineralized bone (osteomalacia), cortical demineralization and coarsening of the trabecular pattern in the shafts occurs, predisposing a person to insufficiency fractures. Paradoxically, periosteal new bone formation also may be seen in rickets even before healing, which likely is an anabolic effect of PTH (see Fig. 139.1).

Bowing in rickets is most pronounced in the tibias and is due to loss of normal bone rigidity in the metaphyses and shafts. The large zone of nonmineralized cartilage and osteoid in the rachitic metaphyses is particularly deformable and subject to bending.

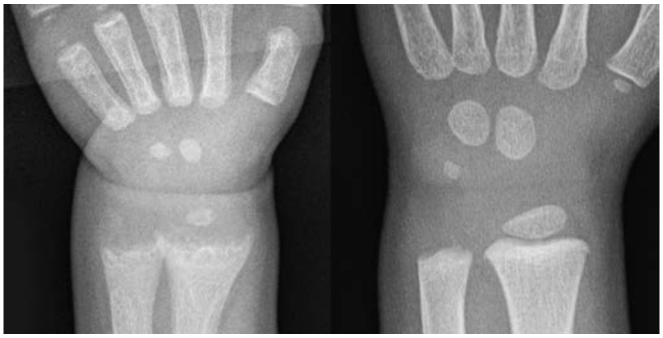


**Figure 139.1. Vitamin D deficiency rickets.** A 14-month-old child with growth failure and severe rickets who responded well to vitamin D therapy. The initial image *(left)* shows loss of definition of the zones of provisional calcification for the distal radial and ulnar metaphyses along with metaphyseal fraying and concavity ("cupping") and physeal widening with an increased distance between the epiphysis and visualized portion of the metaphysis. Periosteal new bone also is present that is seen best along the metacarpals but also is present along the distal radius. With healing *(right),* the zone of provisional calcification is well mineralized and the other findings have resolved.

With healing (see Fig. 139.1, e-Fig. 139.2, and Fig. 139.4), mineral deposition in the zone of provisional calcification and restoration of chondrocyte terminal differentiation occur. The initial radiographic finding of healing is reidentification of the zone of provisional calcification as a thin opaque line separated from the identifiable shaft by the intervening lucent nonmineralized cartilage and osteoid. With further healing, this metaphyseal region calcifies, which may give the false impression of rapid bone growth. Less often, newly mineralized osteoid also may be seen in the metaphyseal equivalent region of the epiphysis (e-Fig. 139.5). With healing of cortical bone, the subperiosteal osteoid becomes calcified, producing either a uniform or lamellated layer.

Additional imaging features of rickets include chest wall (Harrison) grooves, which are deformities of softened ribs at the diaphragmatic insertions. Scoliosis and kyphosis also may be seen.

***Treatment and Follow-up.*** Prevention of vitamin D deficiency is a controversial issue because of lack of consensus regarding the level of vitamin D that is considered sufficient. The 2011 Institute of Medicine report[18] concluded that a serum level of 25-hydroxy-vitamin D of at least 20 ng/mL is normal, although many experts in vitamin D research argue that higher levels are needed. Accordingly, the Institute of Medicine recommends 400 IU of vitamin D daily during the first year of life and 600 IU daily thereafter.

Treatment guidelines for vitamin D deficiency are those of the Lawson Wilkins Pediatric Endocrine Society.[19] Treatment is recommended for clinical manifestations of vitamin D deficiency or 25-hydroxy-vitamin D levels less than 15 ng/mL, beginning with higher doses than those used for prevention. With treatment, if radiographic evidence of healing is seen by 3 months, vitamin D dosage can be reduced to preventive levels.

## Other Forms of Rickets

Many other conditions may result in an insufficient calcium x phosphate product, causing rickets. The radiographic manifestations

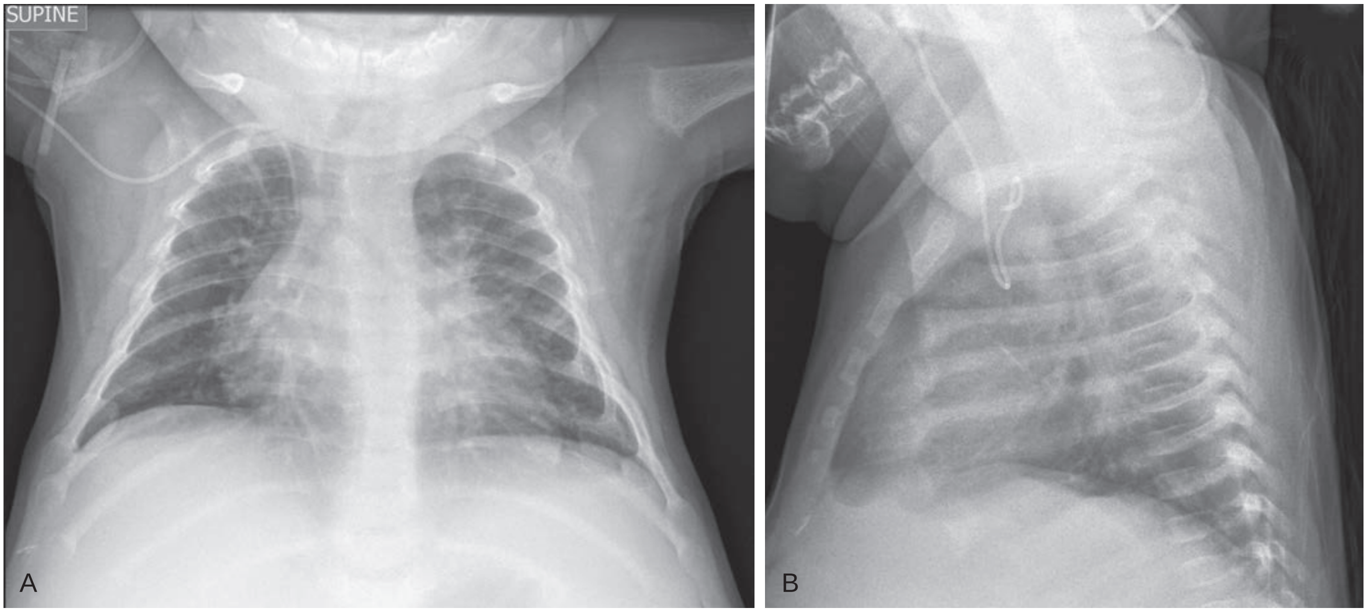

**Figure 139.3. Rickets secondary to biliary atresia in a 5-month-old child.** Anteroposterior (A) and lateral (B) chest radiographs show rachitic changes in the proximal humeral metaphyses and anterior rib ends. The rib findings are best seen on the lateral view.

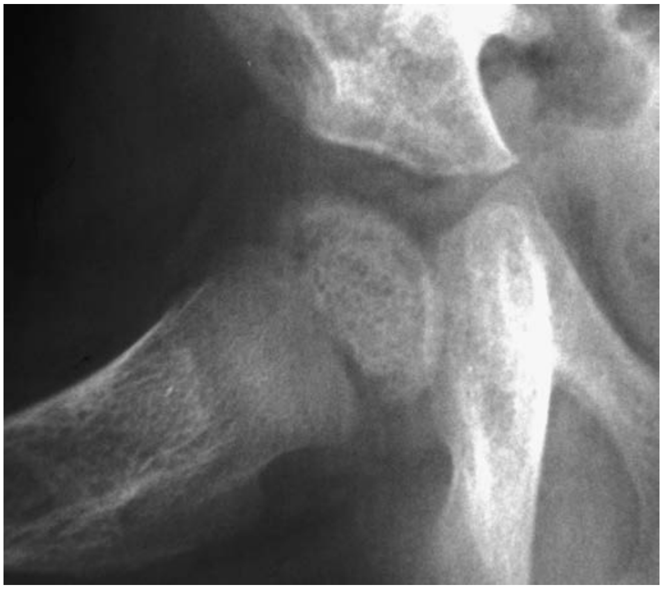

**e-Figure 139.5. Healing rickets with mineralization of previously lucent osteoid.** Newly mineralized bone is seen in the proximal femoral metaphysis, as well as the equivalent portion of the epiphysis.

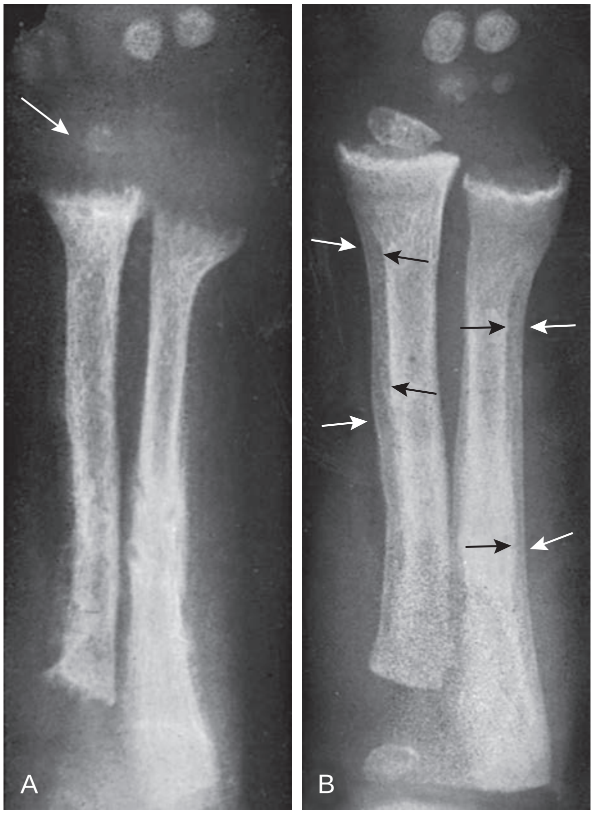

**Figure 139.4. Diaphyseal findings in a patient with severe vitamin D deficiency rickets.** Radiographs of the forearm during the active phase (A) show coarse demineralization and subperiosteal bone resorption, which are indicative of hyperparathyroidism as a result of rickets. Also note the severe rachitic findings in the metaphysis and poor mineralization of the distal radial epiphysis *(arrow)* with loss of the zones of provisional calcification. With healing 3 months later (B), extensive periosteal new bone is seen *(white arrows)* with calcification of previously nonmineralized osteoid *(black arrows)* produced by periosteal osteoblasts.

described for vitamin D insufficiency rickets are etiologically nonspecific and are similar in the other forms of rickets unless otherwise indicated.

**Malabsorption and Hepatobiliary Disease.** Vitamin D malabsorption may cause rickets in disorders such as celiac disease and cystic fibrosis. Rickets with hepatobiliary disease (see Fig. 139.3) is mostly a result of decreased intake and intestinal absorption of fat-soluble vitamins (A, D, E, and K); decreased hepatic 25-hydroxylation of vitamin D usually is not significant. Associated vitamin K deficiency in hepatobiliary disease may lead to recurrent hemarthrosis, most frequently involving the knee.

**Vitamin D–Dependent Rickets, Types I and II.** In autosomal-recessive vitamin D–dependent rickets (VDDR) type I, a defect in the renal 1-α-hydroxylase leads to undetectable or very low calcitriol levels.[20,21] Rickets in VDDR I is severe, presents in the first few months of life, and has more secondary HPTH than do other forms of rickets. VDDR I responds to physiologic doses of calcitriol. Rickets also can result from a defect in the receptor for calcitriol, causing vitamin D nonresponsiveness.[21,22] The designation of VDDR type II for this disorder is inappropriate because it is resistant to all forms of vitamin D, and hence the term "calcitriol-resistant rickets" is preferred. In addition to severe rickets, approximately half of the patients have manifestations of ectodermal dysplasia.

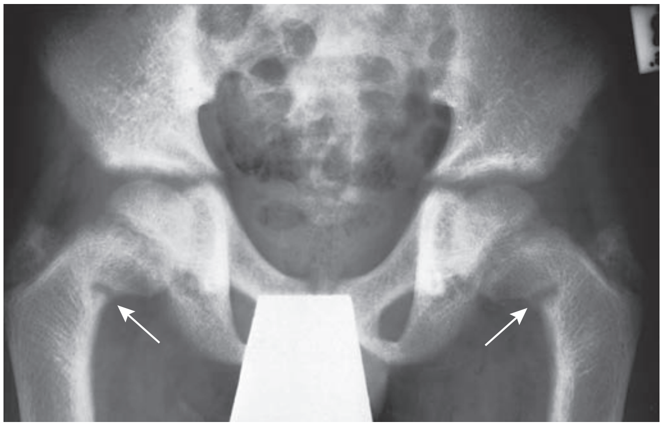

**Figure 139.7. Looser zones in a child with X-linked hypophosphatemia.** Pelvic radiograph shows symmetric transverse lucent areas in the medial aspect of the femoral necks *(arrows)* that are a manifestation of osteomalacia. Also note the patchy increased density, coarse trabeculations, and rachitic irregularity of the metaphyses.

**Phosphopenic Rickets.** Phosphopenic forms of rickets are seen in hereditary hypophosphatemia, tumor-induced rickets and osteomalacia, and intrinsic renal tubular disease. Additionally, a major component of rickets of prematurity (i.e., metabolic bone disease of prematurity) is likely phosphate deficiency.

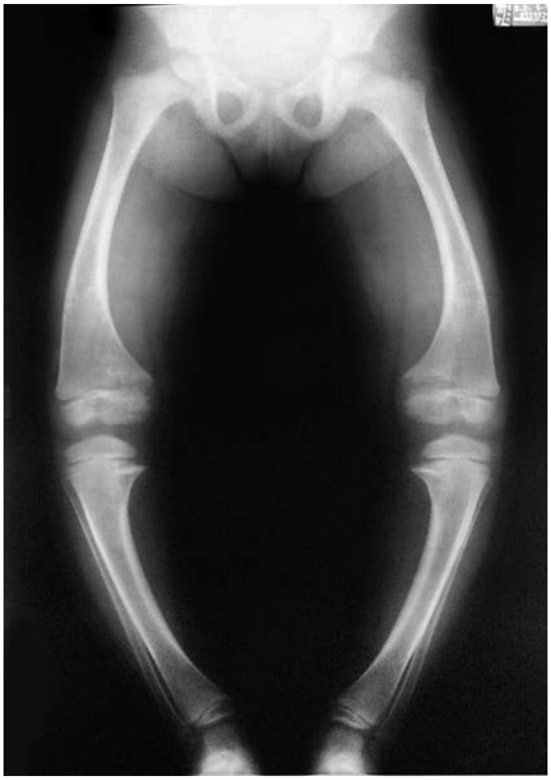
### Hereditary Hypophosphatemic Disorders

***Etiology.*** X-linked hypophosphatemia (XLH), also known as familial vitamin D–resistant rickets, is the most common hereditary cause of hypophosphatemia, with rare autosomal-dominant and recessive variants.[7,9,11] The discovery that the autosomal-dominant variant was due to a gain of function for FGF23 led to the recognition of FGF23 as a major phosphaturic factor. The relationship of FGF23 and mutations of the *PHEX* gene, the causative defect in XLH, is under investigation.[23]

XLH is characterized clinically by short stature and prominent bowing deformities of the lower extremities. Although X-linked dominant, it often is less severe in female heterozygotes than in male hemizygotes. Biochemically, serum phosphate is low and phosphate excretion is elevated. Calcium and PTH are normal and calcitriol is either low or inappropriately normal.

***Imaging.*** Lower extremity bowing usually is quite prominent in XLH (e-Fig. 139.6), whereas the rachitic findings of XLH are often (but not always) relatively mild. Because no hypocalcemia is present, secondary HPTH is not seen in hypophosphatemic rickets. Looser zones (a feature of osteomalacia) are present more often in XLH than in nutritional rickets, likely because of the chronicity of the mineralization disorder. Looser zones, or pseudofractures, are radiolucent lines oriented perpendicular to the cortex as a result of poor mineralization of osteoid at sites of stress, which lead to increased bone remodeling. Characteristic sites include the medial aspect of the femoral neck (Fig. 139.7), the extensor surface of the ulna, the axillary border of the scapula, and the pubic ramus, with these findings often being bilateral. In infants, craniosynostosis may complicate XLH.[24,25] In older patients, XLH may be associated with enthesopathy and paravertebral ossification, similar to diffuse idiopathic skeletal hyperostosis.

***Treatment and Follow-up.*** Treatment of XLH includes oral phosphate replacement and calcitriol because phosphate replacement alone often leads to secondary HPTH. However, excessive calcitriol may lead to hypercalcemia, nephrocalcinosis, and nephrolithiasis; renal ultrasonography often is used to screen for this complication.[26]



**e-Figure 139.6. X-linked hypophosphatemia in a 3½-year-old girl.** Prominent convex lateral bowing of the femurs and tibias is present, along with rachitic findings in the metaphyses.

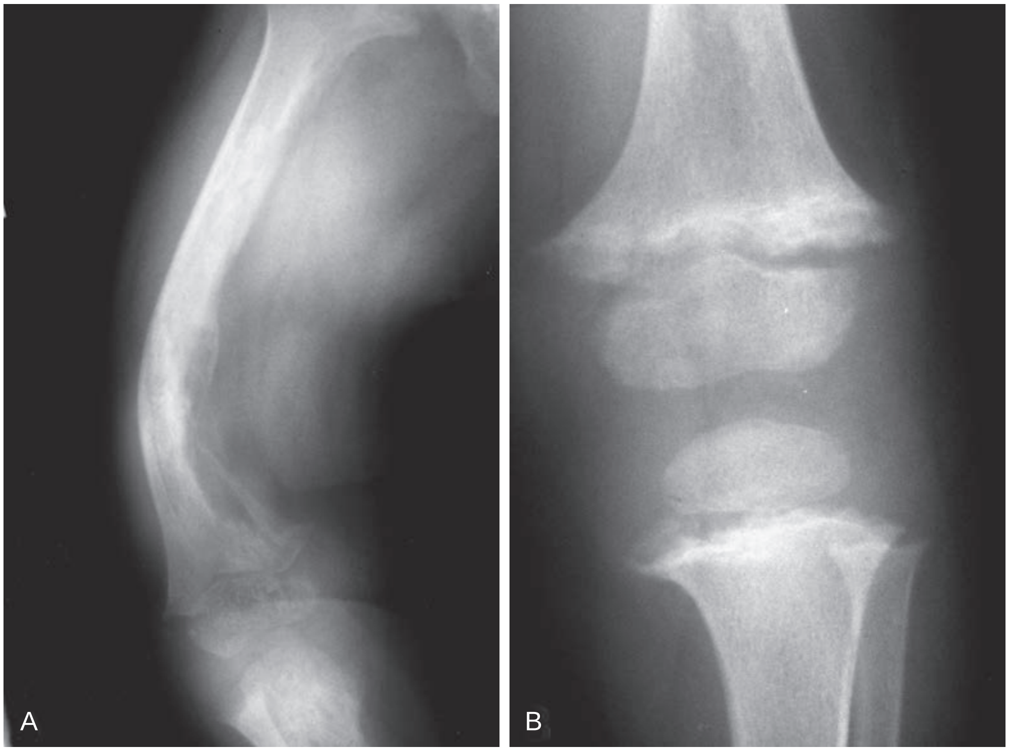


**Figure 139.8. Hypophosphatemic rickets in a girl aged 2 years and 4 months with Gorham massive osteolysis syndrome.** Radiograph of the right femur (A) shows extensive osteolysis. The left hemiskeleton was unaffected by osteolysis, but the left knee (B) shows typical features of rickets.

### Tumor-Induced Rickets and Osteomalacia (Oncologic Osteomalacia)

***Etiology.*** Hypophosphatemic rickets and osteomalacia may be caused by certain tumors and tumor-like conditions that are capable of producing FGF23, with healing of rickets after removal of the tumor.[27,28] Tumor-induced rickets and osteomalacia (TIRO) may occur at any age but is quite uncommon in children. Although a large variety of benign and malignant mesenchymal neoplasms initially were described, many of these neoplasms more recently have been recategorized pathologically as “phosphaturic mesenchymal tumor, mixed connective tissue variant.”[29] Other conditions causing rickets that are considered to be within the spectrum of TIRO include neurofibromatosis, polyostotic fibrous dysplasia (with or without other features of McCune–Albright syndrome), epidermal nevus syndrome, and Gorham massive osteolysis syndrome (Fig. 139.8).

Patients with TIRO may present with chronic vague symptoms, including generalized pain and muscle weakness. TIRO should be suspected in cases of hypophosphatemic rickets with no family history or evidence of renal tubular disease.

***Imaging.*** The radiographic findings of TIRO are similar to those of other forms of chronic rickets such as XLH. Imaging also plays a role in the search for the causative tumor, which usually is small and grows slowly. Because phosphaturic mesenchymal tumors often express somatostatin receptors, In-111 octreotide scintigraphy has been used.[30] Reports also indicate that fluorine-18-deoxyglucose positron emission tomography/computed tomography or whole-body MRI may be helpful.[31,32]

***Renal Tubular Disease.*** Many disorders including cystinosis, tyrosinemia, galactosemia, Lowe syndrome, Wilson disease, and toxins may cause global renal tubular dysfunction, hyperphosphaturia, renal tubular acidosis, and wasting of other substances.

### Rickets of Prematurity

***Etiology.*** Rickets of prematurity, also known as metabolic bone disease of prematurity, is most common in infants with a birth weight below 1 kg or gestational age younger than 28 weeks.[33,34] Normally, 80% of gestational bone mineral accretion occurs during the third trimester,[34] and thus infants born prematurely must accumulate minerals at a high rate to make up for this deficit. Although dietary mineral deficiency is rare in term infants and older children, inadequate intake of calcium and especially phosphorus is a major cause of metabolic bone disease of prematurity. Breast milk and infant formulas do not supply sufficient calcium and phosphorus for premature infants, and this deficiency becomes most pronounced during the period of “catch-up” growth, often near the time of hospital discharge.

***Imaging.*** Radiographic features include generalized osteopenia, fractures, and rachitic changes in the metaphyses (Fig. 139.9). However, the rachitic findings may be masked when the infant is not growing. The fractures often are not recognized acutely and, if first discovered after discharge, may be confused with nonaccidental trauma. Extremity fractures are common and usually do not lead to long-term morbidity because ample opportunity exists for remodeling.

## Hypophosphatasia

***Etiology.*** Hypophosphatasia is a rare inherited condition in which deficient mineralization of cartilage and osteoid are attributed to alkaline phosphatase deficiency rather than an insufficient calcium x phosphate product (which characterizes rickets).[5,35,36] In hypophosphatasia, a defect in the gene encoding alkaline phosphatase results in accumulation of pyrophosphate, which interferes with the formation of hydroxyapatite crystals.

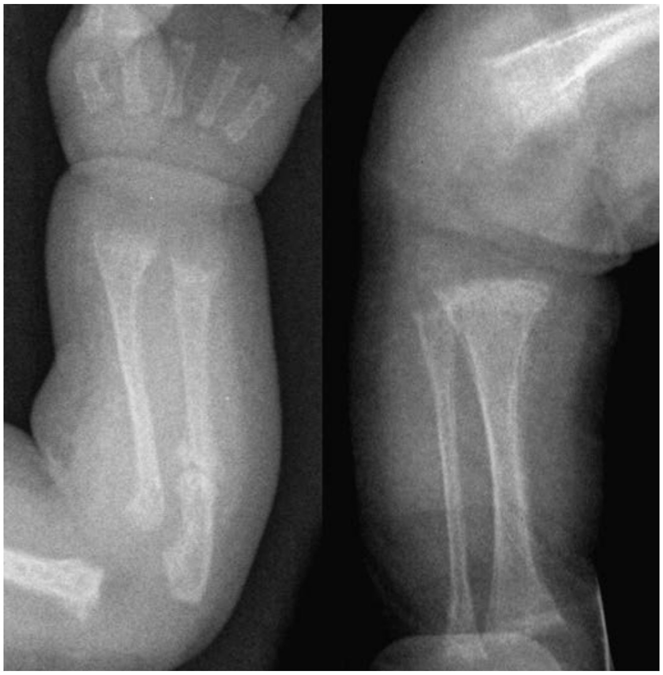

**Figure 139.9. Metabolic bone disease of prematurity in a former premature infant who is now 3 months of age.** Radiographic findings include severe diffuse demineralization, rachitic findings in major long bone metaphyses, and healing fractures of the ulnar diaphysis and distal femur.

Hypophosphatasia is divided clinically into perinatal, infantile, childhood, and adult forms, with decreasing severity as the age of presentation increases. Two other variants have also been described; ondontohypophosphatasia involving only dentition, and benign prenatal hypophosphatasia characterized by spontaneous improvement of prenatal long bone bowing.[37] The perinatal form features severe lack of mineralization of the skeleton and short and deformed limbs. Absence of structural support for the thorax leads to respiratory insufficiency, predisposition to pneumonia, and early death. The infantile form has a less severe mineralization defect. Patients present before 6 months of age with lethargy, leading to poor feeding and failure to thrive. Rachitic-appearing ribs and multiple rib fractures may be seen. Craniosynostosis often is present and may be associated with increased intracranial pressure despite a wide appearance of the sutures radiographically. The childhood and adult forms are milder with extremity pain, gait disturbance, weakness, and premature loss of deciduous teeth. The skeletal manifestations of childhood hypophosphatasia improve during adolescence, but symptoms of the "adult" form recur later in life simulating osteomalacia.

***Imaging.*** The perinatal form (Fig. 139.10) is characterized by severe failure of mineralization of much of the skeleton. Although the skull base usually is mineralized, the calvarium may be nearly completely nonmineralized. The remainder of the axial skeleton has varying mineralization. In infantile and childhood hypophosphatasia, the diaphyses appear normal and the metaphyses are poorly mineralized, suggesting a process similar to rickets. However, the "rachitic" changes of hypophosphatasia are not as uniformly distributed across the growth plate. Rather, it involves a more localized portion of the growth plate with deficient mineralization extending into the metaphysis, creating a "chewed out" appearance of the metaphyses (Fig. 139.11). Because of poor calvarial mineralization, the sutures may appear widened despite actual premature closure. Whole-body MRI of childhood hypophosphatasia shows metaphyseal bone marrow signal T2 hyperintensity predominantly in the lower extremities.[38] The adult form simulates osteomalacia with a coarse trabecular pattern, Looser zones, and metatarsal fractures.

***Treatment and Follow-up.*** Initial attempts to treat severe forms of hypophosphatasia with alkaline phosphatase infusion were ineffective, although more recent work with a bone-targeted human recombinant enzyme is encouraging.[39] Bone marrow transplantation also has been used in the treatment of infantile hypophosphatasia.[40] The milder forms are treated symptomatically.

### Hyperphosphatemic Disorders

***Etiology.*** The major conditions causing hyperphosphatemia include renal insufficiency, tumoral calcinosis (TC), and hyperostosis hyperphosphatemia syndrome (HHS). TC and HHS are now considered to be different manifestations of the same disorder, with some patients showing features of each.[41] TC is an autosomal-recessive disorder characterized by prominent calcific deposits and hyperphosphatemia. It usually is seen in adolescents and young adults but may present earlier. In the United States, TC is most common in African Americans. HHS is most common in the Middle East and usually presents in childhood with extremity pain and swelling along with imaging findings that mimic osteomyelitis. Hyperphosphatemia and elevated or inappropriately normal calcitriol levels are secondary to decreased FGF23 signaling, which in turn is caused by mutations affecting either FGF23, an enzyme that stabilizes it, or its receptor.[42–45]

TC should be distinguished from secondary causes of heterotopic bone formation, such as is seen in chronic renal insufficiency and posttraumatic myositis ossificans.

***Imaging.*** The major finding in TC is the deposition of large calcific masses in the paraarticular soft tissues (Fig. 139.12A).[46–48] In descending order, the hips, elbows, shoulders, and feet are most frequently involved. These masses often are cystic and may show layering of chalky fluid on cross-sectional imaging or horizontal beam radiography. Some patients with TC may also have manifestations of HHS, including medullary sclerosis, extensive periosteal new bone, abnormalities on skeletal scintigraphy, and edema-like signal in the marrow on MRI (Figs. 139.12B and C). These features are related to bone marrow involvement and may mimic osteomyelitis or other infiltrative disorders.

***Treatment and Follow-up.*** The calcified masses of TC are amenable to surgical excision if they become painful or cause deformity or functional impairment. Many forms of therapy have been used to diminish or prevent these deposits, although they all have limited supporting data. Most often used is dietary phosphate restriction, which often is combined with aluminum-based phosphate binders. No forms of therapy have been found to be useful in patients with HHS, a disorder that usually shows spontaneous subsidence, often followed by recurrence.

## ABNORMALITIES OF BONE MATRIX FORMATION

Bone matrix (osteoid) is the organic framework upon which mineral, in the form of hydroxyapatite, is deposited. The prototypical cause of insufficient matrix formation is osteogenesis imperfecta with defects in the genes encoding type I collagen. Normal collagen synthesis also depends on ascorbic acid (vitamin C) and ascorbic acid oxidase, a copper-dependent enzyme. Hence matrix synthesis is impaired in vitamin C deficiency (scurvy), copper deficiency, and some abnormalities of copper metabolism.

### Scurvy

***Etiology.*** Scurvy is caused by dietary deficiency of vitamin C.[49–51] Children with developmental and behavioral disorders such

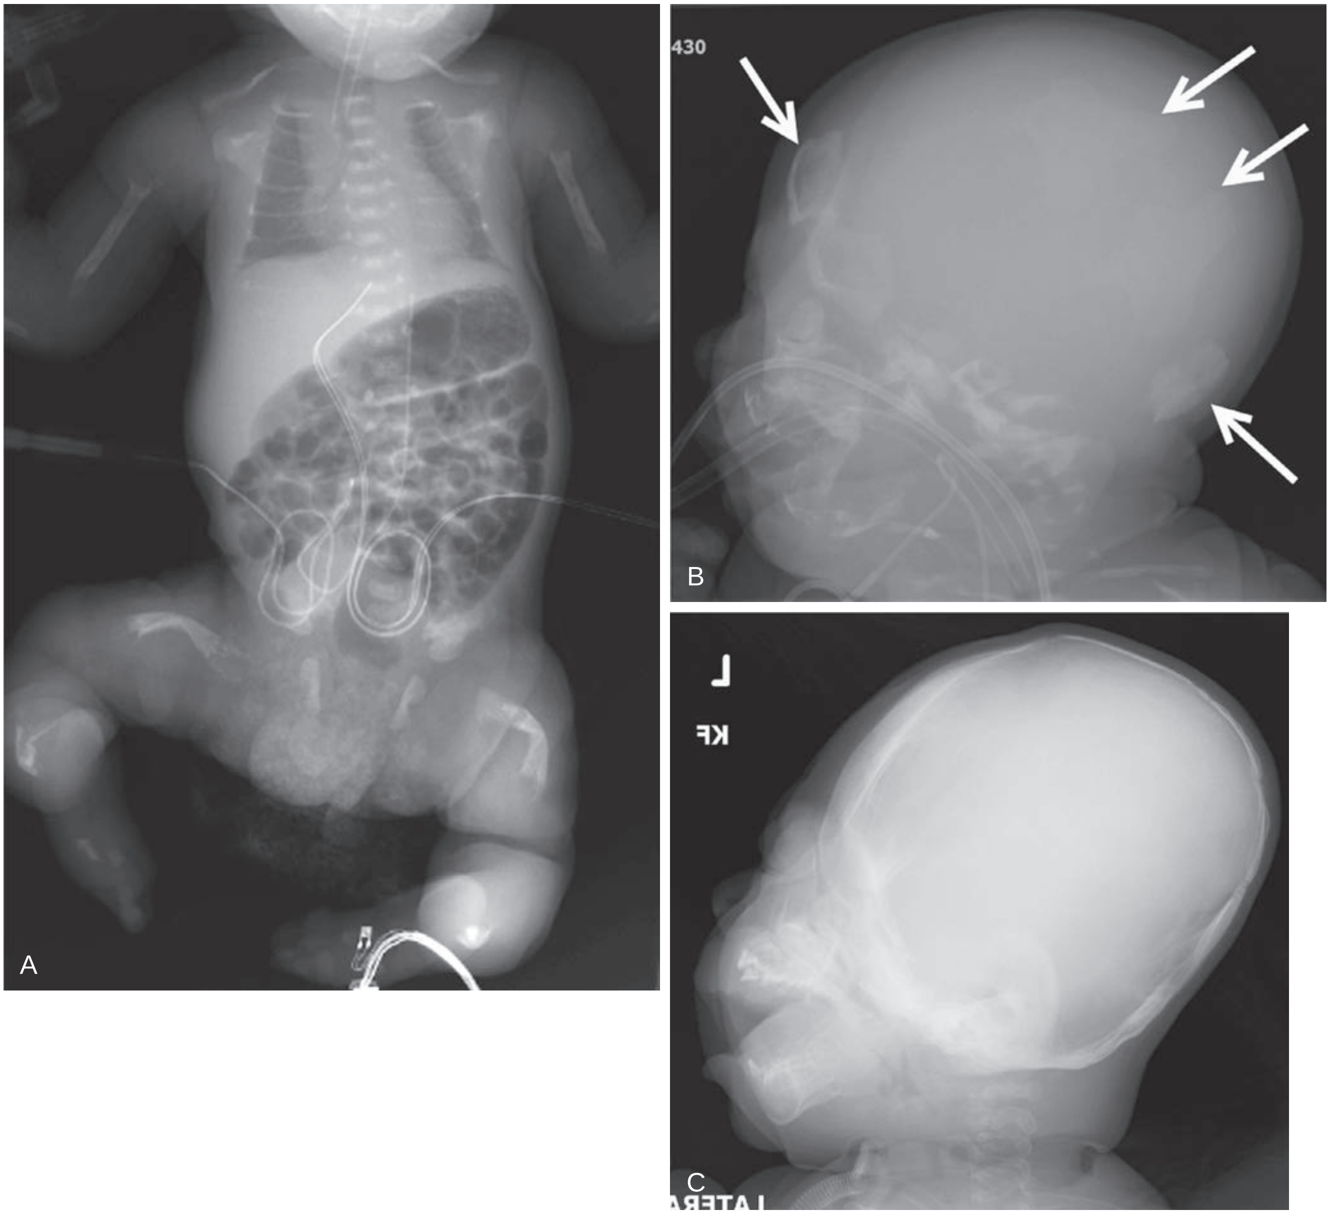

**Figure 139.10. Perinatal hypophosphatasia.** (A) Babygram shows severely gracile ribs with pulmonary hypoplasia. The vertabrae are wafer-like. There is irregular ossification and hypoplasia of the long bones with bowing of the extremities. (B) The skull is nonmineralized except for part of the skull base and small islands of the frontal, parietal, and occipital bones *(arrows)*. (C) With experimental therapy, there has been increased ossification of the skull at 6 months of age, but development of craniosynostosis. The child died 1 month later.

as autism may present with limping due to scurvy caused by a highly restrictive diet.[52] Children with transfusion-related iron overload are also at risk for scurvy due to accelerated ascorbic acid catabolism by high iron stores, exacerbated in the setting of poor diet.[53]

***Imaging.*** Decreased osteoid formation in scurvy causes an imbalance between bone production and resorption, leading to generalized atrophy of the cortex and spongiosa. However, chondrocyte terminal differentiation and cartilage calcification are normal, forming a well-mineralized zone of provisional calcification. On the diaphyseal side of the physis, resorption of calcified cartilage is diminished, leading to a thickened zone of provisional calcification. Radiographically, this thickened zone is seen as a prominent opaque line (Fig. 139.13), designated as the white line of scurvy (white line of Fränkel). Despite its thickness, this zone is brittle and may fracture. The bone just beneath the thickened provisional zone is demineralized and also brittle with a sparse trabecular pattern, producing a lucent zone adjacent to the zone of provisional calcification known as the scurvy zone (the Trümmerfeld zone). Later, transverse fractures may develop through the brittle zone of provisional calcification and the demineralized metaphyseal scurvy zone. If this fracture is limited to a peripheral portion of the scurvy zone, a subphyseal lucent cleft will be seen (Fig. 139.14). With transverse displacement of the epiphysis and zone of provisional calcification from the rest of the shaft, the heavily mineralized zone of provisional calcification projects

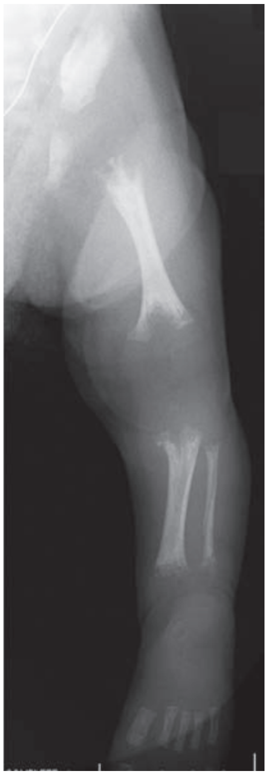

**Figure 139.11. Infantile hypophosphatasia.** Lower extremity radiograph at 1 month of age shows irregular "chewed out" appearance of the metaphyses. There is poor ossification of the epiphyses of the knee as well as the talus and calcaneus.

peripherally, forming a metaphyseal spur (Pelkan spur), another characteristic radiographic feature of scurvy. These changes should not be confused with metaphyseal fractures of child abuse. Similar changes in the epiphyses lead to a thickened peripheral shell of calcified cartilage surrounding rarefied trabecular bone within the epiphysis, producing the Wimberger ring (see Fig. 139.13), one of the most characteristic findings of scurvy. In the diaphyses, the findings are those of generalized osteopenia with cortical thinning, although diaphyseal fractures are uncommon. Subperiosteal hemorrhage due to capillary fragility is a frequent manifestation of scurvy and is most common in the larger tubular bones such as the femur, tibia, and humerus. Initially, subperiosteal hemorrhage is seen as increased soft tissue opacity on radiographs, or as heterogeneous subperiosteal collections on ultrasound or MRI.[54,55] Subsequently, the periosteum produces a cloak of new bone surrounding the shaft, which eventually will become the new cortex (Fig. 139.15).

***Treatment and Follow-up.*** The diagnosis of scurvy usually is based on a combination of the clinical and radiographic findings. An appropriate dietary history and laboratory testing may also be helpful. The clinical response to ascorbic acid is usually rapid, confirming the diagnosis.

## Copper Deficiency and Menkes Disease

Ascorbic acid oxidase is a copper-dependent enzyme, and hence copper deficiency results in deficient matrix formation and osteopenia. Menkes disease, an X-linked neurodegenerative and connective tissue disorder, is caused by deficiency of a cation-transporting enzyme needed for transport of copper.[36,51] This deficiency results in abnormal collagen and elastin, leading to osteopenia and increased bone fragility. Fractures in Menkes disease may follow minor trauma, and metaphyseal fractures with spurring may appear similar to the metaphyseal fractures of nonaccidental trauma[57] (e-Fig. 139.16). C2 posterior arch defects simulating Hangman's fracture have also been described.[58]

## HYPERVITAMINOSIS A

***Etiology.*** Vitamin A is a fat-soluble vitamin needed for vision and many other essential processes. In addition to its role in light reception, it is essential for normal epithelial differentiation of mucous membranes, and hence vitamin A deficiency causes xerophthalmia (dry ulcerating eye), the leading cause of blindness worldwide. Historically, fish liver oil and other preparations used for prevention and treatment xerophthalmia had been the major cause of vitamin A toxicity in young children, with cases often blamed on overly diligent caregivers. Infantile hypervitaminosis A is now quite rare, but vitamin A toxicity can still be seen with excessive supplementation, especially in children with cystic fibrosis and chronic renal failure.[59,60]

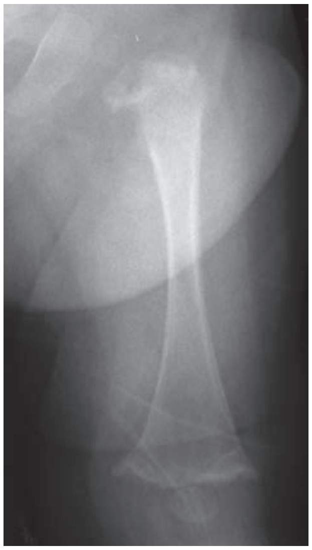
Chronic vitamin A toxicity usually presents at least 6 months after the beginning of excessive vitamin A intake. Initial symptoms are nonspecific, with anorexia and irritability. Dry, pruritic skin with desquamation, lip fissuring, and hepatomegaly may be present. The extremities demonstrate focal regions of swelling and pain that overlie the skeletal findings. Acute vitamin A poisoning is rare and usually presents with central nervous system signs and symptoms from increased intracranial pressure.

***Imaging.*** The skeletal manifestation of hypervitaminosis A may be extremely helpful in establishing this diagnosis in a child with a confusing clinical picture.[61,62] Long bone hyperostosis is the most frequent and most well-recognized finding, with periosteal new bone formation leading to undulating diaphyseal cortical thickening, most frequently involving the ulnae (e-Fig. 139.17) and metatarsals. Radiographically, these findings have been confused with infantile cortical hyperostosis (Caffey disease). However, age and distribution usually differentiate these, with presentation after 11 months and metatarsal involvement suggesting hypervitaminosis A, whereas presentation before 5 months and mandibular involvement suggests infantile cortical hyperostosis.[61] Premature central growth plate closure also may be seen in hypervitaminosis A,[63,64,65] leading to cone-shaped epiphyses that are invaginated into the metaphyses, mimicking the appearance of prior meningococcemia (Fig. 139.18). Retinoids (e.g., isotretinoin), which are chemically related to vitamin A, are used for treatment of dermatologic disorders as well as in chemotherapeutic regimens for certain malignancies (e.g., neuroblastoma) can also cause skeletal deformities and growth disturbances.[66]

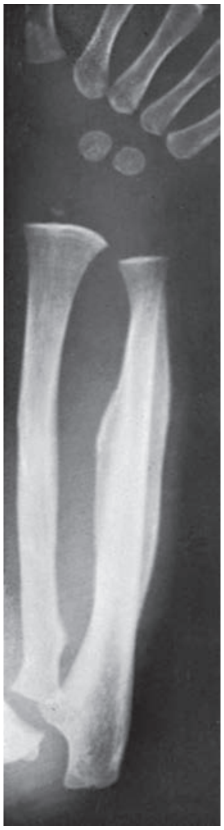
## HYPERVITAMINOSIS D

***Etiology.*** Production of calcitriol, the most active vitamin D metabolite, is a highly regulated process that provides inherent protection against vitamin D toxicity, but acute or chronic intoxication can occur with excessive doses of vitamin $D_2$ or $D_3$ supplements.[67] Most symptoms and signs are associated with manifestations of hypercalcemia. Massive overdosage (4–18 million U/day) may cause severe illness or even death. Manifestations may include vomiting, dehydration, fever, coma, convulsions, abdominal cramps, and "bone pain." In cases of chronic poisoning, the common early symptoms are lethargy, thirst, anorexia, vomiting, diarrhea, and abdominal discomfort. Excessive calcium excretion leads to renal damage.

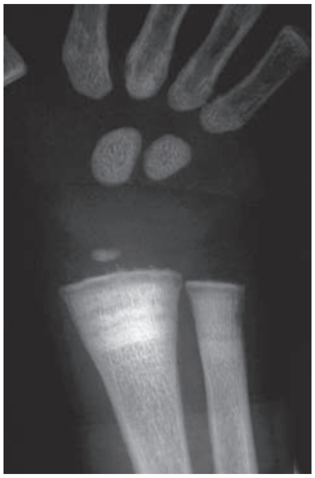
***Imaging.*** Skeletal findings include cortical thickening, osteoporosis, and alternating bands of increased and decreased opacity (e-Fig. 139.19). Metastatic calcifications also may be present in blood vessels, the falx cerebri, and many organs, including the kidneys, stomach, lungs, bronchi, and adrenal gland.[49]



**e-Figure 139.16. Menkes disease.** Radiograph of the left femur shows diffuse demineralization and a proximal femoral metaphyseal fracture. Healing rib fractures also were present. The infant presented with subdural hygromas related to the associated central nervous system disease and initially was suspected to be a victim of child abuse.



**e-Figure 139.17. Vitamin A toxicity.** Radiograph of the forearm shows mature periosteal new bone producing cortical hyperostosis in the right ulna from. The finding was symmetrical with an identical appearance of the left ulna (not shown).



**e-Figure 139.19. Iatrogenic vitamin D intoxication in a child with physiologic bowlegs who mistakenly was thought to have X-linked hypophosphatemia.** Multiple opaque bands are present in the distal radial metaphysis.

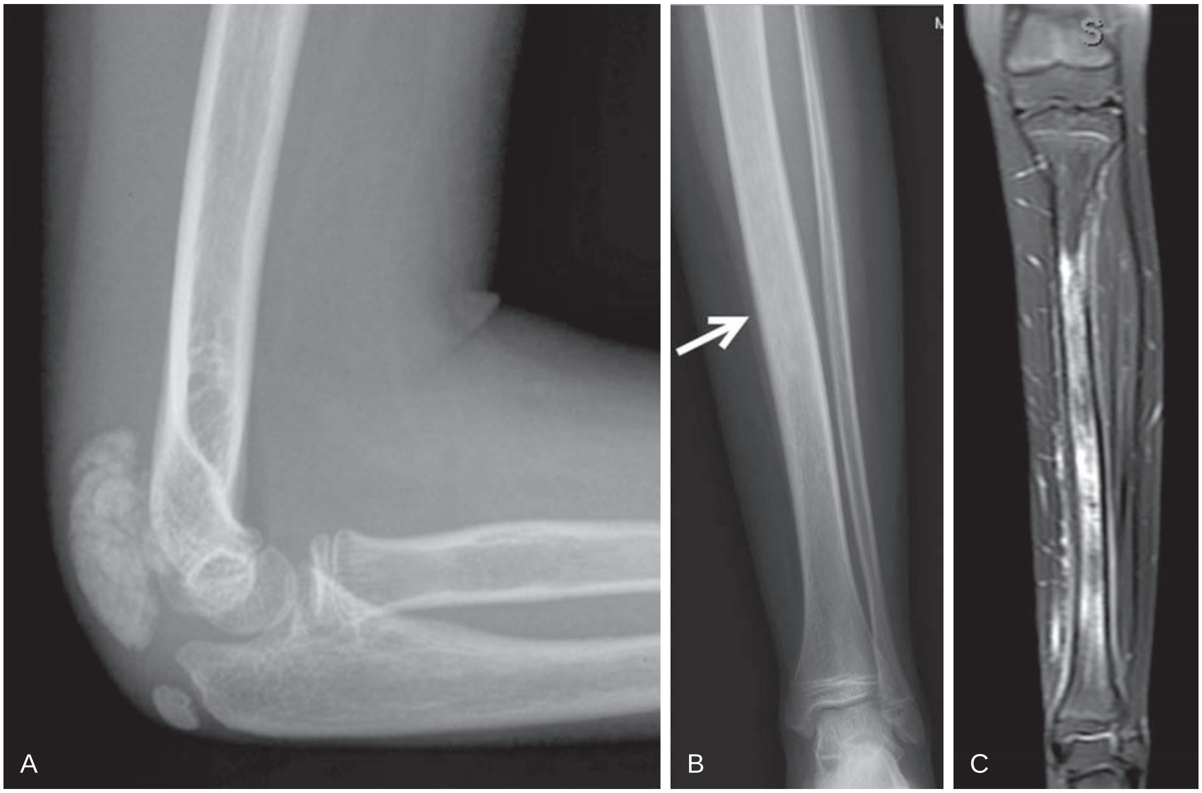


**Figure 139.12. Tumoral calcinosis/hyperostosis hyperphosphatemia syndrome.** (A) Left elbow radiograph in an 8-year-old girl shows a multilobulated calcified mass posterior to the left elbow. The mass was excised with confirmation of tumoral calcinosis. At age 9 years, evaluation for left leg pain included a frontal radiograph (B) showing diaphyseal sclerosis and mild periosteal reaction of the tibia *(arrow),* and a corresponding coronal T2-weighted fat suppresssed MRI (C) demonstrating extensive marrow hyperintensity and periostitis. A nuclear medicine bone scan also showed increased radiotracer activity (not shown). This appearance of "diaphysitis" seen with tumoral calcinosis/hyperostosis syndrome can be confused with osteomyelitis. One year later, she presented with pain and similar findings in the contralateral tibia.

## HEAVY METAL POISONING

***Etiology.*** Lead poisoning is the most common form of heavy metal poisoning. In children, lead poisoning usually occurs as a result of the ingestion of paint chips or dust containing lead in older housing; in the United States, the sale of house paint containing lead was discontinued in 1978. Although the incidence of lead poisoning has declined with public health and education efforts, it remains a significant problem, with growing concern about drinking water contamination from corroded lead pipes. Lead bullets result in toxicity only if they are within a serous space such as a synovium-lined joint, where lead will cause both systemic toxicity and synovitis, resulting in lead arthropathy.

Lead poisoning is characterized by abdominal pain, encephalopathy, peripheral neuropathy, and anemia with basophilic stippling.

***Imaging.*** Chronic lead toxicity causes bands of increased opacity (lead lines) in the metaphyses. The amount of lead in these regions is far below the amount that would be needed to produce opaque bands. Rather, lead toxicity causes defective resorption of calcified cartilage in the primary spongiosa, which builds up, producing the opaque bands. Usually, the more opaque the metaphyseal band, the more likely it is to be pathologic. However, lead lines can be clearly distinguished from normal opaque metaphyseal bands once interval bone growth separates the abnormally sclerotic bone from the zone of provisional calcification. Normal opaque metaphyseal bands are always contiguous with the zone of provisional calcification (Fig. 139.20). Abdominal radiographs may detect ingested radiopaque lead chips within the gastrointestinal tract.

***Treatment and Follow-up.*** Steps to prevent further exposure to lead are mandatory. Removal of radiographically identified lead chips from the stomach by gastric lavage has been performed but is controversial because the lead chips usually are poorly absorbed. In addition, no evidence exists to support the use of charcoal as a gastrointestinal binder to prevent absorption. For patients with particularly high lead levels, chelation therapy is indicated.

### KEY POINTS

- The initial radiographic finding in rickets is loss of mineralization of the zone of provisional calcification.
- Isolated distal ulnar metaphyseal cupping is a normal variant in an infant and should not be confused with rickets.
- In scurvy, maintenance of the zone of provisional calcification with subjacent demineralization occurs and gives an opposite appearance to rickets in both the metaphyses and epiphyses.
- Metaphyseal skeletal changes with scurvy may superficially mimic classic metaphyseal fractures of child abuse.

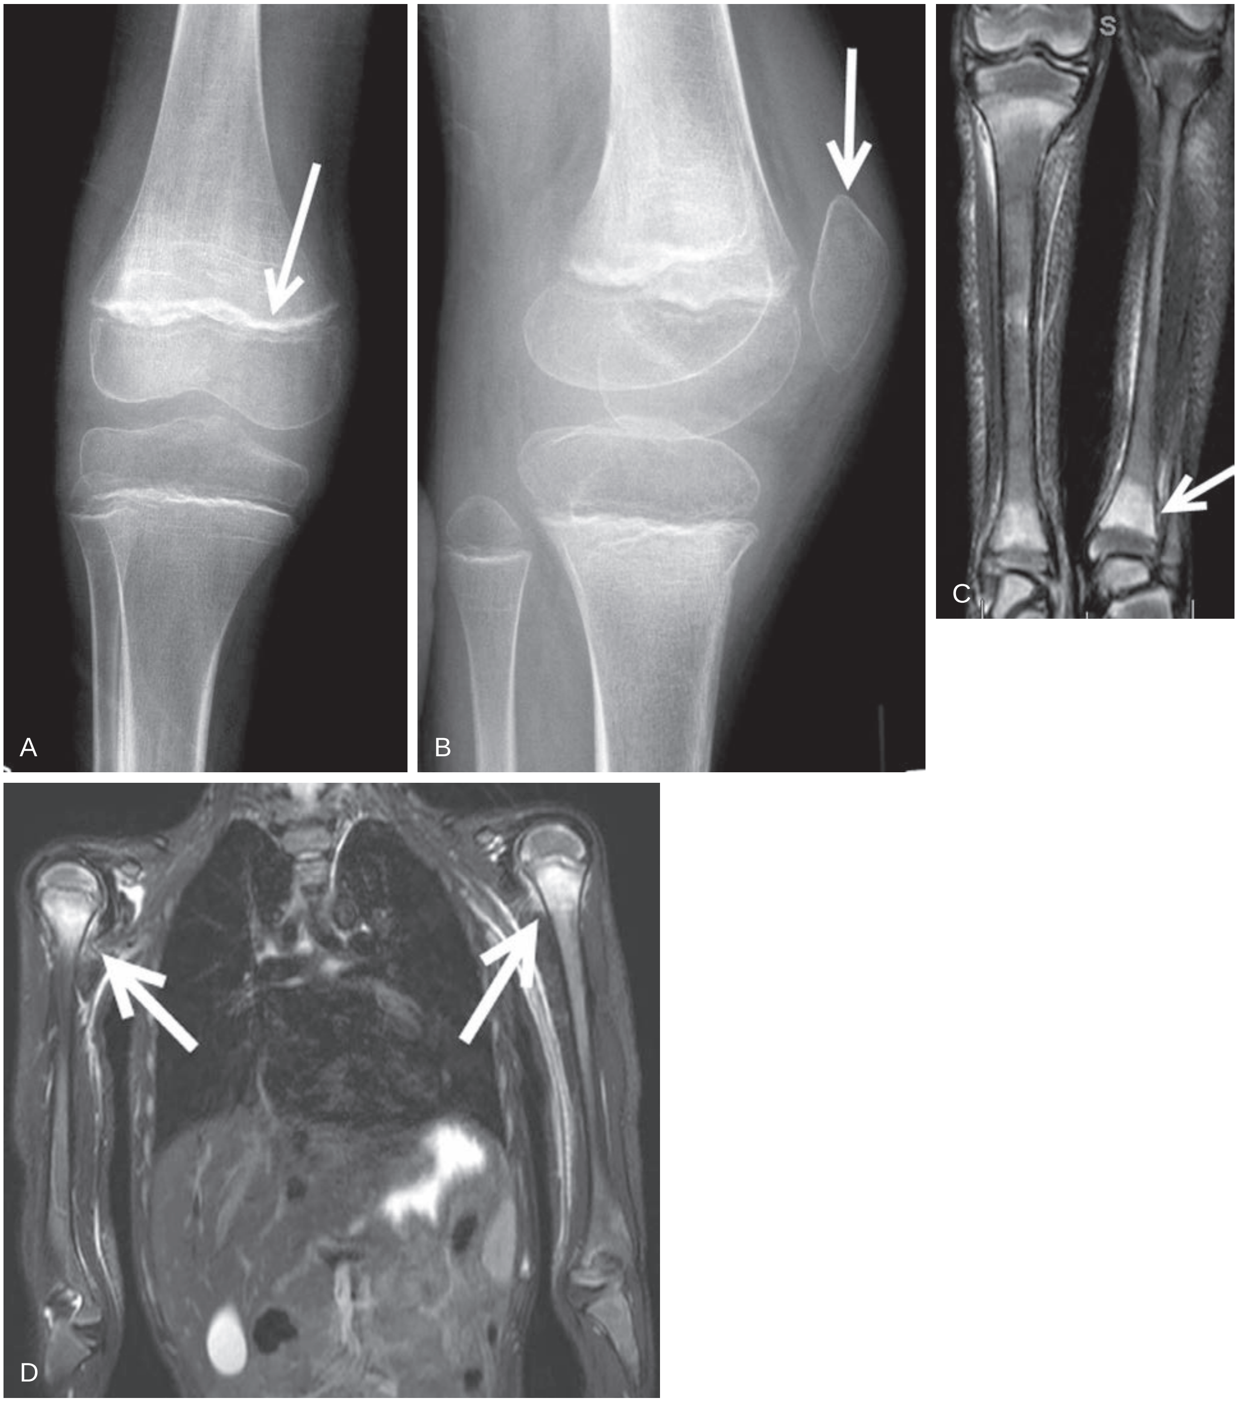

**Figure 139.13. Scurvy.** Eight-year-old boy with behavioral problems, parental neglect, and a severely restrictive diet who presented with lower extremity pain, refusal to bear weight and bleeding gums. (A) Frontal view of the right knee shows prominent zones of provisional calcification, forming the white line of scurvy *(arrow)*. (B) Lateral view of the knee shows the epiphyseal zone of provisional calcification, forming the Wimberger ring surrounding the centrally lucent epiphyses and patella *(arrow)*. (C) A coronal short-tau inversion recovery (STIR) image of the legs from whole-body MRI shows hyperintense bone marrow signal in the metaphyses of the tibiae and fibulae *(arrow),* as well as adjacent periosteal hyperintensity. (D) A coronal STIR image of the chest shows similar hyperintensity in the humeral metaphyses *(arrows)*.

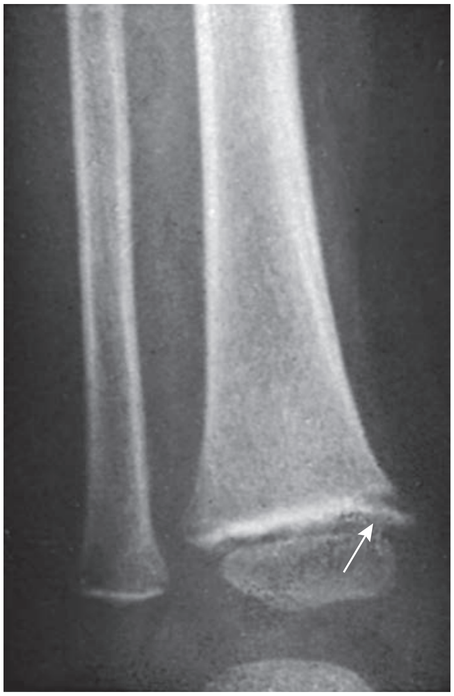

**Figure 139.14. Peripheral metaphyseal cleft in a 14-month-old child with scurvy.** An eccentric lucent cortical and trabecular defect produces a cleft *(arrow)* just beneath the zone of provisional calcification, with the peripheral aspect of the zone of provisional calcification separated from the shaft and tilted off the shaft toward the epiphysis.

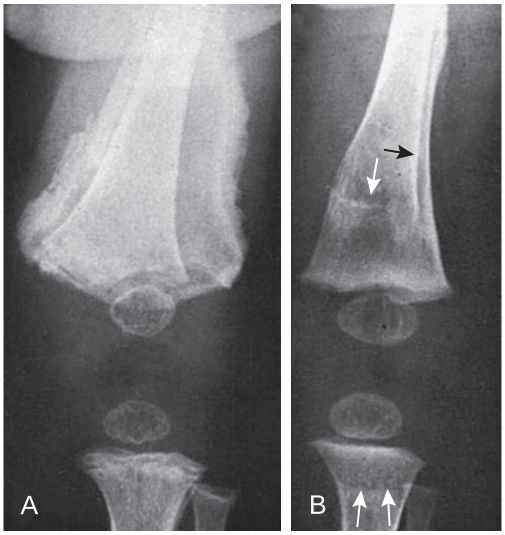

**Figure 139.15. Scurvy with displaced fracture and a subperiosteal hematoma.** (A) The left distal femoral epiphysis is displaced laterally relative to the metaphysis with a fracture through the brittle zone of provisional calcification. A large subperiosteal hematoma is present with periosteal calcification. Also note Wimberger rings of the distal femur and proximal tibia. (B) Four months later, the periosteal new bone is producing a new cortex with remodeling and eventual anatomic alignment of the prior epiphyseal displacement. *Arrows* indicate the initial cortex and zone of provisional calcification.

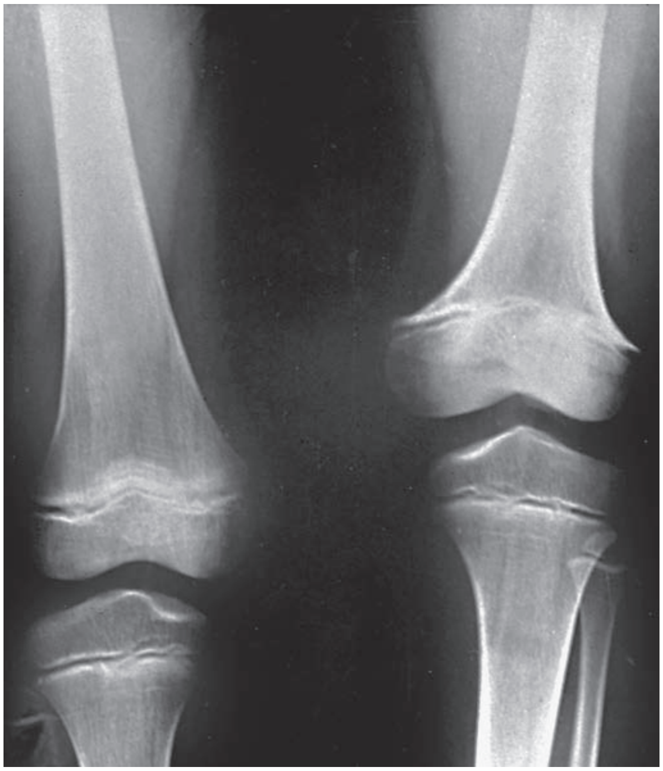

**Figure 139.18. Premature central growth plate closure from vitamin A.** Frontal radiograph shows premature closure of the central portion of the left distal femoral physis causing a left femoral longitudinal growth disturbance. In other cases involvement may be more generalized. *(Courtesy Charles N. Pease, Chicago, IL.)*

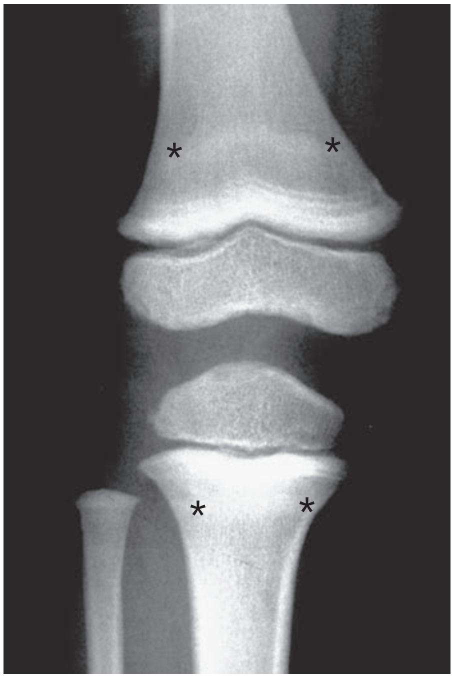

**Figure 139.20. Lead toxicity.** In addition to the opaque bands at the zones of provisional calcification, faint opaque bands also are present (between *asterisks*) that have “migrated away,” clearly establishing that they are abnormal rather than normal-variant opaque metaphyseal bands, which are always in continuity with the zone of provisional calcification.

# 140 Endocrine Disorders

Eric P. Eutsler and Richard M. Shore

Several endocrine glands have significant effects on skeletal growth, maturation, and modeling, and understanding these effects facilitates correct radiographic interpretation.[1,2] Renal osteodystrophy is also included in this chapter because of the importance of hyperparathyroidism (HPTH) in its pathophysiology, as are other related conditions causing disorders of bone physiology.

## HYPERPARATHYROIDISM AND RENAL OSTEODYSTROPHY

***Etiology.*** The parathyroid glands help maintain a normal circulating calcium concentration by releasing parathyroid hormone (PTH) in response to hypocalcemia. PTH then has many effects that increase the serum calcium concentration, such as promoting bone resorption to mobilize calcium. In the kidney, PTH upregulates renal 1-α-hydroxylase to produce calcitriol (1,25[OH]$_2$-vitamin D), which then acts on the gut to absorb calcium. PTH also decreases renal calcium excretion and increases phosphate excretion.

Bone resorption is mediated by multinucleated osteoclasts. Their development is stimulated by osteoclast differentiation factor, which is produced by osteoblasts. Osteoclast differentiation factor (RANKL) binds to a cell surface receptor called *RANK* on osteoclast precursor cells. PTH has a major role in stimulating osteoclastic bone resorption, likely through stimulation of *RANK*. Calcitriol also stimulates osteoclastic differentiation and function through *RANK*, whereas calcitonin transiently inhibits osteoclastic resorption. Activated osteoclasts then form a sealed-off compartment along the resorption surface, where bone is dissolved by highly concentrated enzymes in acidified extracellular fluid.

Primary HPTH may be caused by parathyroid hyperplasia or a parathyroid adenoma. Parathyroid adenomas are infrequent in children and are usually associated with multiple endocrine neoplasia (MEN) I. Parathyroid hyperplasia may be seen with MEN II and MEN III.

In secondary HPTH, PTH secretion is increased in response to hypocalcemia. Secondary HPTH is more frequent than primary HPTH in children and is most often caused by chronic kidney disease. Rickets and some other disorders of calcium metabolism may also cause secondary HPTH.

### Renal Osteodystrophy

Renal osteodystrophy[3–5] comprises a variety of skeletal manifestations of chronic kidney disease, the most important of which is secondary HPTH. In chronic kidney disease, phosphate retention and the resulting slight decrease in the ionized calcium concentration stimulate PTH, which then acts to promote phosphaturia and increase calcium. Although this initially normalizes calcium and phosphate concentrations, it does so at the expense of elevating PTH and mobilizing calcium and phosphate from bone. With advancing renal failure, decreased renal mass also reduces calcitriol synthesis, leading to rickets and osteomalacia. However, this effect on the skeleton is less pronounced than is HPTH, and many of the manifestations of "renal rickets" are actually those of HPTH.

***Imaging.*** PTH stimulation of osteoclasts leads to bone resorption at multiple sites.[3–6] The most specific radiographic manifestation of HPTH is subperiosteal resorption, initially seen along the radial aspects of the index and the middle finger middle phalanges (Fig. 140.1). The distal phalangeal tufts are also involved relatively early (see Fig. 140.1). With progression, subperiosteal resorption occurs at the ulnar aspects of the phalanges and other bones, including the medial aspects of the humeral and femoral necks, and the medial aspects of the proximal tibial metaphyses. Although less specific than subperiosteal resorption, HPTH may lead to intracortical resorption, or "tunneling," causing a striated appearance of the cortex, as well as endosteal, subchondral, and subligamentous resorption (Fig. 140.2). Subphyseal resorption at the zone of provisional calcification on the metaphyseal side of the physis may simulate the appearance of rickets (Fig. 140.3).

Slipped epiphyses (e-Fig. 140.4) are an important complication of renal osteodystrophy in children and are seen most frequently in the proximal femur. Although subphyseal resorption can mimic the radiographic appearance of rickets, the radiolucent material beneath the growth plate is fibrous tissue (osteitis fibrosa cystica), which is weaker than the nonmineralized osteoid in true rickets, accounting for slipped epiphyses occurring in renal osteodystrophy, but not in true rickets. The risk of epiphyseal slippage is particularly high when growth hormone (GH) is used to treat short stature, a major clinical problem in children with chronic kidney disease.

Additional findings of HPTH include resorption of the lamina dura surrounding the tooth roots (e-Fig. 140.5), cystic-appearing "brown tumors" (osteoclastomas), and bone sclerosis. Although brown tumors are more characteristic of primary HPTH, in children they are more commonly seen in secondary HPTH because of its higher prevalence in children. Osteosclerosis, most often seen with renal osteodystrophy, may be generalized or most pronounced subjacent to the vertebral end plates, resulting in a "rugger jersey" appearance (Fig. 140.6).

In patients with chronic kidney disease, true rickets and osteomalacia may also be seen from decreased production of calcitriol. It is often not possible to distinguish true rickets from the rachitic appearance of osteitis fibrosa cystica. Looser zones, if present, indicate true rickets. Renal osteodystrophy usually manifests a "high turnover" state from HPTH. Less often, an adynamic "low turnover" state may also be seen. Previously, adynamic bone disease was often due to aluminum toxicity, which occurred as a complication of aluminum-based phosphate binders. Presently, causes of adynamic bone disease include calcitriol therapy (which suppresses PTH), malnutrition, immobilization, corticosteroid therapy, and prior parathyroidectomy. Fractures may occur in renal osteodystrophy, with HPTH predisposing to metaphyseal fractures (e-Fig. 140.7).

***Treatment and Follow-up.*** Treatment of secondary HPTH in children with chronic kidney disease is directed toward normalization of mineral metabolism to improve growth, decreasing skeletal deformity and fragility, and preventing extraskeletal calcification, most importantly vascular calcification.[4,7] Treatment is often initiated at stage 3 chronic kidney disease (GFR <60 mL/min/1.73 m$^2$) when positive phosphate balance and calcitriol deficiency appear. Dietary phosphate restriction is often difficult to achieve while maintaining adequate protein intake. Hence, intestinal phosphate binders are used. Aluminum-containing phosphate binders may cause aluminum bone disease and should be avoided. Sevelamer is a phosphate binder that does not contain calcium and has been shown to lower phosphate and control the skeletal lesions of HPTH without many of the adverse effects seen with other types of binders.

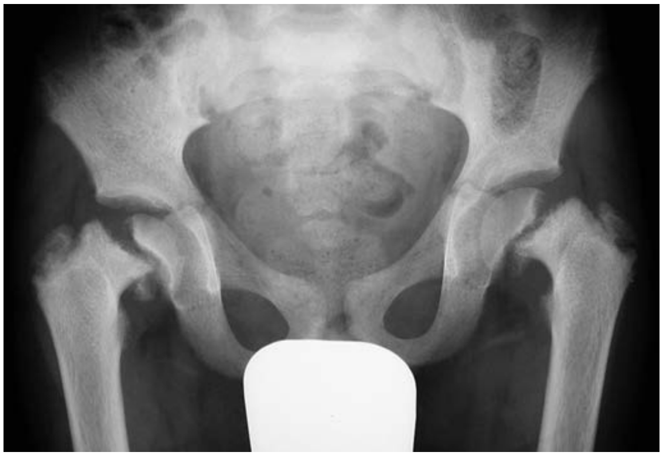
Vitamin D analogs are also important in control of secondary HPTH, as many patients are deficient. Additionally, active vitamin

## Abstract:

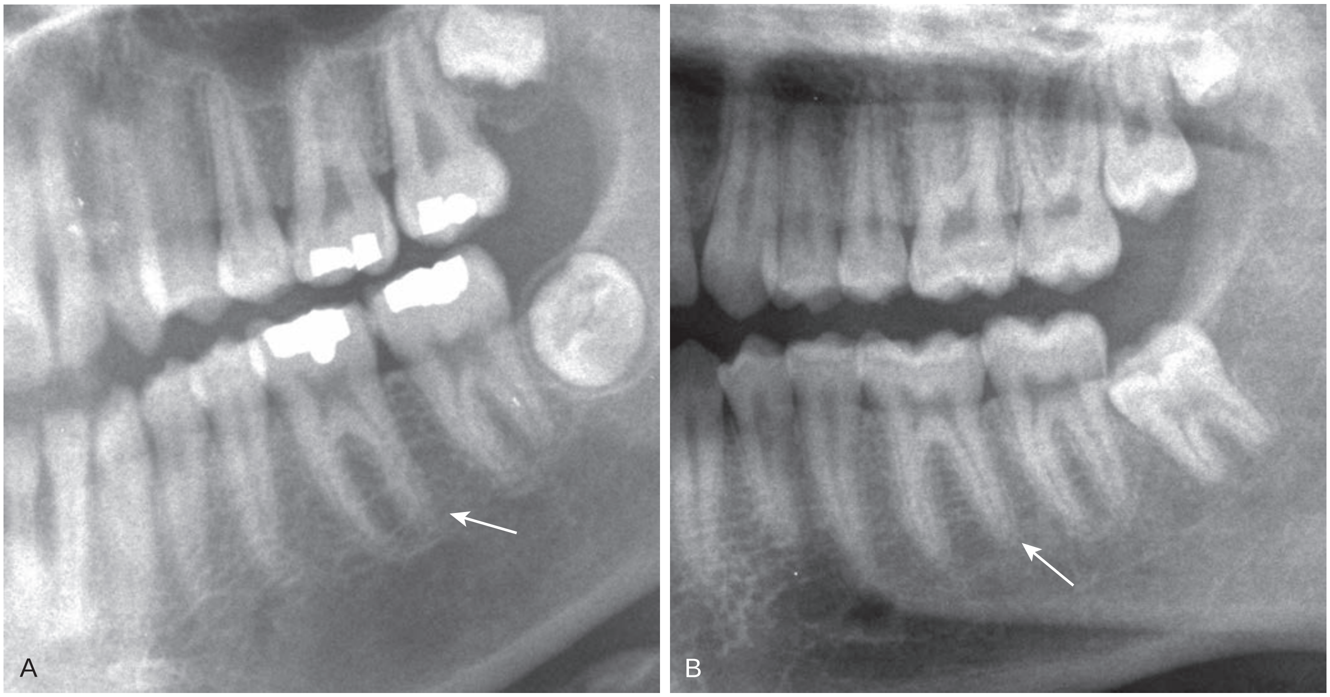
Many endocrine glands affect skeletal growth and maturation. An understanding of the effects of the various endocrine glands on bone development aids in correct radiographic interpretation. This chapter outlines their effects on the appearance of the skeleton in children. Emphasis is given to hyperparathyroidism (HPTH) and renal osteodystrophy.

## Keywords:

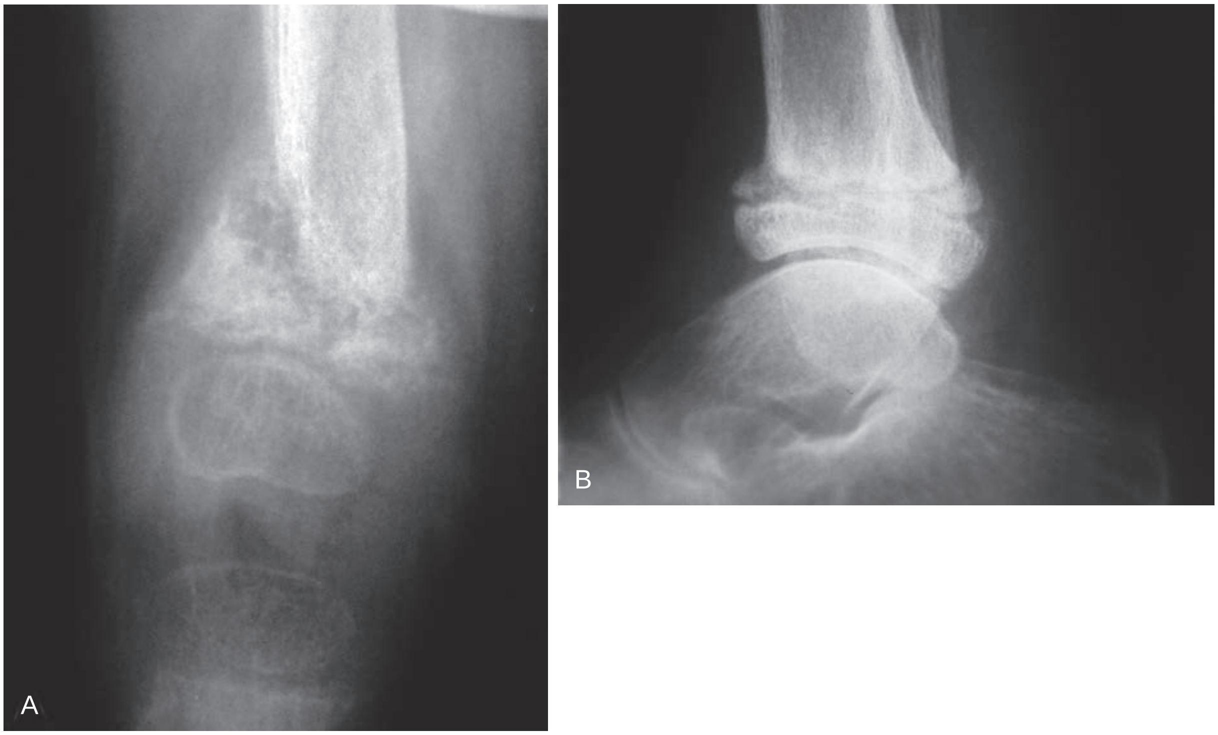
endocrine
hyperparathyroidism
hypoparathyroidism
renal osteodystrophy
hyperthyroidism
gonadal disorders



**e-Figure 140.4. Bilateral slipped capital femoral epiphyses in 11-year-old with renal osteodystrophy.** This finding was made at the time of presentation with previously undiagnosed end-stage renal failure.



**e-Figure 140.5. Loss of normal lamina dura in hyperparathyroidism.** (A) A 16-year-old girl with loss of normal lamina dura *(arrow)* and a history of hyperparathyroidism caused by chronic renal failure. (B) 16-year-old boy with an intact lamina dura *(arrow)* for comparison.



**e-Figure 140.7. Metaphyseal fractures in renal osteodystrophy.** (A) Distal femur in a 2.6-year-old child. (B) Distal tibial fracture in an 18-year-old.

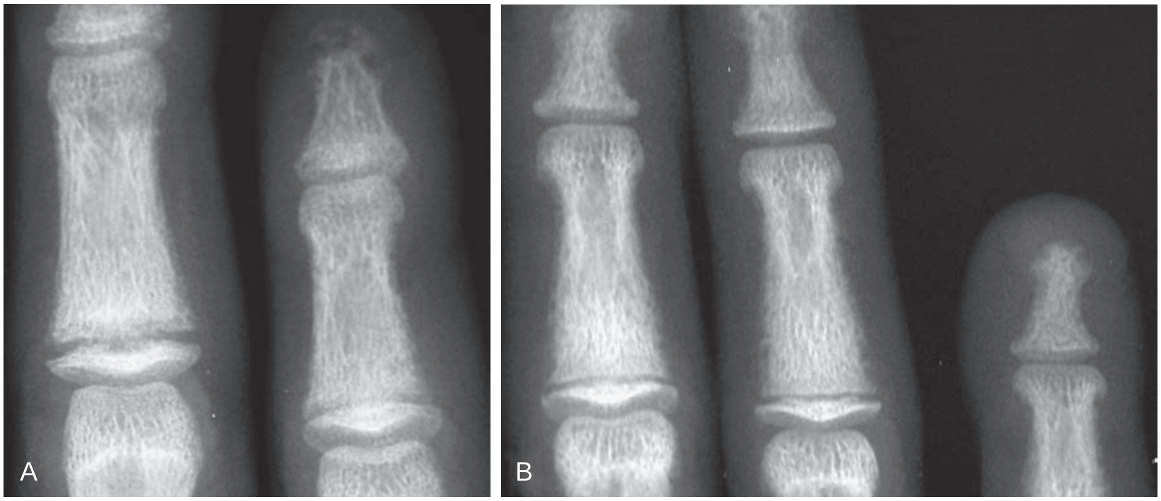


**Figure 140.1. Osseous findings of hyperparathyroidism in renal osteodystrophy.** Magnified frontal radiographs of the (A) left second and third digits and (B) right third to fifth digits show subperiosteal bone resorption involving the radial aspects of the middle phalanges. Areas of reabsorption of the distal tufts of the left second and right fifth fingers are also present.

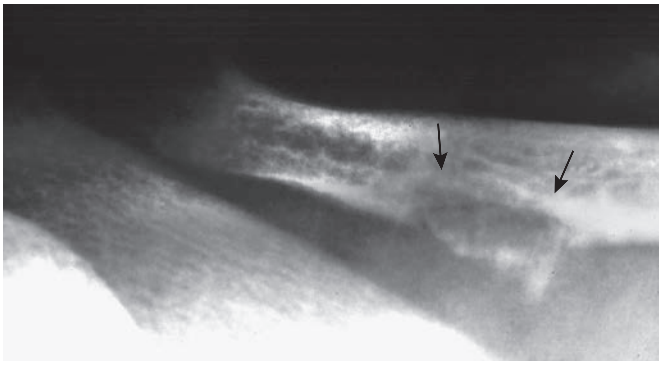

**Figure 140.2. Subligamentous resorption in secondary hyperparathyroidism.** Radiograph of the clavicle shows subligamentous resorption at the coracoclavicular ligament *(arrows)* in this child with secondary hyperparathyroidism of renal osteodystrophy.

D metabolites, most often calcitriol, act to lower PTH both indirectly by increasing intestinal calcium absorption and directly by inhibiting transcription for the gene encoding PTH. The use of calcitriol requires monitoring for hypercalcemia. Calcimimetics increase the sensitivity of the parathyroid calcium sensing receptor to calcium. This effectively lowers the level at which the circulating calcium concentration suppresses PTH synthesis and secretion, thereby lowering both calcium and PTH.

Despite medical therapy, parathyroidectomy may still be needed in some patients with renal osteodystrophy and severe HPTH. Postoperative hypocalcemia should be expected and managed accordingly.

## OTHER DISORDERS OF HYPERPARATHYROIDISM AND CAUSES OF BONE RESORPTION

### Neonatal Hyperparathyroidism

Primary HPTH in neonates is quite rare and is usually caused by hyperplasia rather than parathyroid adenoma.[8] Some cases of neonatal HPTH may result from homozygosity of the gene for familial hypocalciuric hypercalcemia, which usually causes asymptomatic hypercalcemia in adults.[9] Additional causes of HPTH in neonates include Jansen metaphyseal chondrodysplasia and I-cell disease. Although Williams syndrome may also cause neonatal hypercalcemia, PTH is not elevated.

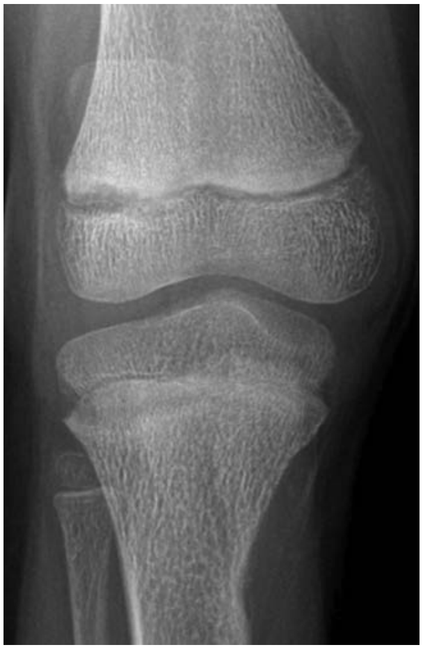

**Figure 140.3. Renal osteodystrophy in a 10-year-old boy.** Frontal radiograph of the knee shows irregularity and widening of the distal femoral and proximal tibial physes. When more diffuse, this appearance can mimic rickets. Also note subperiosteal resorption at the medial aspect of the proximal tibial metaphysis.

### Jansen Metaphyseal Chondrodysplasia

Jansen metaphyseal chondrodysplasia is an autosomal dominant condition with hypercalcemia and other findings suggestive of

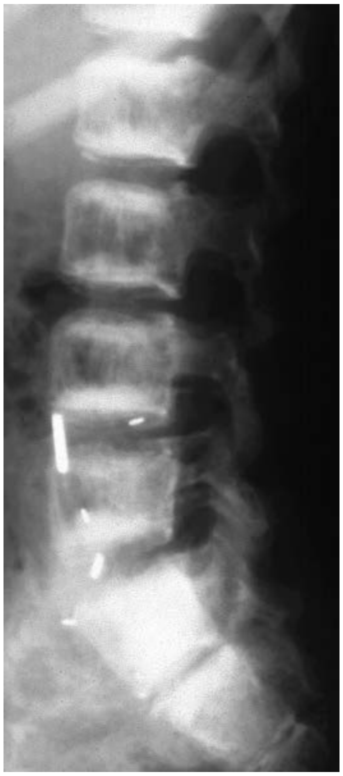

**Figure 140.6. Rugger jersey spine.** Lateral radiograph of the lumbar spine shows vertebral end plate sclerosis producing rugger jersey appearance.

severe HPTH during the neonatal period and short-limbed dwarfism later in life. It is caused by a mutation of the receptor for PTH and PTH-related peptide (PTHrP) that causes the receptor to be constantly activated.[10,11] Hence, even though no PTH nor PTHrP is detectable, PTH signaling is increased, producing effective HPTH with hypercalcemia and bone resorption, which are most prominent early in life (Fig. 140.8). Similarly, constitutive activation of the PTH/PTHrP receptor also leads to excessive PTHrP signaling, which inhibits endochondral ossification by preventing proliferating chondrocytes from entering hypertrophic differentiation.[12] This causes an ossification defect leading to buildup of a large amount nonossified cartilage and creating a lucent gap between the epiphysis and the ossified portion of the shaft (see Fig. 140.8). Subsequently, bizarre chondroid calcifications develop within these regions, which become widened and dysplastic. Eventually, the skeleton becomes fully ossified with residual shortening and deformity.

## Mucolipidosis II

Mucolipidosis II (I-cell disease) is an autosomal recessive storage disorder with radiographic features of dysostosis multiplex, similar to those of the mucopolysaccharidoses. Several additional radiographic findings have recently been shown to strongly suggest this diagnosis, including periosteal cloaking, talocalcaneal stippling, and sacrococcygeal or generalized vertebral body sclerosis and rounding.[13] In addition, some infants have skeletal features of HPTH, including generalized demineralization and subperiosteal bone resorption.[14] Although PTH is elevated, calcium is not, indicating that this is a form of secondary HPTH. It is speculated that placental involvement by this storage disorder impairs calcium transport leading to fetal and neonatal calcium deficiency causing secondary HPTH.

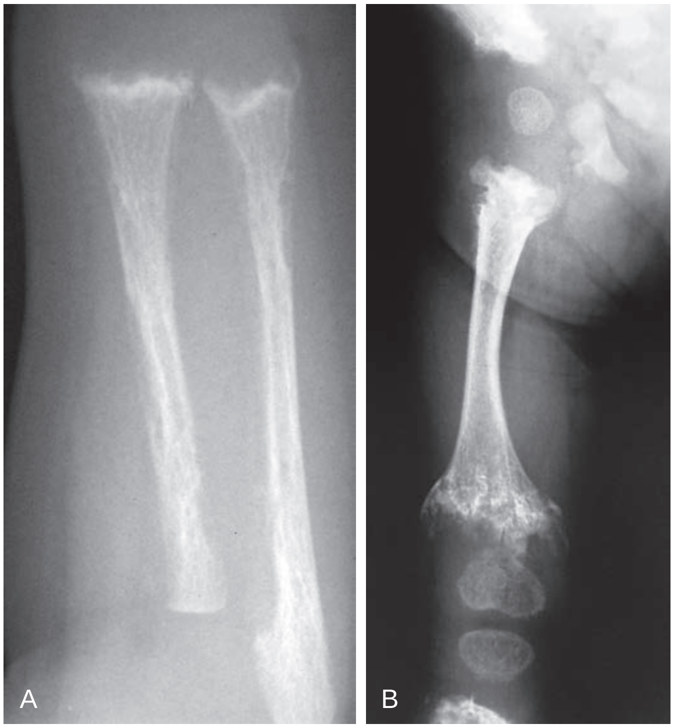

**Figure 140.8. Jansen metaphyseal chondrodysplasia, with manifestations of parathyroid hormone/parathyroid hormone–related peptide (PTH/PTHrP) receptor activation.** (A) At 5 days of age, forearm radiograph shows severe demineralization and subperiosteal resorption indicative of a hyperparathyroid state from increased PTH signaling. Also prominent are rachitic findings in the metaphyses. (B) Impaired endochondral ossification from excessive PTHrP signaling is demonstrated in the right femur at 15 months with a large lucent zone between the shaft and epiphyses, comprising nonossified cartilage. These lucent zones are beginning to fill in with disorganized chondroid calcifications, which are most apparent distally. This disorganized ossification leads to the marked metaphyseal dysplasia of this condition.

## Other Disorders of Bone Resorption

Abnormal bone resorption may also be seen in conditions other than HTPH. Decreased resorption, usually caused by a defect in osteoclastic acidification, leads to osteopetrosis. Increased resorption is seen in hyperphosphatasia and some endocrine disorders such as glucocorticoid excess. Hyperphosphatasia, also known as *juvenile Paget disease*, is a rare autosomal recessive condition with increased bone turnover caused by deficiency of osteoprotegerin, which normally suppresses bone turnover.[15,16] Hyperphosphatasia often presents at 2 to 3 years of age with short stature, bone fragility, and deformity, including long bone bowing, kyphoscoliosis, and pectus carinatum. Unlike adult Paget disease, which most often involves the axial skeleton, hyperphosphatasia is generalized. The radiographic features may be striking, with overall demineralization, coarse trabecular pattern, cortical thickening, widened cylindric long bones with decreased tubulation, and markedly variable bone texture with osteosclerosis intermixed with regions of cystic-appearing lucency (Fig. 140.9). Bowing and pathologic fractures are common. The skull shows thickening and regions of lucency combined with “cottonwool” sclerosis, similar to adult Paget disease. Familial expansile osteolysis is a related condition with deafness, loss of teeth, expansion of bones, painful phalanges, and episodic hypercalcemia caused by duplication of the gene for the osteoclast membrane-bound receptor that is activated by RANKL.[17]

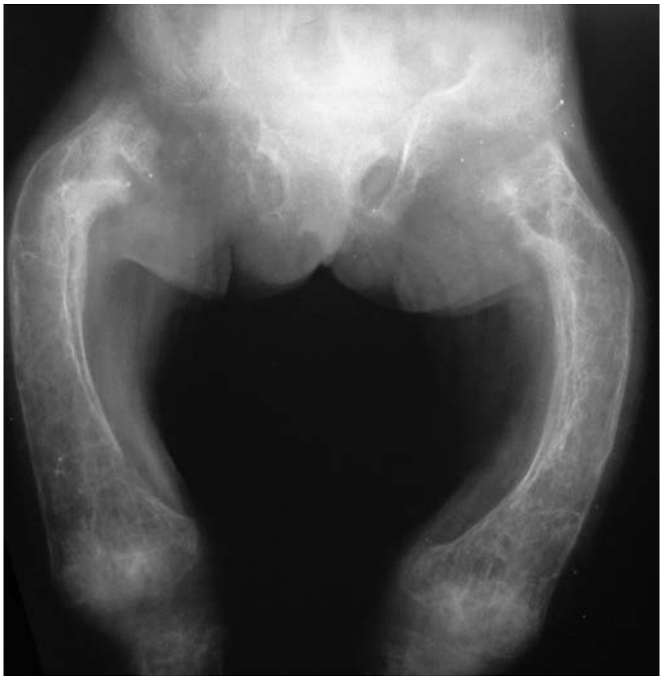

**Figure 140.9. Hyperphosphatasia.** Frontal radiograph shows that the diaphyses of both femurs are expanded and bowed. Demineralization is marked and has a highly heterogeneous pattern. The findings are symmetric and bilateral, unlike adult Paget disease, which is more commonly unilateral in the appendicular skeleton.

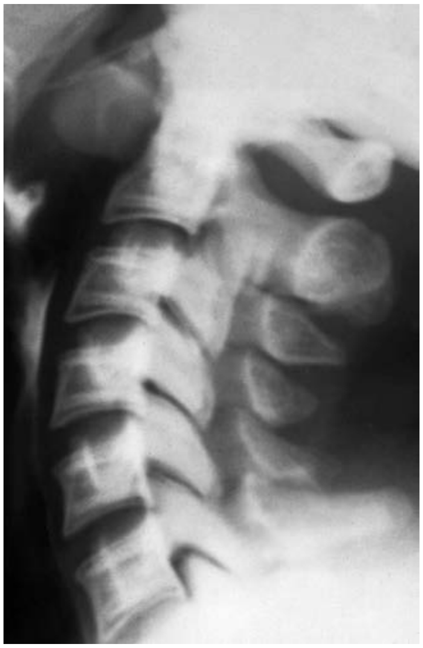

**Figure 140.10. Idiopathic hypoparathyroidism.** Lateral cervical spine radiograph shows bone-within-bone appearance and patchy osteosclerosis of cervical vertebrae.

## Hypoparathyroidism

***Etiology.*** Idiopathic hypoparathyroidism in children is most commonly part of polyglandular autoimmune disease type I.[18] This autosomal recessive condition targets multiple endocrine glands, most frequently the parathyroids and adrenals. Other causes of hypoparathyroidism in children include congenital absence of the parathyroids, which may accompany thymic absence in DiGeorge syndrome, surgical removal during thyroidectomy, and transient suppression of fetal parathyroids by maternal HPTH.[19]

***Imaging.*** Skeletal manifestations of hypoparathyroidism include osteosclerosis, dense metaphyseal bands, cranial vault thickening, intracranial calcifications, and dental abnormalities. Vertebral findings include marginal sclerosis, "bone within bone" appearance (Fig. 140.10), and paravertebral ossification.

## Pseudohypoparathyroidism

***Etiology.*** Pseudohypoparathyroidism is characterized by variable resistance to PTH and, less often, other hormones, as well as typical somatic features known as *Albright hereditary osteodystrophy (AHO)*.[18,20] The hormone resistance results from an inactivating mutation of the *GNAS1* gene. In pseudopseudohypoparathyroidism, the somatic features of AHO are seen without hormone resistance.

***Imaging.*** The somatic features of AHO include short stature, obesity, a round face, variable degrees of subnormal intelligence, subcutaneous calcification and ossification, small exostoses, and brachydactyly of the hands and feet (Fig. 140.11). The brachydactyly is often associated with premature growth plate closure that results from impaired PTHrP signaling leading to accelerated endochondral ossification. Brachydactyly E, Turner syndrome, and acrodysostosis are differential considerations. Resistance to PTH leads to manifestations of hypoparathyroidism including hypocalcemia and soft tissue and basal ganglia calcifications despite elevated PTH levels. Although hormone resistance often involves both kidney and bone, skeletal resistance is variable. With skeletal responsiveness to PTH, manifestations of HPTH such as subperiosteal bone resorption and brown tumors (Fig. 140.12) may be seen.[21,22]

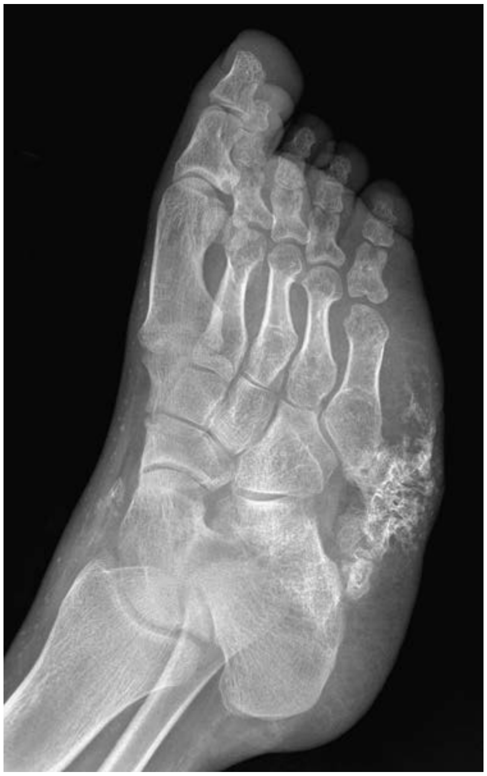

**Figure 140.11. Pseudohypoparathyroidism.** Foot radiograph in a 14-year-old shows extensive heterotopic ossification along the lateral aspect of foot. Also note brachydactyly involving some of the metatarsals.

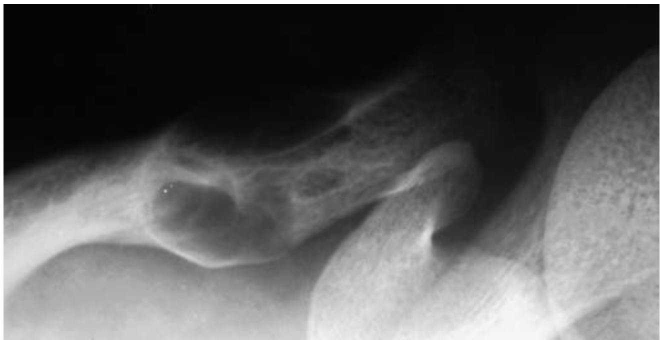

**Figure 140.12. Pseudohypoparathyroidism with skeletal responsiveness to parathyroid hormone leading to a brown tumor in the distal clavicle.** Other manifestations of hyperparathyroidism in this patient included subperiosteal bone resorption and bilateral slipped capital femoral epiphyses (not shown).

## NONPARATHYROID ENDOCRINE DISORDERS

Several other endocrine disorders have important skeletal effects. These primarily influence skeletal growth and maturation often by their effects on endochondral bone formation at the growth plates.

### Growth Hormone Disorders

***Etiology.*** GH is an important positive regulator of postnatal longitudinal growth, acting directly as well as indirectly through insulin-like growth factor (IGF) to stimulate proliferation of physeal chondrocytes.[23–25] Prenatal growth depends mostly on IGF, accounting for the relative preservation of prenatal growth in GH deficiency. In GH deficiency, skeletal growth and maturation are retarded to a similar degree, resulting in similar delays in height and bone age. The effects of GH excess are different in children than in adults. Before skeletal maturity, GH excess causes gigantism, while after skeletal maturity, it leads to acromegaly. The former is typically caused by an isolated pituitary adenoma, while the later may be caused by either a pituitary adenoma or hyperplasia. Approximately 20% of cases of GH excess are associated with McCune–Albright.

***Imaging.*** In GH deficiency, radiographs may show delayed bone age. Maturation of the carpal bones is often more delayed compared with the phalanges. Slipped capital femoral epiphysis (SCFE) may be seen with GH deficiency either before or after GH therapy. The retarded growth and maturation of GH deficiency may be mimicked by deprivational dwarfism ("psychosocial dwarfism"), although the presence of multiple growth restart lines favors deprivational dwarfism (e-Fig. 140.13).[26]

Gigantism, caused by GH excess before skeletal maturity, leads to increased linear skeletal growth. Radiographs in patients with GH excess after skeletal maturity can show increased periosteal bone formation, reactivation of endochondral bone formation at chondro-osseous junctions, and cartilage and soft tissue hypertrophy. These are the processes that lead to acromegaly, which is predominantly an adult disorder. Brain MRI is essential in these patients to evaluate for pituitary lesions.

### Hypothyroidism

***Etiology.*** Thyroid hormone (TH) is essential for normal brain development during the first 3 years of life, as well as for normal skeletal growth and maturation.[23,24,27–29] Although TH does not directly affect chondrocyte proliferation, the positive effects of GH and IGF on proliferation require the presence of TH. Additionally, TH has a major effect on skeletal maturation by inhibiting PTHrP signaling, which ordinarily regulates endochondral ossification. Hence increased PTHrP signaling in hypothyroidism causes abnormalities in endochondral ossification.

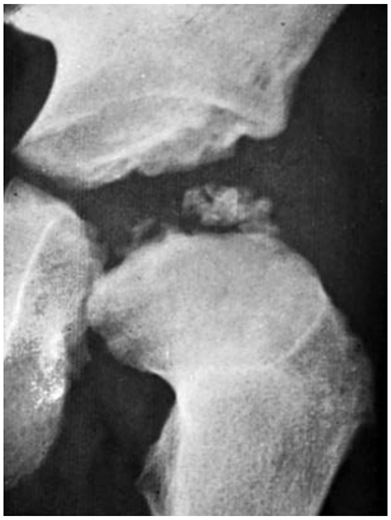

**Figure 140.14. Hypothyroidism and epiphyseal dysgenesis in a 9-year-old girl.** She had started treatment 1 year earlier. Frontal radiograph show a small and flattened femoral head that contains multiple small fragmented ossification centers. At the beginning of treatment 1 year earlier, no ossification of the femoral heads was seen. On follow-up, these ossification centers coalesced, but the femoral heads remained flattened. Similar finding were also present in several major epiphyses.

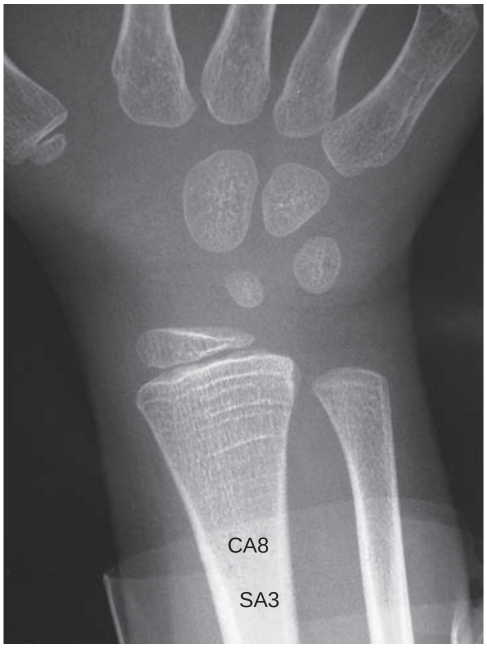
***Imaging.*** Skeletal maturation is delayed to a greater degree than linear growth. Impaired ossification not only delays the appearance of epiphyses but also leads to an abnormal pattern with multiple fragmented ossification centers, which is known as *epiphyseal dysgenesis*, which is particularly common in the hips. Although the fragments eventually coalesce, the epiphysis often has uneven density and irregular margins (Fig. 140.14). With treatment, the findings of epiphyseal dysgenesis resolve. SCFE may be a presenting manifestation of hypothyroidism, often bilateral and occurring at a younger age than idiopathic SCFE (see also Chapter 142).[30,31] In the skull, hypothyroidism may cause multiple wormian bones, enlargement of the sella turcica from pituitary hyperplasia, and brachycephaly from decreased growth at the spheno-occipital synchondrosis. Radiographs of hands may show small projections of bone extending from the distal phalangeal metaphyses into the growth plates (Fig. 140.15).[32]

### Hyperthyroidism

***Etiology.*** As discussed for hypothyroidism, TH inhibits PTHrP and hence promotes hypertrophic differentiation of proliferating chondrocytes leading to accelerated skeletal maturation. Hyperthyroidism in the pediatric age range is most frequent in adolescent girls. Hyperthyroidism may also occur as a manifestation of McCune–Albright syndrome, although precocious puberty is most common.

***Imaging.*** Skeletal maturation in hyperthyroidism may be normal or mildly advanced. Accelerated maturation may be seen in infants born to mothers with uncontrolled hyperthyroidism during the last trimester of pregnancy. Although hyperthyroidism is uncommon in infancy, acceleration of skeletal maturation is greatest in this group and may produce premature craniosynostosis.[33] Other skeletal manifestations of hyperthyroidism include calcification of costal cartilage and tracheal rings, diffuse osteopenia, and cortical striations, which are indicative of increased bone turnover. Due to osteoid overproduction, hyperthyroidism may mimic osteomalacia, including the presence of Looser transformation zones.



**e-Figure 140.13. Deprivational dwarfism.** Delayed skeletal maturation with a skeletal age of 3 years and chronologic age of 8 years. There are multiple growth restart lines in the distal radial metaphysis. Similar findings were also present in the distal femur (not shown). *(Courtesy Andrew K. Poznanski, MD, Chicago, IL.)*

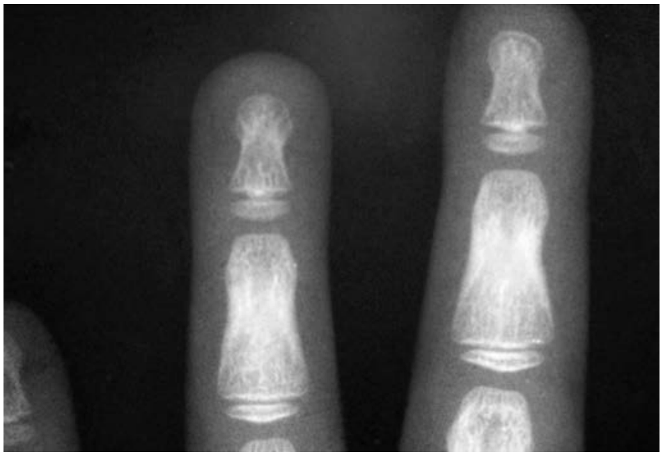


**Figure 140.15. Hypothyroidism in an 11-year-old boy.** Frontal radiograph of the fingers shows small spikelike projections of bone extend into the growth plates from the distal phalangeal metaphyses.

## Glucocorticoid Excess

***Etiology.*** Cushing syndrome refers to the systemic effects of glucocorticoid excess. Most cases of Cushing syndrome in children are iatrogenic and result from pharmacologic dosages of glucocorticoids used for treatment of chronic inflammatory or autoimmune disorders. Endogenous Cushing syndrome in children is uncommon and usually caused by primary adrenal lesions in those below 5 years of age and pituitary lesions in those above 5 years. Glucocorticoids decrease linear growth and maturation, acting at multiple levels to negatively regulate physeal chondrogenesis by decreasing GH secretion and downregulating GH and IGF receptors in physeal chondrocytes.[24]

Glucocorticoids also impair skeletal mineralization by negating the positive influence of sex steroids on mineralization, decreasing calcium absorption in the gut, and by acting directly to decrease bone formation and to increase osteoclastic resorption by increasing RANKL and decreasing osteoprotegerin expression.[34,35] Osteonecrosis is an additional complication of endogenous or exogenous glucocorticoid excess.

***Imaging.*** The skeletal findings of endogenous or exogenous corticosteroid excess are nonspecific and include generalized osteopenia with cortical thinning, trabecular rarefaction, and vertebral compression fractures. In addition, more specific findings include vertebral end plate sclerosis, abundant callus formation at fracture sites, and osteonecrosis. Excessive callus formation associated with compression fractures of vertebral bodies probably accounts for end plate sclerosis, which may be a clue in the diagnosis of Cushing syndrome in a patient with osteopenia (Fig. 140.16). Glucocorticoid induced osteonecrosis most frequently involves the femoral head, with the humeral head and femoral condyles next in frequency. Radiographic findings include subcortical fracture, bone collapse, fragmentation, and patchy osteosclerosis (see also Chapter 141).

## Adrenal Androgen Excess

***Etiology.*** Adrenogenital syndrome, the most frequent cause of excessive adrenal androgens excess, results from a biosynthetic defect in the production of cortisol with a compensatory increase in adrenocorticotropic hormone driving excessive production of adrenal androgens.[35] Excessive amounts of adrenal androgens may also be secreted by adrenal cortical neoplasms. Although they are weaker than testosterone, adrenal androgens promote virilization and accelerate skeletal maturation.

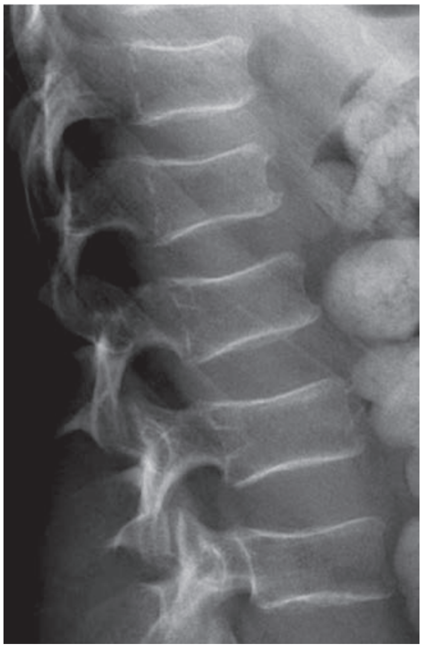

**Figure 140.16. Cushing disease in an 11-year-old boy with a pituitary adenoma and back pain.** Lateral radiograph shows generalized osteopenia with multiple age-indeterminate vertebral body compression fractures and end plate sclerosis, likely a combination of trabecular compression and callus.

***Imaging.*** Although growth is initially accelerated, this effect is less pronounced than is advancement of maturation. Hence, physeal closure occurs prematurely, and final height is decreased rather than increased. Advancement of skeletal maturation caused by excessive androgens is more pronounced than that caused by hyperthyroidism.

## Gonadal Disorders

***Etiology.*** The effects of sex steroids on physeal fusion and bone mineralization are currently believed to be caused by estrogen, with these processes mediated in males by estrogens formed from peripheral conversion of androgens.[36–38]

***Imaging.*** Increased production of androgens and estrogens by gonadal tumors may accelerate skeletal maturation, whereas gonadal insufficiency delays maturation.[24]

### KEY POINTS

- The most common cause of HPTH in children is chronic kidney disease, and the major manifestations of renal osteodystrophy are those of HPTH.
- In renal osteodystrophy, the lucent material adjacent to the growth plates is fibrous tissue of osteitis fibrosa cystica. This simulates the appearance of rickets but is weaker than osteoid, leading to slipped epiphyses.
- In GH deficiency, skeletal growth and maturation are proportionally decreased.
- TH promotes hypertrophic differentiation. Hence, in hypothyroidism, skeletal maturation is impaired to a greater degree than is growth.
- Cushing syndrome is suggested by the combination of osteopenia, vertebral body compression fractures, and vertebral end plate sclerosis.

# Skeletal Manifestations of Systemic Disease

Robert C. Orth and R. Paul Guillerman

## NORMAL BONE MARROW

### Overview

Bone marrow is one of the largest and most dynamic tissues in the body. Its functions include the production of red blood cells, white blood cells, and platelets for tissue oxygenation, cellular immunity, and blood coagulation, respectively. Bone marrow occupies approximately 85% of the medullary cavity and is supported by a network of trabecular bone.[1] In addition to hematopoietic elements, it contains stromal cells, collagen, nerves, and a variable amount of fat.

### Function and Composition

***Physiology.*** On gross examination, bone marrow may be red because of hemoglobin in the erythrocytes and their precursors, indicating active hematopoietic marrow, or it may be yellow due to the presence of carotenoid derivatives dissolved in fat droplets within adipocytes.[1] Hematopoietic marrow is rich in vascular sinusoids, whereas fatty marrow is considerably less vascular. During periods of decreased hematopoiesis, the fat cells increase in size and number. During periods of increased hematopoiesis, the fat cells atrophy.

The cellularity of bone marrow diminishes most rapidly in the first two decades of life. The cellularity of hematopoietic marrow is near 100% at birth and decreases to between 50% and 75% by 15 years of age. By adulthood, hematopoietic marrow is composed of approximately 40% fat, 40% water, and 20% protein, with 60% of cells being hematopoietic and 40% being adipocytes.[1] In contrast, fatty marrow is composed of 80% fat, 15% water, and 5% protein, with 95% of cells being adipocytes (e-Fig. 141.1).[1,2]

***Imaging.*** Conventional radiography, computed tomography, and ultrasonography are of limited value in the assessment of bone marrow.[3] Since the first reports of magnetic resonance imaging (MRI) of the marrow in children were published in 1984, MRI has emerged as the primary imaging modality to evaluate the bone marrow. It provides a noninvasive method for visualizing the gross anatomic structure of a large sample of the bone marrow and for inferring alterations in its chemical and cellular composition related to a variety of physiologic and pathologic processes. Furthermore, MRI can provide valuable information about regions of the bone marrow that may be inaccessible or difficult to biopsy.

The constituents of bone marrow that contribute to the signal characteristics on MRI are fat, water, and, to a lesser extent, mineralized matrix.[3] Fat is the dominant contributor to both hematopoietic and fatty marrow signal intensity patterns. Most fat protons are in hydrophobic methylene ($-CH_2-$) groups of relatively heavy molecular complexes, conferring very efficient spin-lattice relaxation; this results in a short T1 relaxation time, which results in high signal intensity on T1-weighted sequences.[1] The T2 relaxation time of fat is much shorter than that of free water protons, and water contributes much more to the signal intensity of hematopoietic marrow than fatty marrow.[1] The mineralized matrix of bone has a low density of hydrogen protons that lack mobility within the crystalline structure of bone, accounting for very long T1 and short T2 relaxation times and low signal intensity of mineralized matrix on T1- and T2-weighted sequences. In addition, local field gradients at the trabecular surface are generated by the fixed dipole from the immobile protons and cause magnetic field inhomogeneity. This magnetic susceptibility effect, as well as that resulting from iron deposition, can play a large role in the signal characteristics of hematopoietic and fatty marrow on gradient echo (GRE) images.[1]

The normal intervertebral disks, skeletal muscle, and subcutaneous fat have little interindividual and intraindividual signal intensity variation on T1-weighted sequences during childhood and consequently serve as convenient internal reference standards for comparison with bone marrow.[1,4] Fatty marrow has high signal intensity on conventional spin echo T1-weighted sequences. The relative amounts of fat, water, and protein contribute in a complex fashion to produce a longer T1 relaxation time in hematopoietic marrow, with signal intensity that ranges from intermediate to low (less than that of muscle or intervertebral disks) in fat-poor hematopoietic marrow to intermediate-high (greater than that of muscle or the intervertebral disks but less than that of subcutaneous fat) in hematopoietic marrow with larger proportions of fat.[1,5] In neonates, hematopoietic marrow contains minimal fat and has low signal intensity on T1-weighted sequences. With aging, hematopoietic marrow signal intensity progressively increases on T1-weighted sequences, reflecting a progressive increase in fat content. After the neonatal period, hematopoietic marrow has signal intensity equal to or slightly greater than muscle and the intervertebral disks but much less than subcutaneous fat on T1-weighted sequences, whereas fatty marrow approaches the signal intensity of subcutaneous fat on T1-weighted sequences.[5] Because of the similar proton densities of hematopoietic and fatty marrow, proton density sequences without fat suppression are less useful than T1-weighted sequences.[6]

On fat-suppressed fast spin echo (FSE) T2-weighted and short-tau inversion recovery (STIR) sequences, normal hematopoietic marrow in childhood shows higher signal intensity than fatty marrow and higher signal intensity than muscle; the signal intensity of hematopoietic marrow decreases with age and approaches that of muscle by adolescence.

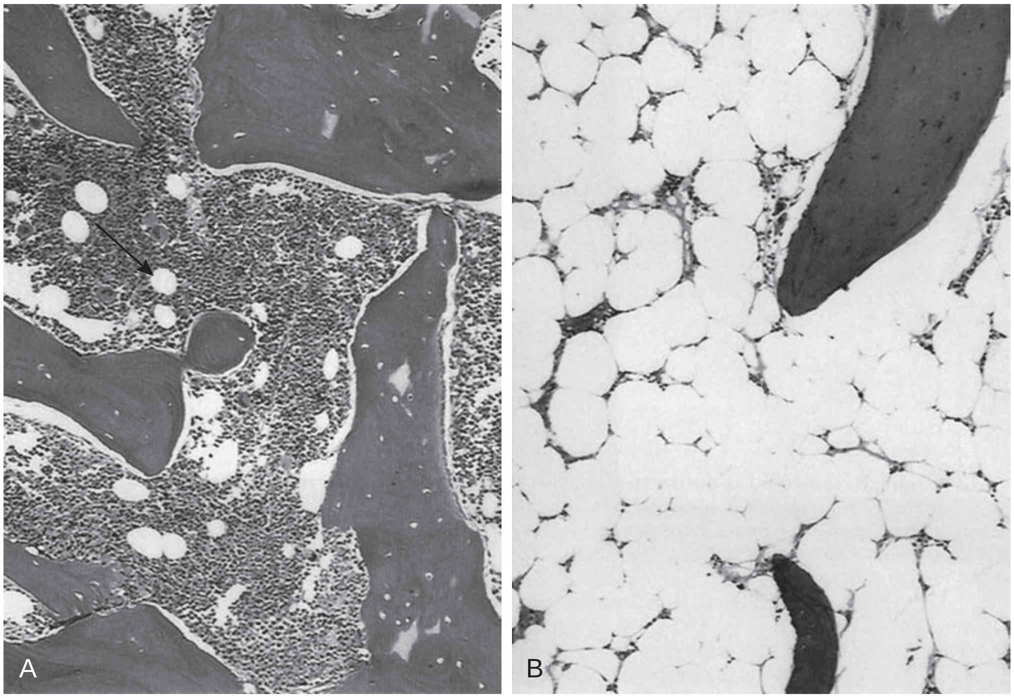
The degree of contrast enhancement of normal marrow varies with the contrast dose, timing of image acquisition following contrast administration, age of the patient, and composition of the marrow. Marrow enhancement peaks within a minute of contrast administration and then slowly declines.[7] Enhancement is greater in children than in adults, greater in the metaphyses than in the epiphyses, and greater in hematopoietic marrow than in fatty marrow. Enhancement can be imperceptible by visual inspection in the marrow of adults and in the marrow of the epiphyses in patients aged more than 2 years. The variation between individuals in the degree of enhancement is also substantial.[7] If gadolinium-enhanced T1-weighted sequences are acquired without fat suppression, contrast between hematopoietic and fatty marrow is decreased, which potentially obscures marrow lesions or age-related marrow conversion changes.[8] Image-subtraction and fat-suppression techniques facilitate the detection of abnormal marrow enhancement on postcontrast T1-weighted sequences.[6]

## Abstract:

In this chapter, normal attributes of bone marrow are discussed including function, composition, distribution, and conversion. Subsequently, skeletal manifestations of systemic diseases are reviewed with specific attention to those processes affecting marrow reconversion, hyperplasia, and infiltration. The etiology, pathophysiology, and clinical presentation of several forms of osteonecrosis are presented. Finally, the effects of several systematic and localized therapies on the pediatric skeleton are considered.

## Keywords:

bone marrow
thalassemia
sickle cell disease
leukemia
lymphoma
osteonecrosis



**e-Figure 141.1. Histologic sections of normal bone marrow (hematoxylin-eosin, ×75).** (A) Hematopoietic elements and bony trabeculae of hematopoietic marrow with few adipocytes *(arrow)*. (B) Fatty marrow contains numerous adipocytes. *(From Babyn PS, Ranson M, McCarville ME. Normal bone marrow: signal characteristics and fatty conversion.* Magn Reson Imaging Clin N Am. *1998;6:474.)*

A combination of T1-weighted and fat-suppressed FSE T2-weighted or STIR sequences is sufficient for the detection and characterization of most marrow lesions.[9] Contrast-enhanced T1-weighted sequences increase the cost and duration of the MRI examination while providing only modest incremental added sensitivity; because of this, they should be reserved for cases with unclear findings on the precontrast sequences. GRE sequences are valuable for the assessment of the iron content of the marrow, and chemical-shift techniques are useful to detect subtle changes in the fat and water fractions of the marrow.[10]

Practical time constraints initially limited MRI scanning of the marrow to only sections of the skeleton. This disadvantage has been mitigated by the development of fast, whole-body MRI scanning techniques that include FSE and single-shot sequences, parallel imaging, rolling table platforms with a large field of view, and global matrix coil concepts.[11–13] Obscuration of lesions by motion artifact may be overcome to some extent by the use of respiratory triggering or other motion-suppression techniques. The lower signal-to-noise ratios in smaller children on whole-body MRI exams can be ameliorated by using magnetic resonance (MR) systems with a higher field strength.[14]

Diffusion-weighted whole-body MRI holds particular promise as a technique to globally assess bone marrow for hematologic disorders and tumor metastases.[15–18] A positive correlation exists between the degree of marrow cellularity and the marrow apparent diffusion coefficient (ADC). Hematopoietic marrow or marrow infiltrated by neoplastic cells has more abundant microvasculature and more intracellular and interstitial free water than fatty marrow, and it exhibits higher ADC values.[19]

Motion and susceptibility artifacts are especially problematic in diffusion-weighting imaging (DWI) of the marrow, which is contained by bone and in proximity to physiologic motions, such as cerebrospinal fluid pulsations in the case of the spine.[17] Recent advances have largely overcome these technological challenges, and diffusion-weighted whole-body MRI is being used to evaluate an increasing number of benign and malignant conditions that include chronic recurrent multifocal osteomyelitis, Langerhans cell histiocytosis, and bony metastases.[20–22]

## Distribution and Conversion

***Physiology.*** Hematopoiesis occurs in the yolk sac in the early stages of fetal development; later in gestation it shifts to the liver and to a lesser extent the spleen. Bone marrow begins hematopoiesis in the fourth intrauterine month, overtakes the liver in this function by the sixth month, and is entirely responsible for hematopoietic cell production by birth.[23] Shortly before birth, conversion from hematopoietic to fatty marrow begins in the distal phalanges of the hands and feet and proceeds in a centripetal fashion from the distal to the more proximal portions of the appendicular skeleton.[4] Within the long bones, conversion from hematopoietic to fatty marrow proceeds from the mid diaphyses to the distal metaphyses and then to the proximal metaphyses. Conversion also progresses from the central medullary canal to the endosteum. Fatty transformation in the epiphyses and apophyses begins almost as soon as they begin to ossify. In infants, the skull and limbs contain about half of the total amount of hematopoietic marrow.[1,4] By early adulthood, hematopoietic marrow becomes confined to the vertebrae, sternum, ribs, pelvis, skull, proximal humeri, and proximal femurs. Approximately half of the bone marrow volume is fatty marrow in early adulthood and is located in the appendicular skeleton. The involution of hematopoietic marrow continues throughout adult life, although at a slower pace than during childhood.[1,4,24] Unlike skeletal maturation, there are generally no gender differences in the rate of marrow conversion during childhood.[2] Knowledge of the normal age-related changes in the distribution of hematopoietic and fatty marrow is necessary for the recognition of abnormal conversion and reconversion patterns and for the detection of marrow infiltration by other pathologic processes.

***Imaging.*** Conversion from hematopoietic to fatty marrow is readily detected by MRI because of the high sensitivity of T1-weighted spin echo sequences to fat (e-Table 141.1).[1] In fact, marrow conversion is observed earlier by MRI than by gross pathologic inspection because of the capability of MRI to detect microscopic fat present in marrow.[2,4,5,25] Numerous publications detail the temporal and spatial sequence of marrow conversion revealed by MRI. Although there are discrepancies among these publications in the precise ages of transformation, the sequence of conversion is consistent along the long axes of individual bones and in the skeleton as a whole. Conversion occurs at a faster pace in the appendicular skeleton (extremities, shoulders, and pelvic girdle) than in the axial skeleton (skull, spine, ribs, and sternum).[1,4]

### Appendicular Skeleton

Marrow conversion follows a similar pattern in both the upper and lower limbs. Within the long bones, conversion initially begins within the diaphysis before spreading to the metaphysis.[25] In general, low signal intensity on T1-weighted images marrow within the long-bone diaphyses is unusual after 10 years of age.[1,5] Long-bone metaphyseal marrow demonstrates high signal intensity on T1-weighted images by 15 to 25 years of age, except for low to intermediate signal intensity hematopoietic marrow that may persist through adulthood in the proximal femoral metaphyses, the metaphyses around the knee, and the proximal humerus, particularly in populations with increased hematopoiesis, such as smokers, endurance athletes, and obese women.[1,4,26]

Under normal circumstances, the epiphyseal ossification centers do not participate in hematopoiesis to any appreciable degree. Soon after the onset of epiphyseal ossification, the low signal intensity bony trabeculae and hematopoietic marrow begin to be replaced by high signal intensity fatty marrow, with near complete conversion within 6 to 8 months from the onset of ossification.[27] Fatty marrow appears earlier in the proximal humeral epiphysis, compared with the femur, because of the earlier onset of proximal humeral epiphyseal ossification.[1,28] The apophyses and sesamoid bones follow patterns similar to the epiphyses.

Fatty marrow conversion first occurs within the phalanges and is completed in the fingers and toes by 1 year of age.[4] Conversion in the femurs begins in infancy. Fatty marrow is seen in the femoral diaphyses as early as 3 months of age and is commonly observed by 12 months of age.[25] At 1 to 5 years of age, the diaphyseal fat signal becomes homogeneous, and the hematopoietic marrow in the distal femoral metaphyses becomes replaced by fatty marrow at 6 to 15 years of age (Fig. 141.2).[25] However, a mottled pattern of relatively low to intermediate signal intensity in the proximal femoral metaphyses may remain, related to persistent hematopoietic marrow and bony trabeculae extending from the inferolateral aspect of the femoral neck to the superomedial aspect of the femoral head.

Bone marrow conversion in the humerus follows a similar predictable pattern. Conversion to fatty marrow is complete in the proximal humeral epiphyses by 1 year of age, nearly complete in the diaphyses by 5 years of age, and nearly complete in the distal metaphyses by 10 years of age.[28] Conversion occurs less rapidly in the proximal humeral metaphyses but is nearly complete by 15 years of age. However, low to intermediate signal intensity hematopoietic marrow is retained in the proximal humeral metaphyses and subchondral medial aspects of the humeral heads into adulthood, particularly in women.[2,29] The acromion behaves like an epiphysis in regard to marrow distribution and conversion rate.[2]

Conversion of marrow in the forearm and leg bones may lag slightly behind the proximal arms and thighs. Conversion to fatty marrow begins in the diaphyses between 1 and 5 years of age and is complete in all portions of the forearm and leg bones by 10 to 15 years of age.[4] Marrow conversion ensues in the tarsal and carpal

**e-TABLE 141.1** T1-Weighted Signal Intensities Associated with Bone Marrow Conversion

| | Signal Intensity | | | | |

*Intensity of vertebral bodies compared with intervertebral disks. All other marrow sites compared with muscle (hypointense) and fat (hyperintense).

bones at 2 to 6 months of age and is complete by 6 years of age, with the possible exception of small foci of residual hematopoietic marrow that persists in the tarsal bones up to 15 years of age.[30]

In the first year after birth, hematopoietic marrow is present in the pelvis. Conversion to fatty marrow initially occurs in the anterior ilium and acetabulum, beginning as early as 2 years of age (Fig. 141.3). In the second decade of life, the remainder of the pelvic marrow increases to intermediate signal intensity. Except in infancy, heterogeneous signal intensity of the pelvic marrow is a normal finding and is most prominent in adolescents and adults in the acetabulum and anterior ilium because of macroscopic foci of both hematopoietic and fatty marrow.[31]

## Axial Skeleton

During the first month after birth, the vertebral marrow lacks fat and exhibits uniformly lower signal than the adjacent cartilaginous disks on T1-weighted sequences. Later in infancy, as the vertebral ossification center increases in size and the cartilaginous end plates decrease in prominence, the vertebral body marrow increases in signal intensity on T1-weighted sequences, particularly adjacent to the cartilaginous end plates.[4] Compared with the intervertebral disks and cartilaginous end plates, vertebral body marrow is usually hypointense on T1-weighted images up to the age of 1 year.[32] Vertebral body marrow is commonly isointense or hyperintense on T1-weighted images compared with the intervertebral disks from 1 to 5 years of age. After the age of 5 years, vertebral body marrow signal on T1-weighted images is typically greater than that of the intervertebral disks, and a band of fatty marrow may be conspicuous in the vertebral body centrally or along the basivertebral venous plexus (Fig. 141.4).[4,32] The spine continues as a site of hematopoietic marrow throughout life, although the proportion of fatty marrow gradually rises approximately 7% per decade.

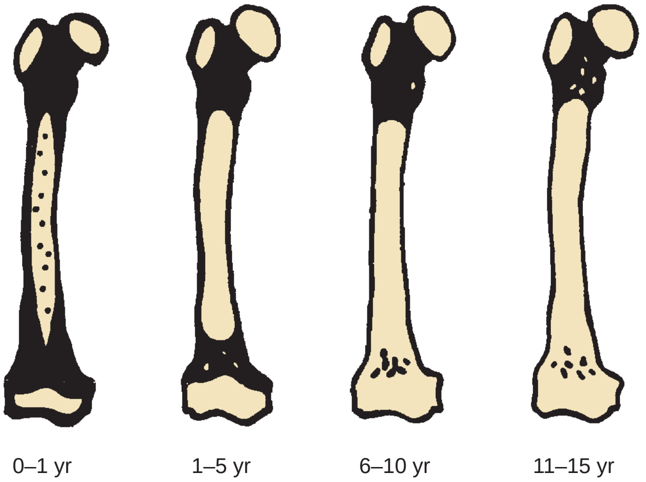

**Figure 141.2. Diagrammatic representation of changes in magnetic resonance imaging appearance of the femoral marrow with increasing age.** *Black areas* represent hematopoietic marrow, *yellow areas* represent fatty marrow, and *stippled areas* indicate heterogeneous hematopoietic and fatty marrow. *(From Waitches G, Zawin JK, Poznanski AK. Sequence and rate of bone marrow conversion in the femora of children as seen on MR imaging: are accepted standards accurate?* AJR Am J Roentgenol. *1994;162:1401.)*

The skull is where the bone marrow is most frequently imaged by MRI in childhood, typically incidentally in studies obtained to evaluate the brain.[33] The skull contains 25% of the active hematopoietic marrow at birth, and conversion to fatty marrow begins by 2 years of age within the facial bones and skull base before proceeding to the calvarium.[4] Marrow at the site of the future paranasal sinuses becomes fatty before pneumatization.[33] By 3 to 4 years of age, foci of high signal intensity on T1-weighted sequences are seen in the clivus, and complete conversion is typical by 15 years of age. In the calvarium, conversion begins earlier in the frontal and occipital bones than in the parietal bones.[24] Conversion in the calvarium should be obvious by 7 years of age, and it is complete in the great majority by 15 years of age.[4] The conversion to fatty marrow in the calvarium may occur more slowly in females, an exception to the rule of no gender differences.[3]

Marrow conversion in the sternum precedes that in the ribs. Development of foci of intermediate to high signal intensity on T1-weighted sequences occurs in the sternum after 5 years of age and in the ribs by 10 years of age.[4] The sternum and, to a lesser extent, the ribs remain hematopoietic into adulthood.

Detection of primary or systemic pathology that affects the marrow is usually easier in fatty marrow than in hematopoietic marrow.[34] This includes processes associated with hematopoietic hypercellularity (hemolytic anemia, hematopoietic growth factor treatment, leukemoid reaction, glycogen storage disease type 1b [GSD1b], myelodysplastic syndrome, leukemia), marrow infiltration (metastatic tumor cells, inflammatory cells, Gaucher cells), iron overload, and myelofibrosis.[7] Some of these processes are also associated with an increase in free water in the marrow and manifest as signal intensity higher than that of normal hematopoietic or fatty marrow on fat-suppressed FSE T2-weighted or STIR sequences.

Features that favor normal hematopoietic marrow include signal intensity equal to or only slightly higher than that of muscle on

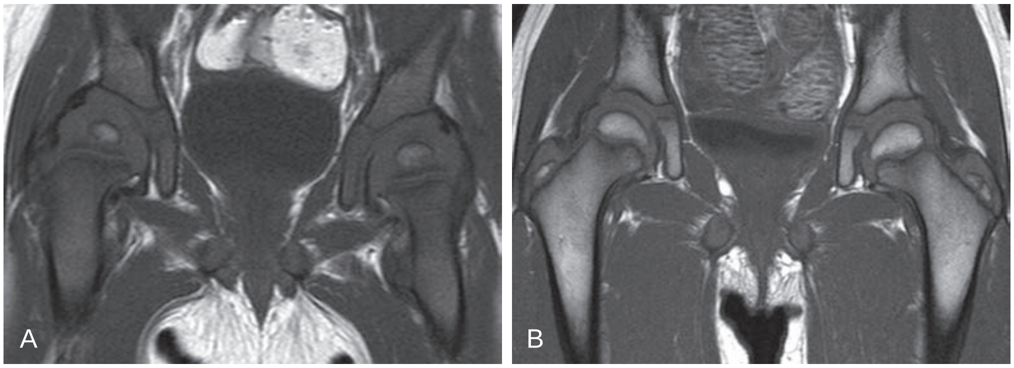

**Figure 141.3. Normal marrow changes.** (A) Coronal T1-weighted magnetic resonance (MR) image of the pelvis in an 11-month-old boy shows normal low signal intensity hematopoietic marrow is present in the pelvis and proximal femurs. (B) In a 3-year-old girl, normal conversion to fatty marrow has occurred by this age, manifested by increased signal intensity throughout the pelvis and proximal femurs.

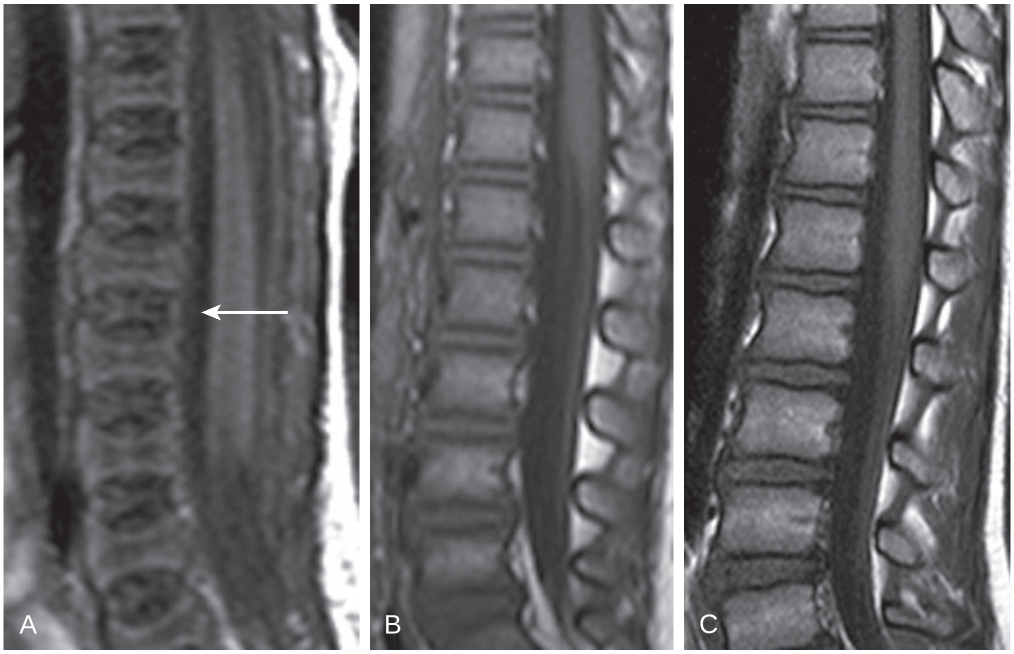

**Figure 141.4. Changes in signal intensity of vertebral body marrow with age.** Sagittal T1-weighted magnetic resonance images of the lumbar spine show (A) in a 2-day-old infant girl, the paucity of marrow fat accounts for the low signal intensity of the marrow of the vertebral body *(arrow)* relative to the that of the adjacent intervertebral disks. (B) In a 2-year-old girl, vertebral body marrow is hyperintense compared with that of the intervertebral disks. (C) In a 7-year-old girl, marrow signal intensity is greater than the signal intensity of the intervertebral disks, and there is a central band of more fatty, higher signal intensity marrow in the vertebral bodies.

fat-suppressed FSE T2-weighted or STIR sequences, dropout of signal intensity on opposed-phase GRE sequences, a "flame" or "paintbrush" shape (Fig. 141.5), no underlying trabecular disruption, symmetry with the contralateral side, and no associated abnormalities of the cortical bone or extraosseous soft tissues. Residual red marrow may sometimes have a globular appearance on T1-weighted sequences, and this is a normal finding (Fig. 141.6). However, a low-grade infiltrative or edematous process of the marrow can be difficult or impossible to distinguish from hematopoietic marrow on MRI, particularly when the hematopoietic marrow is relatively hypercellular, such as in very young children and in states of marrow reconversion in patients on granulocyte colony-stimulating factor (G-CSF) therapy (Fig. 141.7). Normal red marrow should never have a round, well-circumscribed configuration, which typically indicates a neoplastic process (Fig. 141.8).[35]

Processes in which the proportion of fat is increased relative to other components of the bone marrow appear as a focal or diffuse increase in the bone marrow signal intensity on T1-weighted sequences. This occurs physiologically during aging with the conversion from active hematopoietic marrow to hematopoietically quiescent fatty marrow. A pathologic example is the hematopoietic cell depletion associated with aplastic anemia. Some processes are associated with varying degrees of marrow cellularity and fat content, and their MRI appearances vary correspondingly. These include the myelodysplastic syndromes and the responses of marrow to chemotherapy, radiation therapy, and hematopoietic cell transplantation.

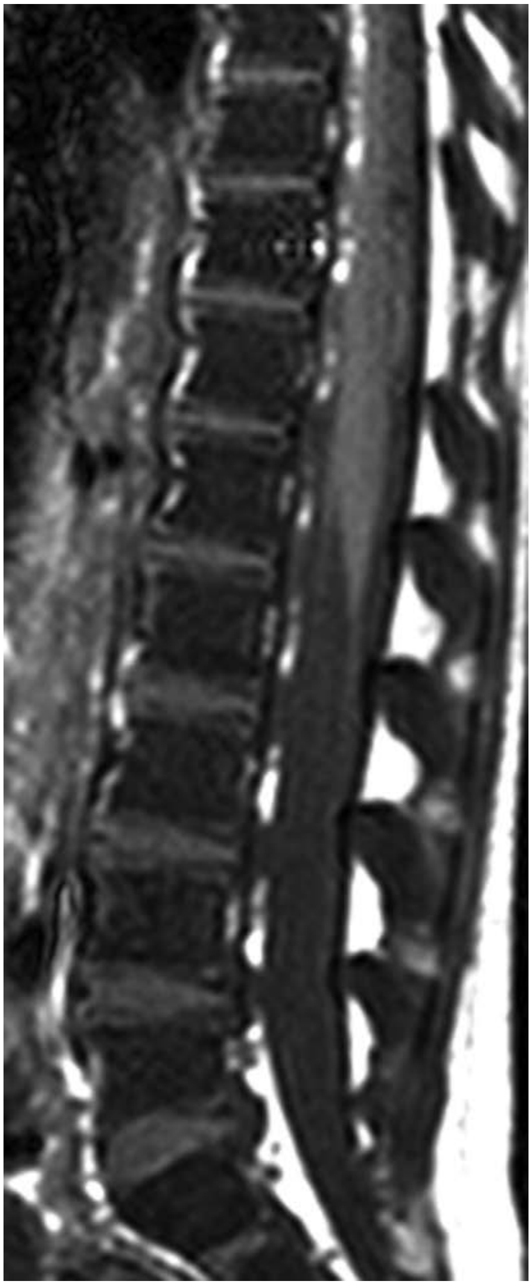
## MARROW HYPERPLASIA AND RECONVERSION

***Overview.*** Reconversion is a process by which established fatty marrow is replaced by hyperplastic hematopoietic marrow in response to conditions that create a demand for increased hematopoiesis. In children, reconversion is commonly encountered in patients with chronic anemia—such as from sickle cell disease, thalassemia, and spherocytosis—and in those administered hematopoietic growth factors, such as G-CSF, granulocyte-macrophage colony-stimulating factor (GM-CSF), and erythropoietin.

***Etiology, Pathophysiology, and Clinical Presentation.*** The stimulus for increased oxygen-carrying capacity of the blood in cyanotic congenital heart disease patients, endurance athletes, heavy smokers, and high-altitude dwellers also induces hematopoietic marrow hyperplasia and reconversion. Because marrow conversion is a process that occurs throughout childhood, some of what is construed as reconversion in children actually represents an arrest or delay in conversion from hematopoietic to fatty marrow and is attributable to increased hematopoietic demands (e-Fig. 141.9).[4]

Reconversion occurs in the reverse order of normal marrow conversion, beginning in the axial skeleton and proceeding sequentially to the proximal metaphyses, distal metaphyses, and diaphyses of the long bones of the appendicular skeleton.[4,6] The more distal long bones are the last to undergo this process. The epiphyses are usually spared but can undergo reconversion in response to very high hematopoietic demands.

***Imaging.*** On MRI, reconverted marrow follows the signal intensity of hematopoietic marrow and tends to involve the appendicular skeleton in a symmetric fashion.[1,4] The reconverted hematopoietic marrow may be distributed in either a homogeneous or patchy pattern and may have an appearance overlapping with that of pathologic processes, such as leukemia and storage disorders. Although MRI is very sensitive to changes in marrow fat content, disease specificity is low. Also, some of the conditions that exhibit marrow reconversion have additional superimposed marrow processes that complicate MRI interpretation, such as transfusion hemosiderosis in thalassemia and marrow infarction and fibrosis in sickle cell disease. Positron-emission tomography (PET) with 18-fluorodeoxyglucose (FDG) is also sensitive to marrow conversion and may reveal increased FDG uptake in areas of marrow hyperplasia because of the metabolic demands of increased hematopoiesis.[36]



**e-Figure 141.9. Homozygous sickle cell disease in a 5-year-old girl.** Sagittal T1-weighted magnetic resonance image of the lumbar spine shows that the marrow signal intensity is lower than the adjacent intervertebral disks because of the hematopoietic marrow hyperplasia associated with chronic hemolytic anemia.

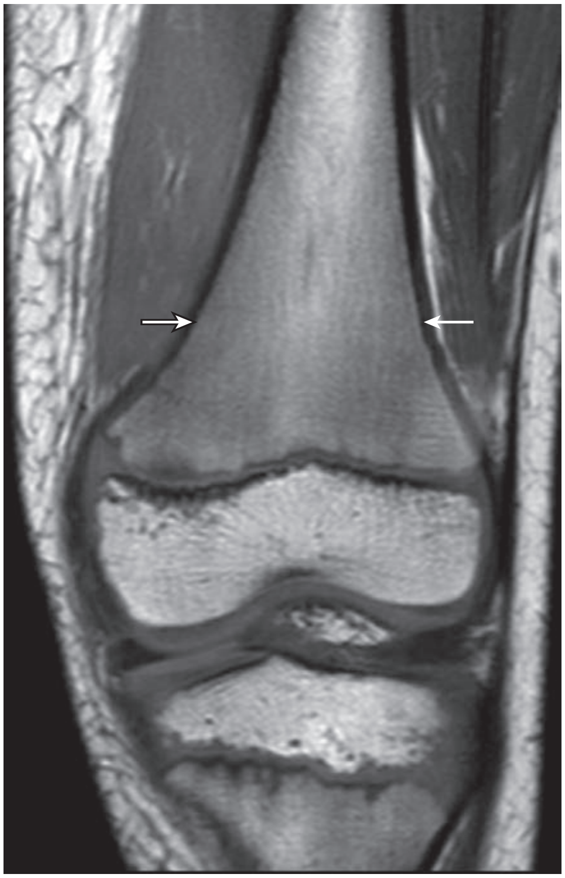


**Figure 141.5. Normal marrow in an 8-year-old boy.** T1-weighted coronal MR image demonstrates paintbrush-like pattern of hypointensity *(arrows)* in the femoral metaphysis without underlying trabecular disruption, consistent with normal residual red marrow.

## Thalassemia

***Etiology, Pathophysiology, and Clinical Presentation.*** Thalassemia is an inherited hemoglobinopathy characterized by ineffective erythropoiesis, intramedullary hemolysis, and anemia. With effective transfusion therapy, hematopoietic to fatty marrow conversion may proceed in the extremities by puberty. However, hematopoietic marrow hyperplasia in the skull, spine, and pelvis can remain pronounced. The paranasal sinuses often fail to develop, in part as a result of abrogation of the normal fatty conversion of marrow that precedes sinus pneumatization.[33]

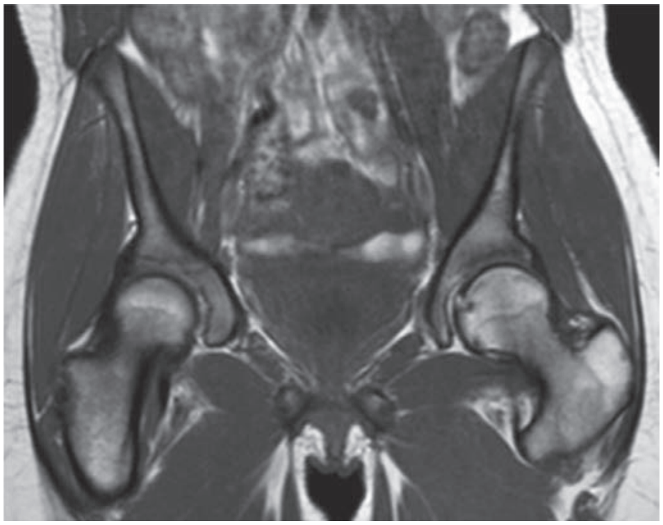

**Figure 141.6. Normal marrow in a 15-year-old girl.** T1-weighted coronal MR image demonstrates globular areas of decreased signal throughout the proximal femurs and pelvic bones, consistent with normal, residual hematopoietic marrow.

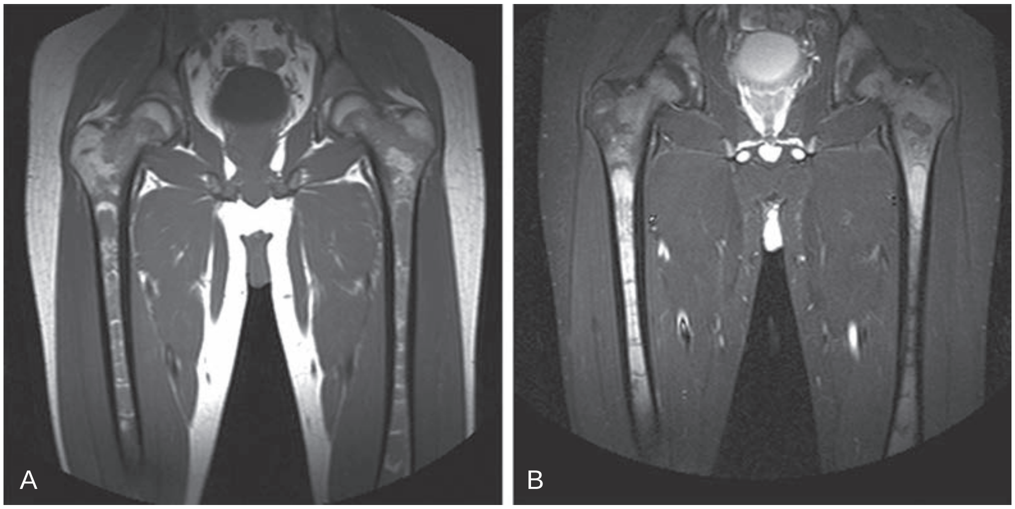

**Figure 141.7. A 17-year-old boy on granulocyte colony-stimulating factor (G-CSF) therapy for myelosuppression related to chemotherapy for Hodgkin disease.** Coronal T1-weighted MR image (A) and coronal short-tau inversion recovery (STIR) MR image of the thighs (B) show masslike, patchy, bilateral foci of marrow replacement with low signal intensity on T1-weighted images and high signal intensity on STIR images representing regenerating granulopoietic marrow in response to G-CSF stimulation. Clinical correlation with the timing of therapy is necessary to distinguish these findings from neoplastic involvement of the marrow.

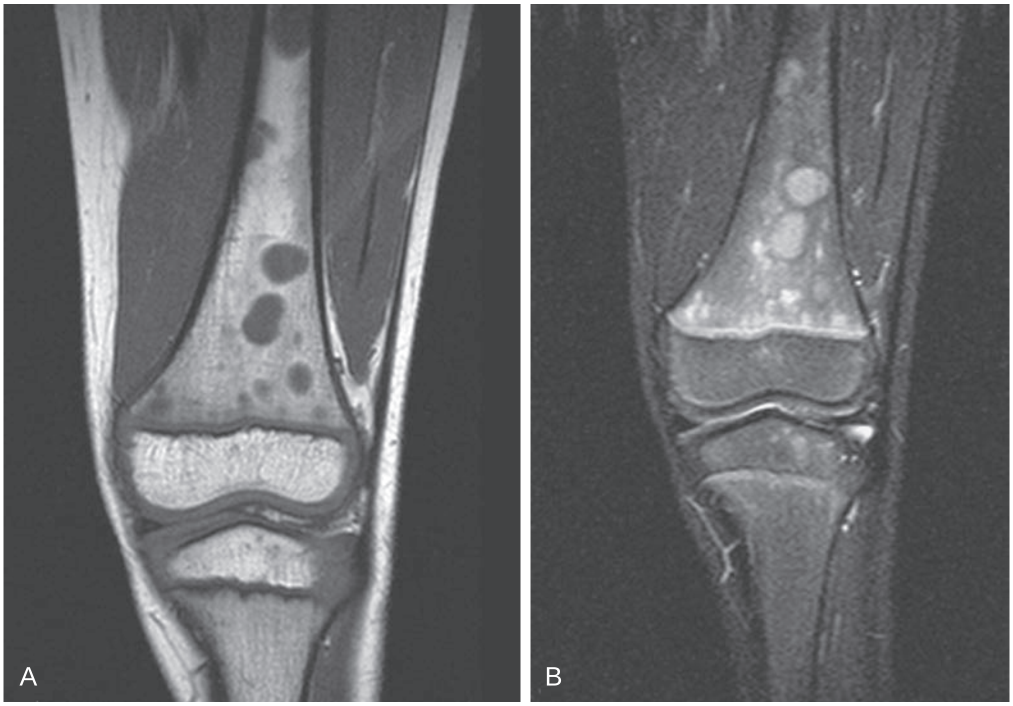

**Figure 141.8. Burkitt lymphoma and knee pain in a 6-year-old boy.** (A) Coronal T1-weighted and (B) short-tau inversion recovery (STIR) MR images of the left knee. Multiple round, sharply defined hypointense masses identified on the T1-weighted image are hyperintense on the STIR image because of marrow involvement by Burkitt lymphoma.

Thalassemia patients are at increased risk of pathologic fractures from osteopenia, arthralgias that are believed to result from iron overload or the use of chelation therapy, and back pain from scoliosis and early intervertebral disk degeneration.[37]

***Imaging.*** The radiographic changes of thalassemia are due to chronic hematopoietic marrow hyperplasia. These include diffuse osteopenia, undertubulization of bone, premature physeal fusion, "hair-on-end" appearance of the calvarium with widening of the diploic space (Fig. 141.10), decreased pneumatization of the paranasal sinuses, coarse trabeculation of appendicular bones, expansion of costochondral junctions, scoliosis, and soft tissue masses related to extramedullary hematopoiesis.[38]

The appearance of the bone marrow on MRI is a reflection of the diffuse erythroid marrow hyperplasia, chronic transfusions, and iron chelation therapy.[4] Iron deposition in the marrow results in lowered signal intensity on T1-, T2-, and especially T2*-weighted sequences because of T2 relaxation-time shortening and magnetic susceptibility effects.[39] Excess iron deposition can even be identified by MRI in some patients whose chelation is thought to be clinically adequate on the basis of serum ferritin levels, and the degree of iron deposition in bone marrow and other organs can be quantified by R2 relaxometry with MRI.[40] In severe cases of thalassemia, bone marrow transplantation may be pursued as a potentially curative treatment, and MRI can reveal the consequent degree of marrow conversion. FDG-PET in patients with thalassemia shows diffuse increased marrow uptake.[41]

***Treatment.*** Transfusion therapy suppresses the marrow hyperplasia of thalassemia but at the cost of iron overload. The iron deposition occurs preferentially in areas of hematopoietic marrow and is reduced by chelation therapy.[39]

## Sickle Cell Disease

***Etiology, Pathophysiology, and Clinical Presentation.*** Sickle cell disease is an inherited hemoglobinopathy characterized by deformation of red blood cells and resultant hemolytic anemia and intravascular sludging of blood. The bone marrow imaging manifestations of sickle cell disease are primarily related to hematopoietic marrow hyperplasia, osteonecrosis, and perivascular fibrosis.[42] Because the circulation normally passes centrifugally from the medullary cavity to the cortex, sludging of blood flow in the nutrient artery branches places increased demands on the radially arranged periosteal-cortical system of anastomosing blood

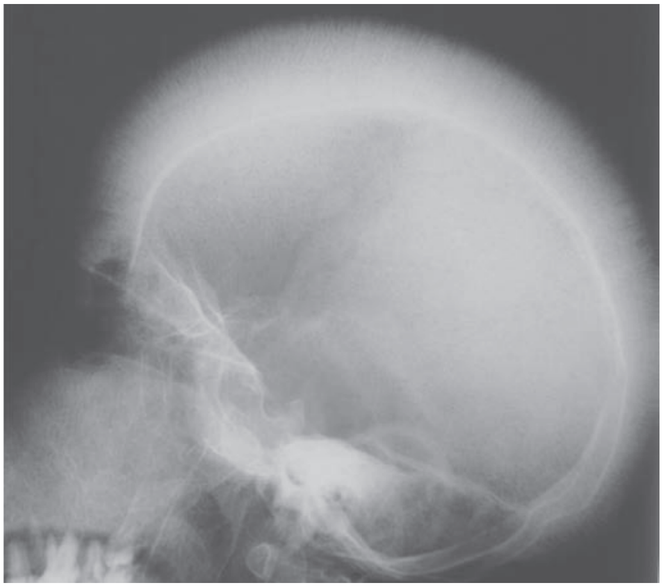

**Figure 141.10. Thalassemia.** Lateral radiograph of the skull shows diffuse "hair-on-end" appearance of the calvarium. *(Courtesy Edward Singleton, MD.)*

vessels to supply the marrow, particularly in the peripheral subcortical medullary cavity.[42,43] This, coupled with the increased oxygen needs from increased hematopoietic activity, accounts for the vulnerability of the bone marrow to osteonecrosis.

***Imaging.*** Osseous abnormalities in sickle cell disease are secondary to osteonecrosis and, less often, osteomyelitis. Radiographic findings are similar to osteonecrosis from other causes, with geographic and patchy areas of sclerosis (Fig. 141.11) that most commonly involve the femoral heads. Other common radiographic abnormalities include dactylitis (e-Fig. 141.12), H-shaped or "Lincoln log" vertebral bodies from central growth plate osteonecrosis (Fig. 141.13), diffuse osteosclerosis, and widespread periostitis.[44]

Findings on MRI include bone marrow changes that reflect red marrow reconversion secondary to chronic anemia, with decreased signal intensity on T1-weighted sequences and increased signal intensity on fat-suppressed T2-weighted and STIR sequences. Marrow changes secondary to osteonecrosis are more complex and often reflect a combination of acute and chronic processes. Foci of low, serpentine signal intensity on T1-weighted sequences and abnormal high signal intensity on fat-saturated T2-weighted or STIR sequences are classic imaging features of osteonecrosis. Chronic osteonecrosis may be suggested when these findings are confined to the marrow itself with absent joint effusions or juxtacortical soft tissue edema (Fig. 141.14). Acute osteonecrosis may be suggested when there is also infiltrative marrow edema, periostitis, and/or juxtacortical soft tissue edema (Fig. 141.15).

Acute osteomyelitis may be difficult to differentiate by MRI from the more common acute osteonecrosis and vasoocclusive crisis (see Fig. 141.15). Ultimately, aspiration and biopsy may be necessary to distinguish these entities, because both can manifest with marrow signal intensity abnormalities, periosteal reaction, and intraosseous, subperiosteal, or extraosseous soft tissue fluid collections. Gadolinium-enhanced MRI can distinguish vascularized inflammatory tissue from fluid collections and can guide fluid aspiration.[45] Some evidence suggests the ability of unenhanced T1-weighted fat-saturated images to differentiate acute osteonecrosis from acute osteomyelitis based on the T1 shortening effects of sequestered red blood cell aggregates in the marrow. However, adequately powered studies have not been undertaken and published studies to date present conflicting results.[46,47]

***Treatment.*** The two most common acute musculoskeletal manifestations of sickle cell disease are vasoocclusive crisis followed by infection. Osteonecrosis is the most frequent presentation of vasoocclusive crisis and is treated with supportive care and pain management.[48] Infections include osteomyelitis, with or without associated subperiosteal abscesses, and less commonly septic arthritis. Unlike the general pediatric population with musculoskeletal infections, *Salmonella* is most commonly identified by culture, followed by *Staphylococcus aureus*.[44]

## Glycogen Storage Disease Type 1b

***Etiology, Pathophysiology, and Clinical Presentation.*** The musculoskeletal manifestations of GSD1b are related to a defect in myeloid maturation that leads to bone marrow hypercellularity

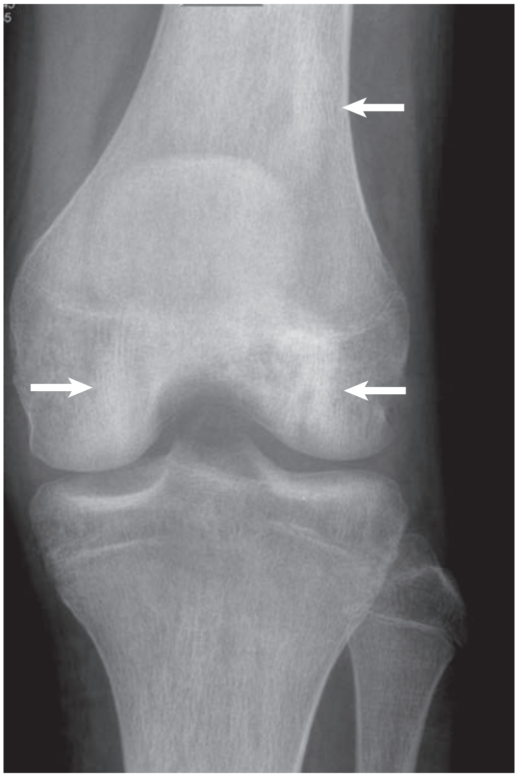

**Figure 141.11. Sickle cell disease in a 17-year-old boy.** Anteroposterior radiograph of the knee demonstrates multiple areas of sclerosis in the condyles and femoral shaft consistent with areas of osteonecrosis *(arrows)*.

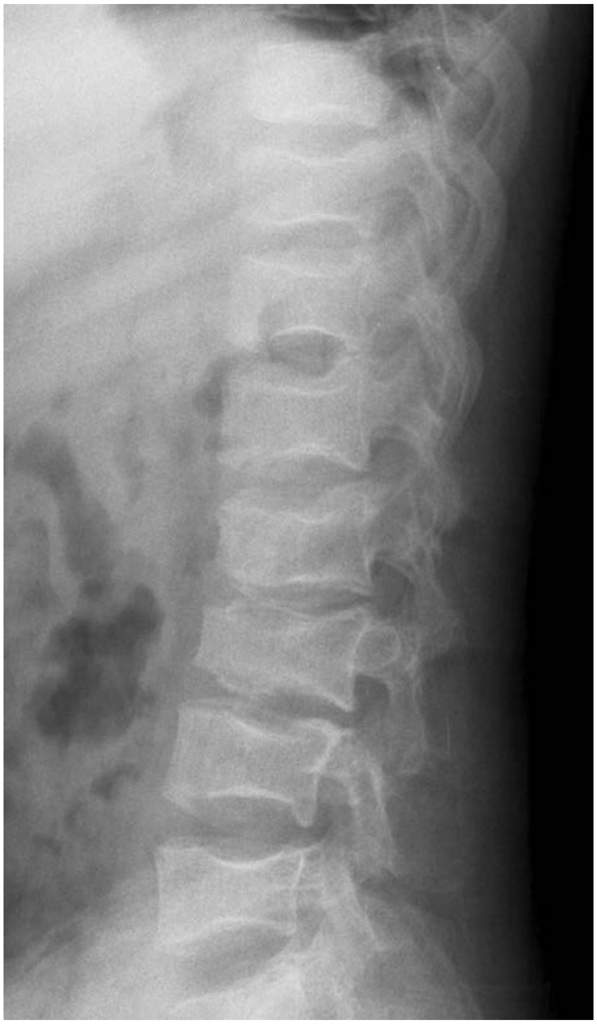

**Figure 141.13. Sickle cell disease in an 18-year-old man.** Numerous angulated end plate depressions ("H-shaped" or "Lincoln log" vertebrae) are consistent with central growth plate osteonecrosis.

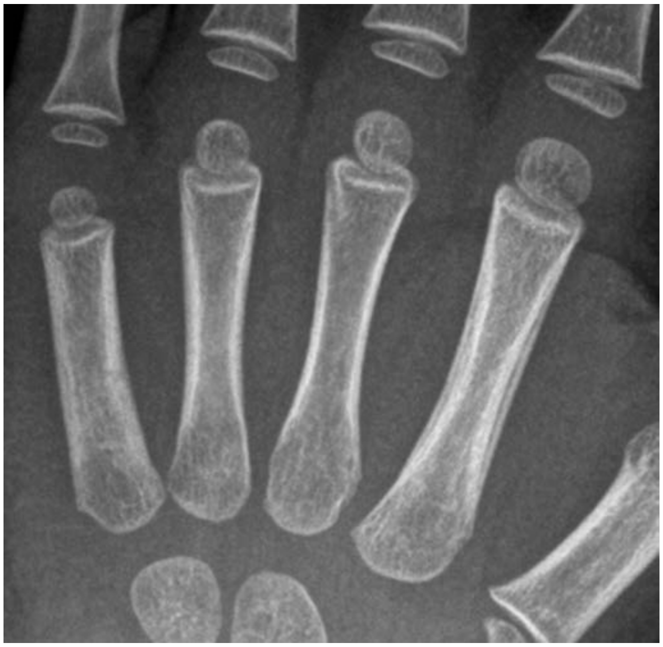

**e-Figure 141.12. Sickle cell dactylitis in a 2-year-old girl with left hand swelling.** Radiograph of the left hand shows smooth periosteal new bone formation along the second metacarpal.

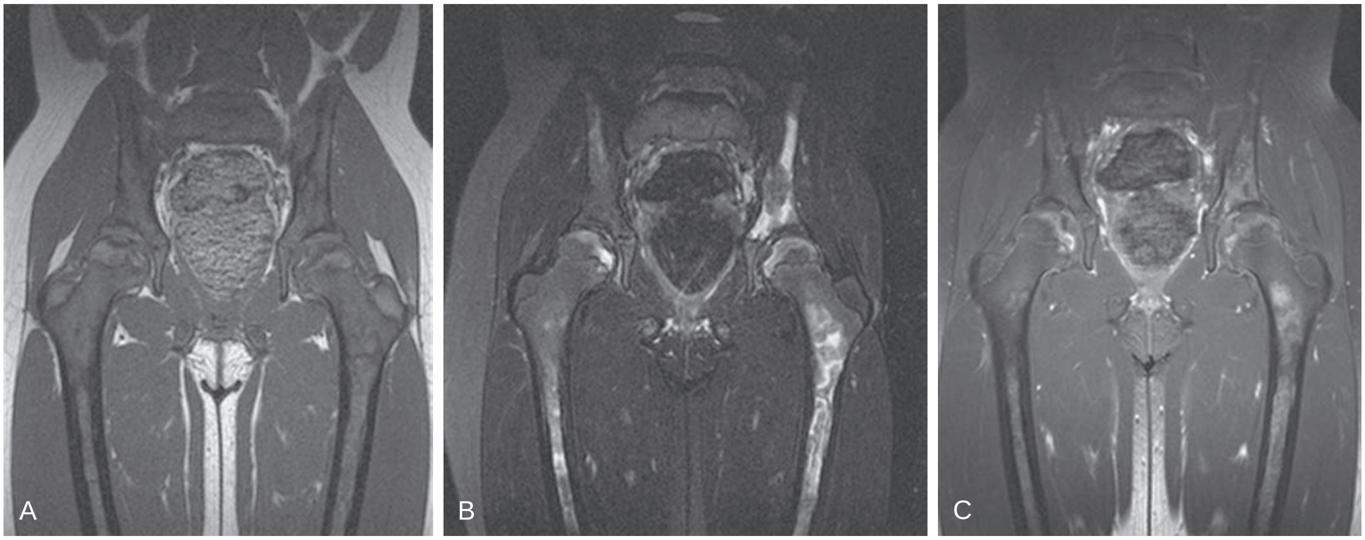

**Figure 141.14. Homozygous sickle cell disease in a 10-year-old girl with diffuse changes of osteonecrosis of the pelvic bones and femurs.** Coronal T1-weighted (A), T2-weighted fat-saturated (B), and postgadolinium T1-weighted fat-saturated (C) MR images of the pelvis. Note absence of juxtacortical soft tissue edema or hip joint effusions, suggesting that the process is subacute or chronic in nature.

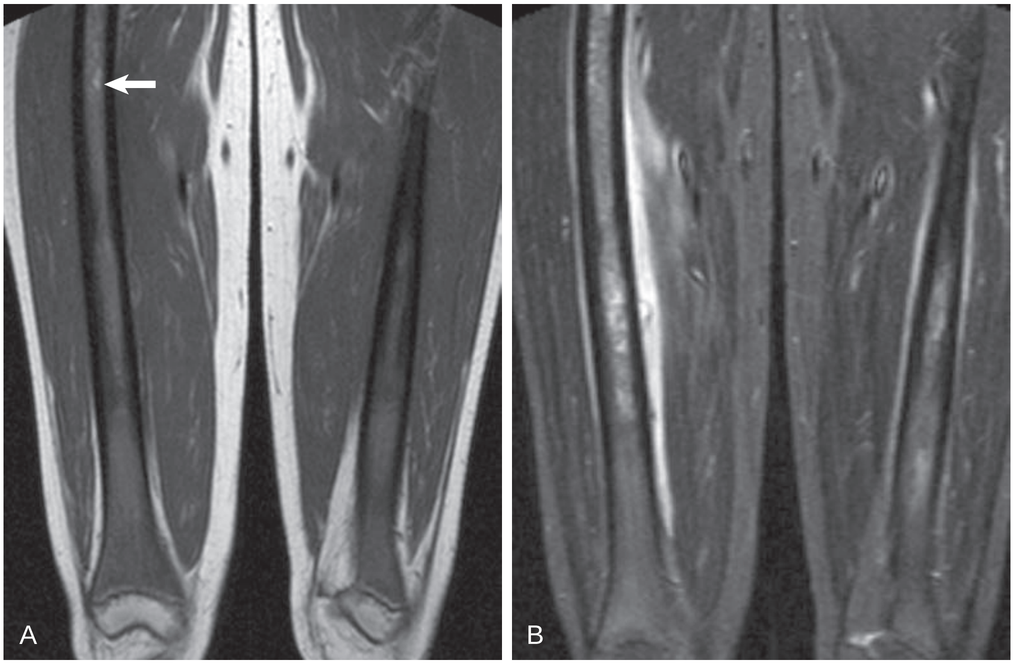

**Figure 141.15. Sickle cell disease acute vasoocclusive crisis in a 16-year-old girl.** (A) T1-weighted coronal MR image demonstrates diffuse hematopoietic marrow hyperplasia with variegated sclerosis throughout the femoral shafts consistent with prior episodes of osteonecrosis. Note hyperintense T1 focus *(arrow)*, which may represent sequestered blood. (B) Short-tau inversion recovery coronal sequence reveals diffuse marrow edema bilaterally, as well as exuberant periostitis bilaterally, and exuberant juxtacortical soft tissue edema on the right.

with hyperplasia of the myelopoietic cells and a propensity to develop bacterial infections related to chronic neutropenia.[49]

***Imaging.*** The most common radiographic changes in GSD1b during childhood are osteoporosis, undertubulization of appendicular bones, marked growth retardation, and delayed physeal closure.[50,51] Epiphyseal ossification is often delayed and irregular, and open physes may persist into early adulthood.

On MRI, the signal intensity of the bone marrow varies and is dependent upon whether G-CSF has been administered for treatment. Without such treatment, patchy areas of low signal intensity on T1-weighted sequences and high signal intensity on T2-weighted FSE and STIR sequences reflect myeloid hyperplasia throughout the axial and appendicular skeleton. MRI features of glycogen storage disease may be indistinguishable from marrow hyperplasia related to profound anemia or leukemia. With G-CSF treatment, marrow hyperplasia becomes even more profound, and replacement of yellow marrow at the epiphyses may occur. In addition, G-CSF therapy often creates transverse bands of increased signal intensity on T2-weighted FSE and STIR sequences at the level of the juxtaphyseal metaphysis, likely related to hematopoietic recruitment.[26,49]

***Treatment.*** Medical nutrition therapy is the primary treatment. Additional therapies include allopurinol to prevent gout, lipid-lowering agents, citrate supplementation to help prevent urinary calculi, angiotensin-converting enzyme inhibitors to treat microalbuminuria, surgery for hepatic adenomas, human G-CSF for recurrent infections, and organ transplantation for end-stage kidney and liver disease.[52]

## MARROW INFILTRATION

### Storage Disorders

#### Gaucher Disease Type 1

***Etiology, Pathophysiology, and Clinical Presentation.*** Gaucher disease is the most prevalent heritable lysosome storage disorder. Mutations that confer a deficient level of β-glucocerebrosidase activity lead to accumulation of the lipid glucocerebroside in the lysosomes of macrophage-like Gaucher cells.[53] The symptoms and pathology of the type 1 form of Gaucher disease result from the accumulation of Gaucher cells in various organ systems, including the skeletal system. Those with Gaucher disease are subject to recurrent painful bone crises, like those with sickle cell disease.

***Imaging.*** Skeletal imaging manifestations relate to marrow infiltration by Gaucher cells, leading to osteonecrosis, osteosclerosis, osteomyelitis, and predisposition to fractures.[53,54] The most common radiographic abnormality in untreated Gaucher disease is undertubulation of the distal femoral metaphysis as a result of marrow infiltration, termed the *Erlenmeyer flask deformity* (Fig. 141.16). This undertubulation is not specific to Gaucher disease (e-Fig. 141.17) and is much less commonly identified in treated patients.

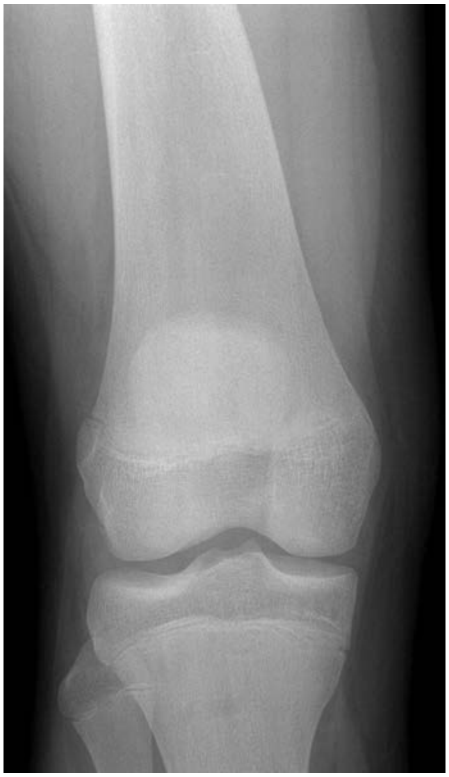

**Figure 141.16. Gaucher disease with undertubulation in a 16-year-old boy.** Frontal radiograph of the distal right femur shows mild to moderate Erlenmeyer deformity of the distal right femur.

On MRI, replacement of fatty marrow by Gaucher cells results in low signal intensity on T1- and T2-weighted sequences. Initially, marrow replacement is often diffuse and homogeneous and mimics a number of systemic metabolic disorders.[55] Marrow replacement is usually confined to the metaphysis and diaphysis, and epiphyseal involvement is unusual except in severe cases.[56] With time and treatment, marrow changes become patchy. Islands of Gaucher cells are separated by intervening fatty marrow throughout the skeleton with relative preservation of the epiphyseal fatty marrow (Fig. 141.18). The intramedullary presence of Gaucher cells is thought to hinder blood flow within the marrow, thereby predisposing these patients to osteonecrosis (e-Fig. 141.19).

***Treatment.*** Enzyme-replacement therapy results in degradation of Gaucher cell deposits and reconversion to normal fatty marrow.[56] MRI has been advocated to monitor the bone marrow fat fraction as an indicator of therapy response. Several MRI-based methods of quantifying the bone marrow infiltration and the effects of treatment on patients with Gaucher disease are under investigation, including Dixon chemical-shift imaging, T1 relaxation-time calculation, and MR spectroscopy.[51,57,58]

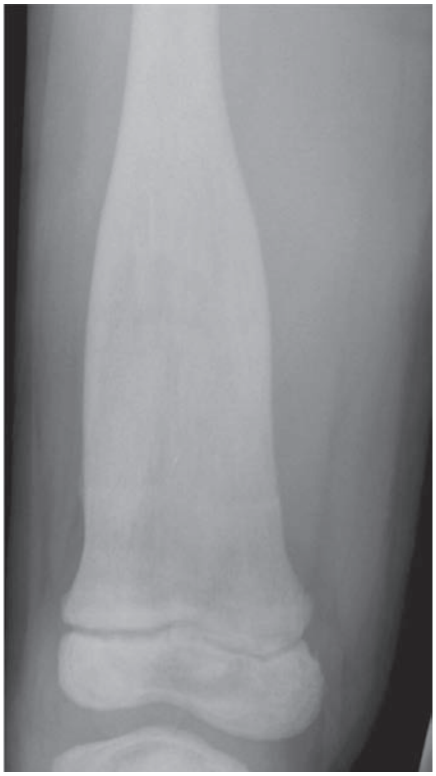
### Neoplasms

#### Leukemia

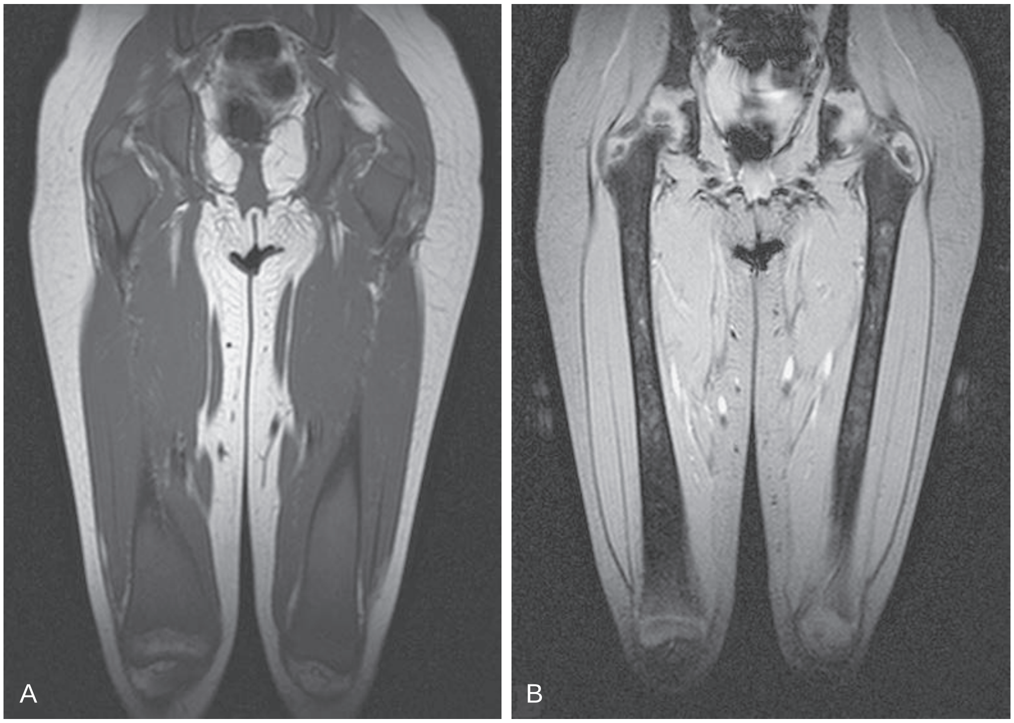
***Etiology, Pathophysiology, and Clinical Presentation.*** Leukemia is the most common childhood malignancy, accounting for up to one-third of childhood cancer.[59] Leukemia is classified by the morphology, immunophenotype, and cytogenetics of the leukemic cells. Acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) account for three-quarters and one-fifth of childhood leukemia cases, respectively. The peak incidence of childhood ALL is 2 to 3 years of age, and there is evidence that ALL can initiate in utero.[60] AML rates are highest in the first 2 years of life, decline to a nadir at 6 years of age, and slowly increase during the adolescent years.[61] An increased risk of leukemia is associated with certain genetic disorders, including trisomy 21, monosomy 7, neurofibromatosis type 1, and DNA repair disorders such as ataxia-telangiectasia.[59] Of particular interest to the radiologist is the reported increased risk of leukemia from prenatal or postnatal radiation exposure.[62,63]

***Imaging.*** Radiography of the appendicular and axial skeleton is most often normal when the patient is brought to medical attention. When radiographs are abnormal, the most common finding is osteopenia. *Leukemic lines* refer to juxtaphyseal radiolucent metaphyseal bands (Fig. 141.20), which have been attributed to various causes, including disruption of the zone of hypertrophy related to leukemic infiltration and insufficiency fractures of the metaphysis just above the physis. Leukemic lines have even been proposed to be a visual artifact related to profound osteopenia. Periostitis at initial presentation may be due to the disease process itself or to insufficiency fractures resulting from osteopenia (e-Fig. 141.21).

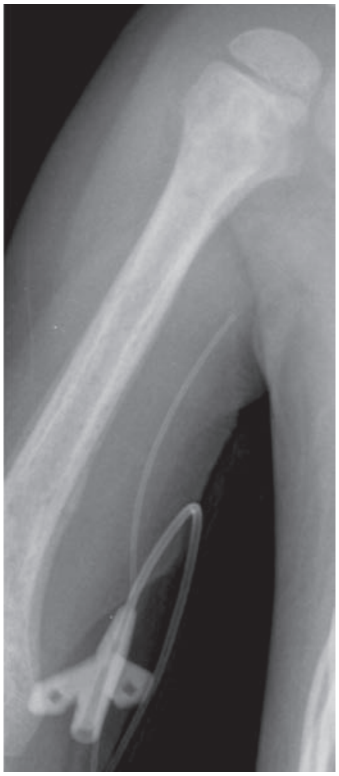
On MRI, leukemic infiltration causes diffusely decreased signal intensity on T1-weighted sequences[64,65] and increased signal intensity on fat-suppressed T2-weighted and STIR sequences. The epiphysis is often involved (Fig. 141.22). Marrow involvement may also have a well-defined nodular appearance, especially in the setting of leukemic relapse.[35] The findings are less conspicuous in hematopoietic marrow than in fatty marrow, and consequently are more difficult to appreciate in younger children, in whom marrow conversion has not yet occurred.[34] The MRI appearance of diffuse cellular infiltration of the marrow in children is not specific for acute leukemia and can also be seen in conditions associated with hematopoietic marrow hyperplasia, in myelodysplastic and myeloproliferative syndromes, and in lymphoma and



**e-Figure 141.17. Osteopetrosis and undertubulation in a 12-year-old.** Frontal radiograph of the distal right femur shows Erlenmeyer deformity resulting from moderate to severe diaphyseal undertubulation.



**e-Figure 141.19. Type 1 Gaucher disease in a 5-year-old girl with diffuse Gaucher cell infiltration and osteonecrosis.** Diffuse metadiaphyseal low signal intensity of the marrow is noted on the coronal T1-weighted MR image, (A) and corresponding patchy high signal intensity with intervening serpentine margins related to osteonecrosis is evident on the coronal fast field echo T2*-weighted MR image (B).



**e-Figure 141.21. Three-year-old boy with trisomy 21 and anemia.** Coned-down image of the right humerus from a chest radiograph shows an aggressive, permeative lesion with a poorly defined zone of transition and periosteal reaction that affects the mid and distal humerus. Bone marrow biopsy revealed acute myeloid leukemia.

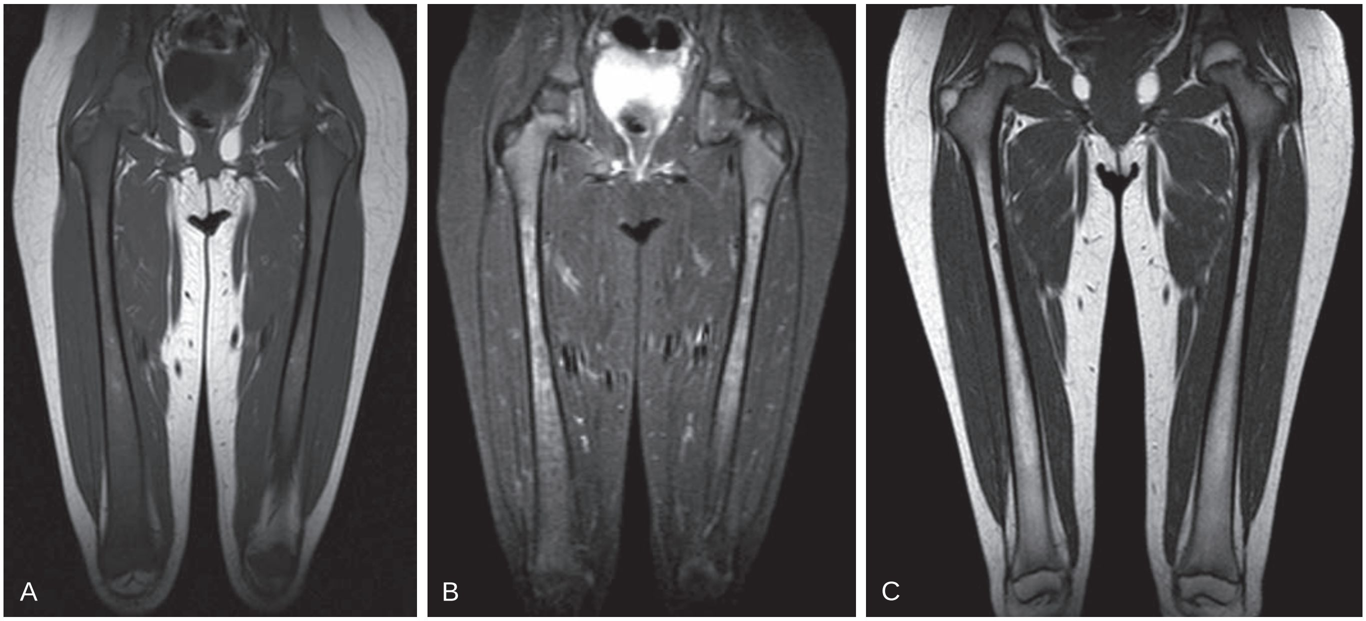


**Figure 141.18. Gaucher disease in a 4-year-old girl.** (A) T1-weighted coronal MR image shows diffuse fatty marrow replacement with small diaphyseal islands of fatty marrow. (B) Short-tau inversion recovery coronal image shows lobulated marrow replacement with increased signal with respect to muscle. (C) T1-weighted coronal image after treatment 7 years later shows fatty marrow conversion.

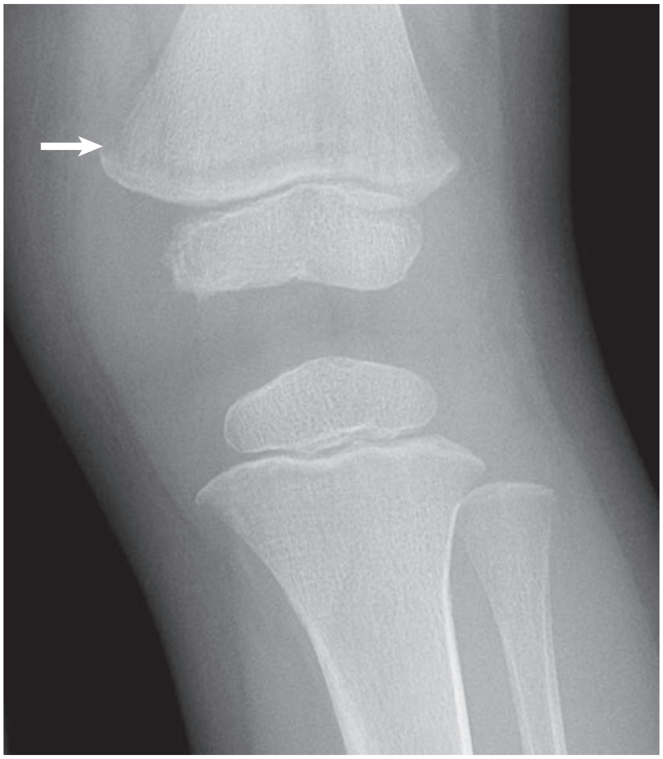

**Figure 141.20. Newly diagnosed acute lymphoblastic leukemia in a 1-year-old boy.** Leukemic lines manifesting as juxtaphyseal metaphyseal lucency are most pronounced in the distal femur *(arrow)*.

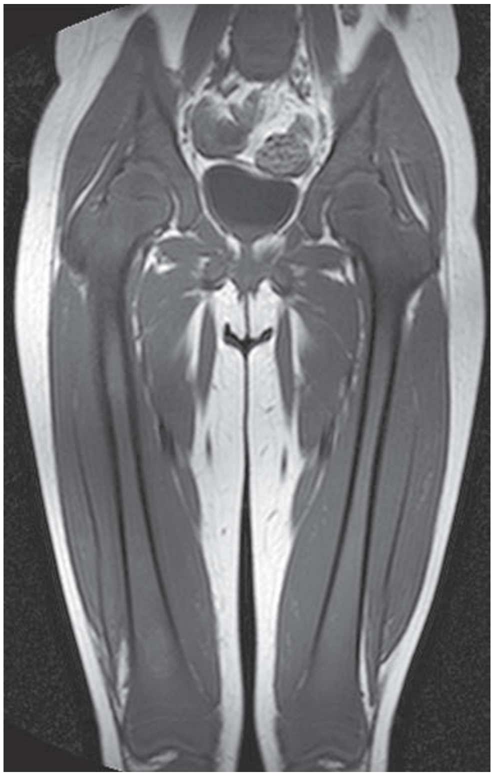

**Figure 141.22. Newly diagnosed acute lymphoblastic leukemia in a 6-year-old girl.** Coronal T1-weighted MR image of the pelvis and thighs demonstrates diffuse low signal intensity of the bone marrow consistent with leukemic replacement.

solid tumor metastases. The findings of periostitis, geographic replacement of fatty marrow by hematopoietic marrow throughout the entirety of the long bones and axial skeleton, and juxtacortical soft tissue edema favor a diagnosis of leukemia over hematopoietic marrow hyperplasia. During chemotherapy for leukemia, the bone marrow becomes hypocellular and edematous. Following chemotherapy, there is progressive regeneration of normal hematopoietic cells and fat (e-Fig. 141.23).[66] In children with ALL who enter remission, marrow T1 relaxation time normalizes, whereas it remains prolonged in those who do not enter remission.[65,67]

***Treatment and Follow-up.*** No standard guidelines exist for routine imaging follow-up in children with leukemia. PET imaging, bone densitometry, and whole-body MRI at presentation, treatment, or follow-up may be components of clinical trials or other research investigations but are not part of routine clinical practice.

Musculoskeletal complaints are common in children treated for leukemia at presentation and during follow-up.[68] The most common complications amenable to imaging diagnosis are osteonecrosis and insufficiency fractures. Up to 70% of children with leukemia screened by MRI are diagnosed with osteonecrosis, and 15% to 20% have symptoms.[69] The reported incidence of fractures in leukemic patients is 18.5% with low lumbar spine bone mineral density and age greater than 10 years as independent predictors of fracture risk.[70]

The most common site of ALL relapse is the marrow, followed by the central nervous system and testes.[61] MRI may be used to evaluate for relapse; however, its specificity is limited by difficulty in differentiating relapse from the effects of therapy.[71–73] Because of this limitation, MRI has not replaced marrow aspirate or biopsy for assessment of therapeutic response in leukemia.[74]

## Lymphoma

***Etiology, Pathophysiology, and Clinical Presentation.*** Marrow involvement by lymphoma in children usually occurs with Burkitt lymphoma, lymphoblastic lymphoma, and with lymphocyte-depleted Hodgkin disease. The pattern of involvement is usually multifocal, and there is a predilection for sites of predominantly hematopoietic marrow. When involvement is diffuse, an arbitrary threshold of neoplastic lymphoid cells constituting 25% or greater of the marrow cellularity differentiates the diagnosis of lymphoblastic leukemia from lymphoma.[75]

Primary lymphoma of bone should be distinguished from Hodgkin and non-Hodgkin lymphoma with bone involvement. When isolated disease is confined to the bone marrow without disease elsewhere for at least 6 months, a diagnosis of primary bone lymphoma can be made.[76]

***Imaging.*** Disseminated lymphoma with marrow involvement may be indistinguishable from leukemia by imaging. However, primary lymphoma of bone initially present as isolated focal bone involvement that may mimic other primary bone neoplasms. The most common radiographic pattern is lytic-destructive (Fig. 141.24).[77] The lytic pattern may be permeative, consisting of many uniform small lucencies or “moth-eaten” areas made of larger, poorly marginated lucencies.[76] Primary bone lymphoma often involves the flat bones of the pelvis and shoulder girdle as well as the diaphyses of long bones, similar to Ewing sarcoma.

Unlike leukemia, primary bone lymphoma often presents as a well-defined intramedullary mass with variable cortical destruction and soft tissue extension. The involved sites typically show low signal intensity on T1-weighted sequences and high signal intensity on fat-suppressed T2-weighted and STIR sequences (see Fig. 141.8). When primary bone lymphoma is unifocal on MRI with masslike features, it cannot be distinguished from other aggressive lesions, such as Ewing sarcoma and Langerhans cell histiocytosis. When diffuse, involvement is often patchy, and up to one-third of lymphoma patients with negative bone marrow biopsies have lymphoma involvement visible by MRI distant from the standard iliac crest biopsy sites.[73,78]

Although MRI is a sensitive modality for detecting marrow infiltration, it is not routinely used for the staging of lymphoma. FDG-PET detects lymphoma on the basis of increased metabolic activity and may be used as a complement to bone marrow biopsy for initial staging as it can guide the biopsy location to areas of active marrow involvement.[79]

***Treatment and Follow-up.*** Marrow involvement in patients with systemic lymphoma portends a worse prognosis and is considered stage IV disease.[59] Imaging follow-up is based on nonosseous

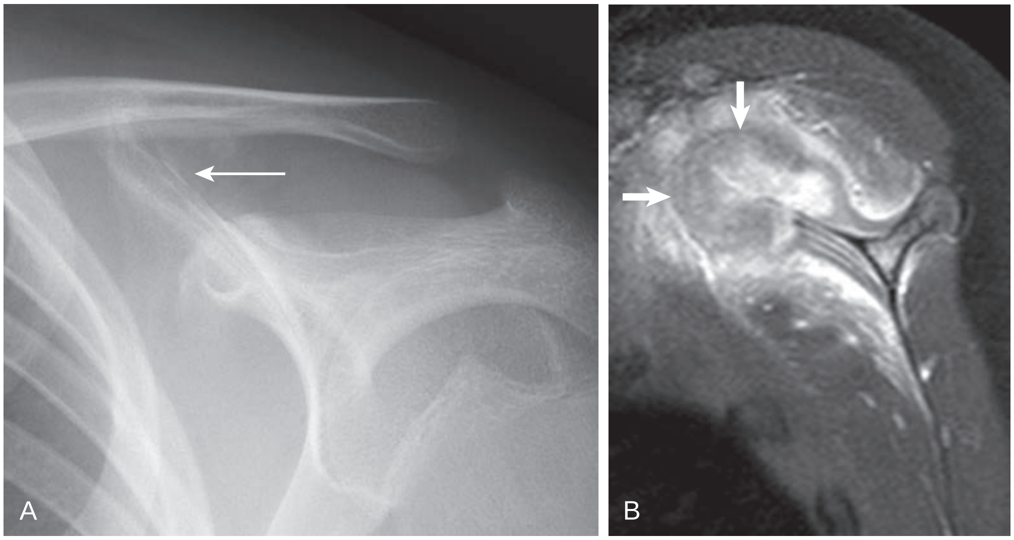

**Figure 141.24. Primary bone lymphoma in a 14-year-old boy with left shoulder pain.** (A) Frontal radiograph of the left scapula at initial presentation shows periosteal reaction and irregularity *(arrow)* at the superomedial scapula. (B) T1-weighted MR image with fat saturation shows cortical destruction, bone marrow edema, and a large heterogeneously enhancing soft tissue mass arising from the superior scapula *(arrows)* with adjacent soft tissue edema. Open surgical biopsy revealed large cell anaplastic lymphoma.

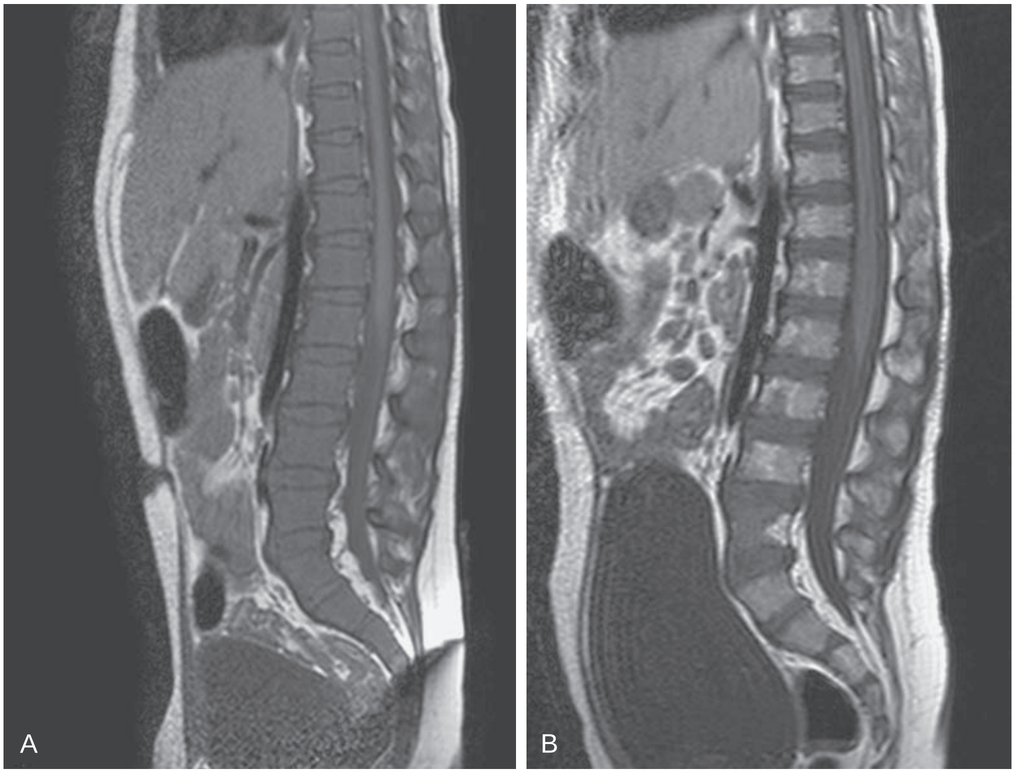

**e-Figure 141.23. Down syndrome and acute lymphoblastic leukemia in a 5-year-old boy.** Sagittal T1-weighted MR image of the lower spine at the time of leukemia diagnosis shows that the marrow is hypercellular owing to diffuse infiltration of the marrow by lymphoblasts and resultant diffuse abnormal low signal intensity of the marrow (A). The increase in marrow signal intensity after chemotherapy is consistent with an increase in the fat content and a reduction in the cellularity of the marrow (B).

disease, including nodal involvement. Patients with primary bone lymphoma have an excellent prognosis, and treatment is usually tailored to the site of involvement.[80]

## OSTEONECROSIS

***Etiology, Pathophysiology, and Clinical Presentation.*** Although often asymptomatic and rarely extensive enough to impair hematopoietic function, osteonecrosis can cause pain and disability. It can be separated into *epiphyseal* and *nonepiphyseal* osteonecrosis. The terms *aseptic* and *avascular necrosis* are alternative terms for *epiphyseal osteonecrosis*, and *bone infarction* is an alternative term for *nonepiphyseal osteonecrosis*.

Epiphyseal osteonecrosis portends a worse prognosis compared with nonepiphyseal osteonecrosis. This is because epiphyseal osteonecrosis and its complications—including cartilage injury, subchondral collapse, and subsequent early osteoarthritis—may compromise joint function.

Conditions associated with an increased risk of osteonecrosis include repetitive trauma, sickle cell disease, Gaucher disease, chronic renal failure, bone marrow transplantation, steroid therapy, pancreatitis, and highly active antiretroviral therapy for HIV infection.[81] Putative pathophysiologic mechanisms related to nontraumatic spontaneous osteonecrosis include vascular occlusion, elevated medullary cavity pressure, coagulopathy, and altered lipid metabolism. Osteonecrosis most commonly occurs in regions of fatty marrow and is unusual in hematopoietic marrow, except in patients with hemoglobinopathies.[81]

*Legg-Calvé-Perthes (LCP) disease*, also called *idiopathic osteonecrosis of the capital femoral epiphysis*, is one of the most common forms of epiphyseal osteonecrosis. LCP is a classic illustrative example of the clinical course and prognosis related to epiphyseal osteonecrosis at the femoral head and elsewhere. LCP affects boys between 2 and 14 years of age with peak incidence around 5 to 6 years (male/female ratio, 5 : 1). Involvement is bilateral in 10% to 15% of cases, although it is almost always asynchronous.[82] Forms of idiopathic osteonecrosis that affect other bones include but are not limited to Kienböck disease (lunate) (Fig. 141.25), Köhler disease (navicular; Fig. 141.26), and Freiberg infraction (second or third metatarsal head; Fig. 141.27).

For LCP, deformity of the femoral head, neck, and acetabulum is a common cause of degenerative disease of the hip, particularly in men. Children who come to medical attention before 6 years of age generally have a benign course, whereas those who seek care after 8 years of age fare less well and often require surgery.[83]

Children with LCP are typically seen after having had several weeks or months of limping, often without pain. Physical findings include spasm, limitation of abduction and internal rotation, and atrophy of the thigh and buttocks in an otherwise normal child.

***Imaging.*** In acute osteonecrosis, radiographs are usually normal. With subacute and chronic osteonecrosis, radiographs will show geographic and patchy areas of sclerosis (see Fig. 141.11).

During the acute phase of osteonecrosis, MRI findings of marrow hemorrhage, edema, and liquefactive necrosis may be difficult to distinguish from infection and/or superimposed stress reaction. Acute-on-chronic osteonecrosis may occur, and the

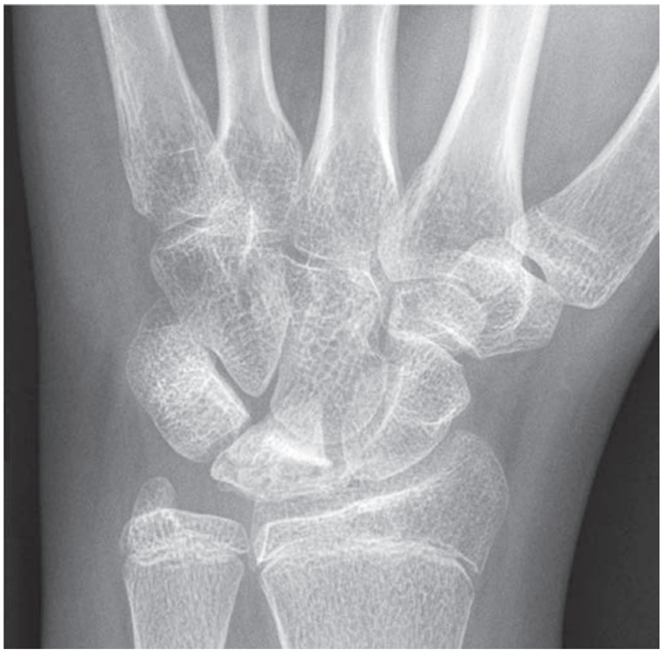

**Figure 141.25.** Fourteen-year-old girl with Keinböck disease with flattening and sclerosis of the lunate bone.

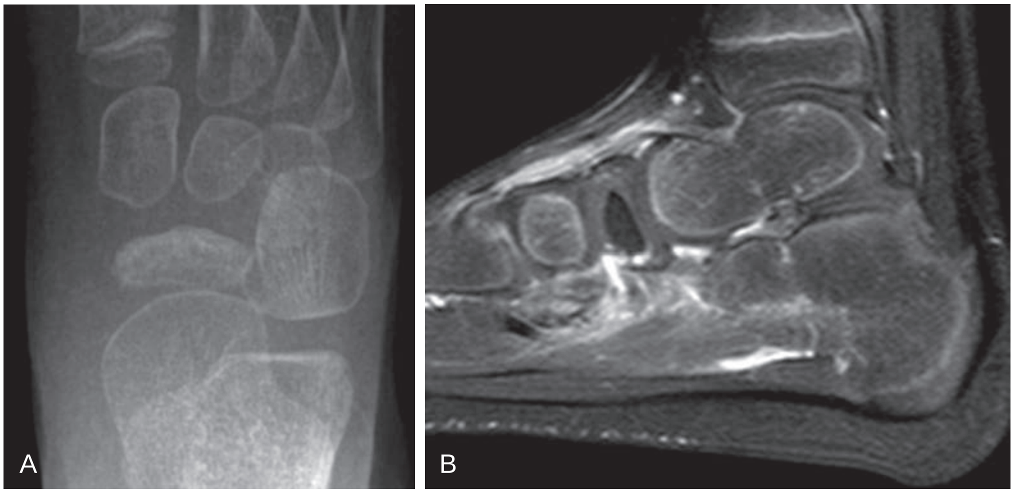

**Figure 141.26. Köhler disease in a 15-year-old girl.** (A) Anteroposterior view of the foot shows sclerosis and mild flattening of the navicular bone. (B) Postcontrast T1-weighted fat-saturated sagittal MR image shows nonenhancement of the navicular bone and soft tissue edema about the dorsal and plantar surface of the midfoot.

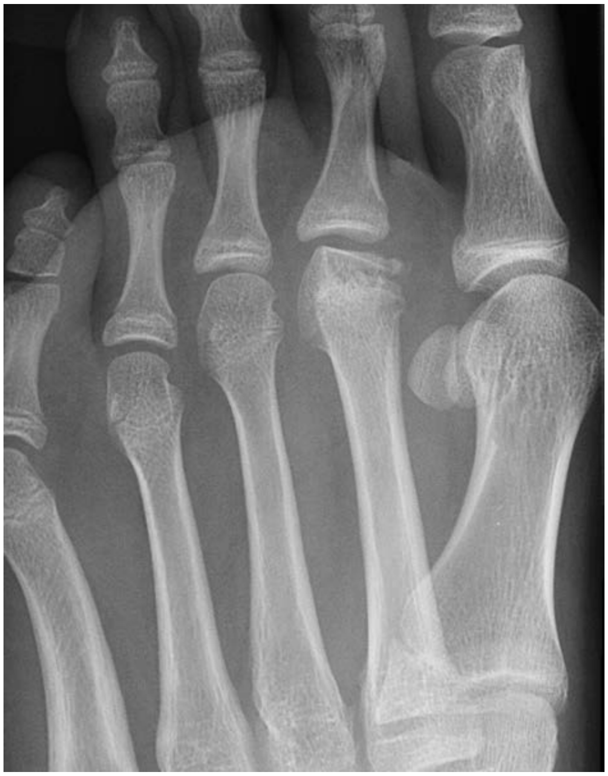

**Figure 141.27. Freiberg infraction in an 11-year-old girl.** Oblique view of the forefoot shows flattening and collapse of the second metatarsal head.

presence of edema and periostitis are helpful clues to identify the acute component (Fig. 141.28). Rarely, this may superficially mimic a neoplastic process. Unfortunately, early infection and superimposed stress reaction may be indistinguishable. During the reparative phase, central fatty marrow replacement usually occurs (Fig. 141.29). Osteonecrosis often has a geographic shape with a serpentine margin of low signal intensity on T1-weighted sequences that often does not respect epiphyseal, metaphyseal, and diaphyseal boundaries of the long bones (see Fig. 141.29). T2-weighted sequences may demonstrate a characteristic “double-line sign” consisting of an outer rim of low signal intensity corresponding to sclerotic bone and an inner rim of high signal intensity corresponding to vascularized granulation tissue (Fig. 141.30). Areas of low signal intensity on both T1- and T2-weighted sequences related to osteonecrosis represent fibrosis or calcification. Fatty marrow infiltration manifested by increased signal intensity on T1-weighted sequences within the area of osteonecrosis is believed to indicate central revascularization (see Fig. 141.29). Intense contrast enhancement is common at the periphery of evolving areas of osteonecrosis, and dynamic contrast-enhanced MRI has been advocated for early diagnosis but probably is not necessary in children with established osteonecrosis. The diagnosis can usually confidently be made on conventional MRI sequences without intravenous contrast.[81]

Imaging findings of epiphyseal osteonecrosis related to other causes are indistinguishable from those of LCP, which progresses through four main stages: (1) avascularity, (2) revascularization, (3) healing, and (4) residual deformity (Fig. 141.31). Early radiographic diagnosis is based on the detection of periarticular osteoporosis, medial joint space widening, lateral displacement of the femoral head, and eventually a relatively smaller and denser appearance of the femoral head.[84,85]

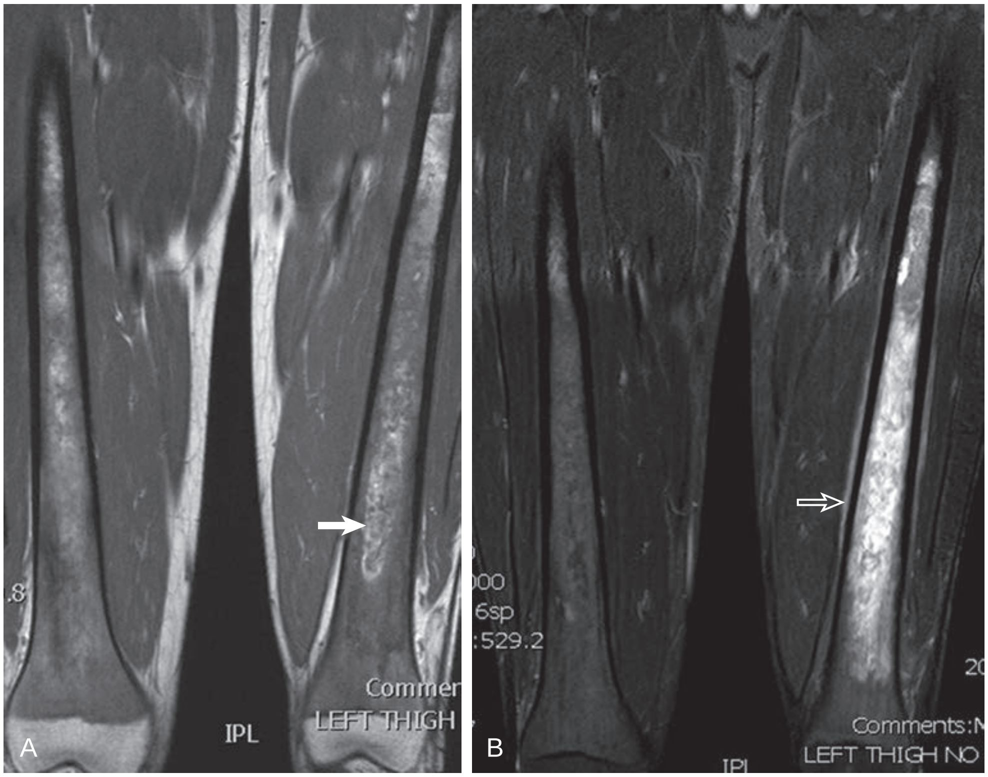

**Figure 141.28. Sickle cell disease with acute bone infarction in a 20-year-old man.** (A) T1-weighted coronal MR image shows diffuse red marrow of the metaphyses and diaphyses. Hyperintense foci are apparent within the medullary cavity *(arrow)*, presumably representing sequestered blood. (B) Short-tau inversion recovery coronal image shows diffuse marrow edema and periostitis *(open arrow)*, consistent with acute bone infarction.

During the revascularization stage, which lasts from 1 to 4 years, surrounding tissues react to the dead bone. In this stage, the child experiences pain, and the most dramatic radiographic changes occur.[86] The ossific nucleus appears even denser because of new bone formation that occurs within the dead trabeculae; it is easily flattened and deformed. A pathologic subchondral fracture in the anterosuperior ossific nucleus creates the radiographic "crescent sign." The epiphyseal ossification center undergoes varying degrees of fragmentation, primarily in its central portion (Fig. 141.32). The adjacent metaphysis sometimes develops cystic changes and broadens. Disturbed endochondral ossification from ischemia probably results in residual cartilage in the metaphysis.[87]

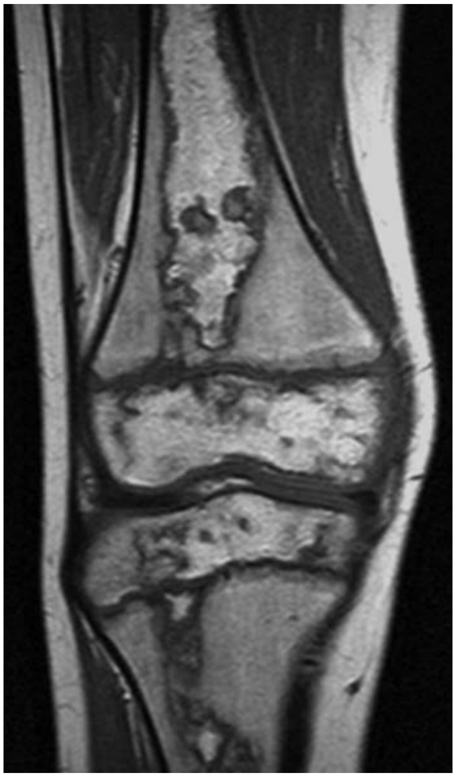

**Figure 141.29. Diffuse osteonecrosis in an 11-year-old boy.** T1-weighted coronal MR image shows diaphyseal, metaphyseal, and epiphyseal involvement of osteonecrosis. Note the central areas of increased signal intensity within the areas of osteonecrosis, consistent with fatty marrow conversion.

During the healing phase, new bone slowly replaces granulation tissue in the ossific nucleus, and the epiphysis regains its height. The better the femoral head is contained by the acetabulum, the more spherically the femoral head will remodel. On MRI performed during the healing phase, the physeal cartilage may exhibit irregularity or bridging. Epiphyseal deformity is more pronounced anteriorly; hence sagittal images are an essential part of the evaluation.

Residual deformity persists after healing, although the articular cartilage is reasonably preserved. As a result, joint function may be satisfactory for several years. Abnormal shape of the healed epiphysis is characterized by *coxa magna*, a residual enlargement of the femoral head and neck, and *coxa breva*, a short femoral neck as a result of premature physeal arrest. Subsequent varus or valgus hip deformity may occur, depending on the location of the physeal fusion. A deformed femoral head, especially with a large anterolateral segment that is uncovered, can impinge on the lateral acetabular lip and cause clinical symptoms of decreased range of motion, pain, and a "clunking" sensation. This joint incongruity leads to labral pathology and degenerative joint disease later in life.

***Treatment.*** Treatment for osteonecrosis is aimed at managing the underlying condition or modifying administration of the causative agent, such as decreasing corticosteroid dosage. Resting the affected joint may help slow disease progression and may prevent complications, including pathologic fractures. Children with osteonecrosis are predisposed to pathologic fractures, and subchondral collapse occurs with epiphyseal osteonecrosis and pathologic long-bone fractures with nonepiphyseal involvement. For epiphyseal osteonecrosis, the most important predictors of patient outcome, aside from age of onset, are joint congruency and motion.

Treatment of LCP is individualized on the basis of clinical and radiographic findings, including age of onset, range of motion in the hip joint, extent of femoral head involvement, presence or absence of femoral deformity, and lateral subluxation of the femoral

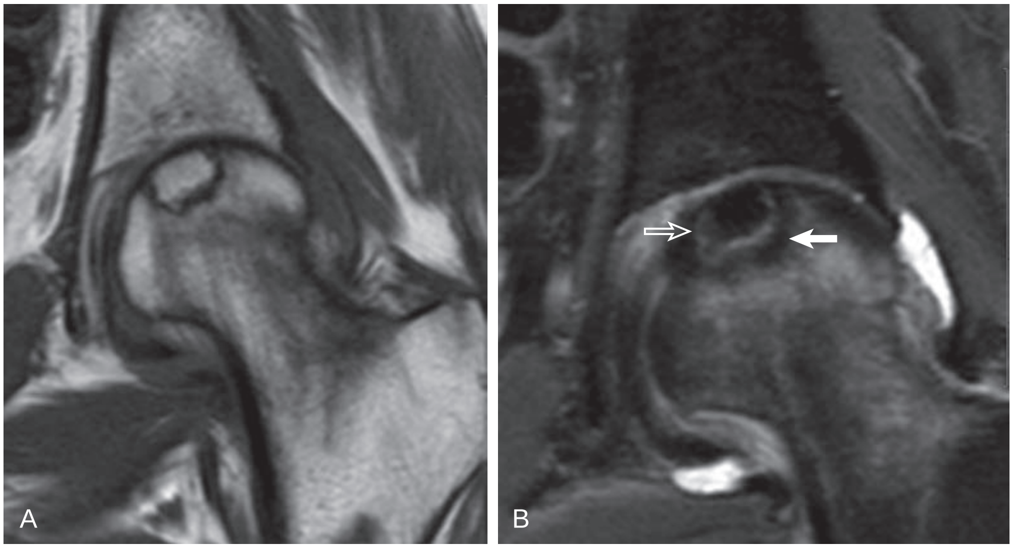

**Figure 141.30. Epiphyseal osteonecrosis of the femoral head in an 18-year-old woman.** T1-weighted (A) and short-tau inversion recovery coronal MR images (B) demonstrate a "double-line sign" with inner white line *(open arrow)* and outer dark line *(solid arrow)*. Note central area of increased T1 signal consistent with fatty marrow replacement.

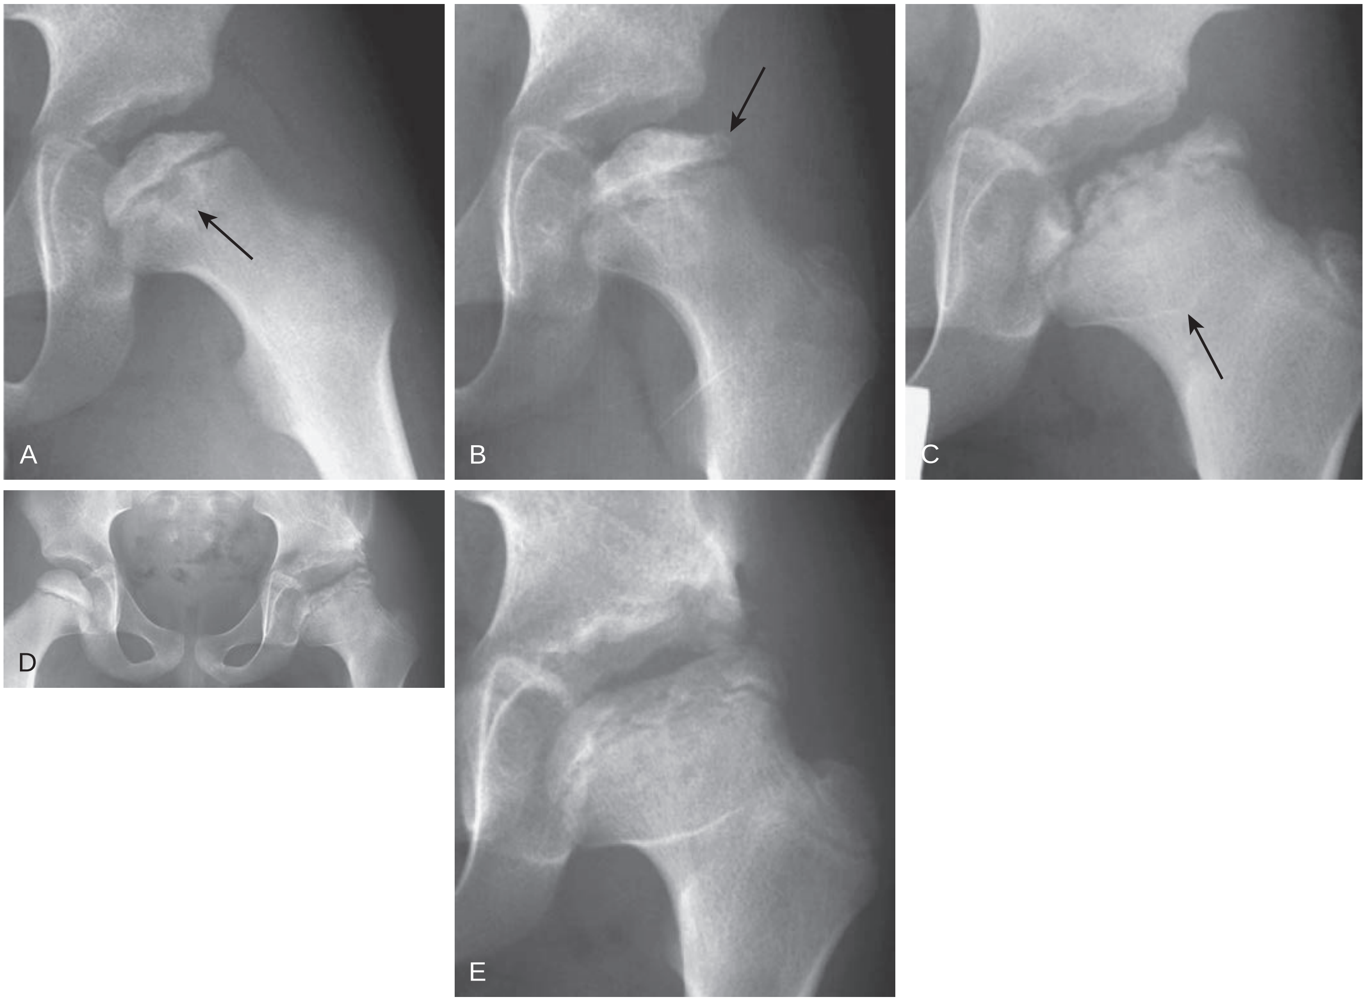

**Figure 141.31. Osteonecrosis of the left proximal femoral epiphysis in a 7-year-old boy with a limp.** (A) Radiograph of the left hip reveals a small, sclerotic proximal femoral epiphysis with an irregular articular surface. The metaphysis of the proximal femur also shows cystic changes *(arrow)*, which indicates a poor prognosis. (B) Radiograph performed 2 months later shows continued sclerosis and flattening. Very early fragmentation of the epiphysis is noted in the lateral pillar *(arrow)*. (C) At 18 months after presentation, a radiograph of the left hip reveals further fragmentation with lateral extrusion of the epiphysis. The acetabulum is beginning to impinge on the portion of the lateral column that is uncovered, and incongruence of the hip joint is apparent. The "sagging rope sign" *(arrow)* is produced by the outline of an abnormally oriented physis, which indicates growth arrest, and widening of the femoral neck (coxa magna) is seen. (D) At 25 months after diagnosis, a left iliac osteotomy is evident, attempting to cover the widened, flattened, left capital femoral epiphysis that is starting to coalesce. Early sclerosis of the right proximal femoral epiphysis indicates early avascular necrosis in the contralateral hip. (E) At 3 years after presentation, the left hip radiograph shows healed Legg-Calvé-Perthes disease with residual flattening, coxa magna, and an irregular acetabulum.

head. For many patients, a combination of traction treatment with an abduction cast, nonsteroidal antiinflammatory agents, and gentle range-of-motion exercises are used to enhance molding of the femoral head by the acetabulum. Surgery is indicated in children younger than 8 years who have femoral head deformity and in those older than 8 years even in the absence of deformity. Because LCP often affects the proximal femoral physeal vertex while preserving normal medial physeal physiology, a relative coxa valga may develop related to vertex physeal growth disturbance. As a consequence, surgical reduction to contain the femoral head is often indicated, including subtrochanteric varus osteotomies with or without congruent periacetabular shelf osteotomies, particularly in older patients (second decade). The main goals of surgical therapy are to preserve joint congruity during the active phase of the disease and to contain the femoral head within the acetabulum, preventing extrusion and subluxation. A femoral head that is contained by the acetabulum tends to heal more spherically than one that is partially subluxed. In severe cases, a vicious cycle ensues in which decreased containment leads to increased deformity that in turn leads to further subluxation. Surgery can prevent this progression and can be used to maintain a full range of motion at the hip joint.[88]

## EFFECTS OF THERAPY

### Hematopoietic Growth Factors

***Etiology, Pathophysiology, and Clinical Presentation.*** Hematopoietic growth factors such as G-CSF, granulocyte macrophage colony-stimulating factor (GM-CSF), and erythropoietin are

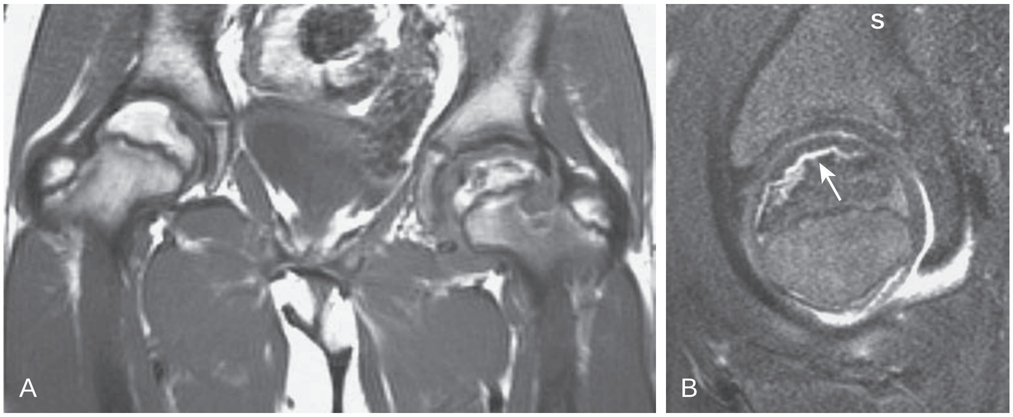

**Figure 141.32. Legg-Calvé-Perthes disease in a 10-year-old boy.** (A) Coronal T1-weighted MR image reveals crescentic low signal in the left proximal femoral epiphysis with irregularity of the articular surface. Epiphyseal height is also decreased. Some normal high signal is present, indicating preserved fat in the epiphysis. The lateral left femoral metaphysis reveals a rounded area of lower signal, indicating cystic changes. Additionally, cartilaginous hypertrophy is evident within the left hip joint that often accounts for apparent radiographic joint space widening. (B) Sagittal T2-weighted fat-saturated MR image shows a hyperintense crescentic fracture *(white arrow)* along the anterior portion of the left femoral epiphysis with an associated joint effusion.

cytokines that regulate the proliferation and differentiation of hematopoietic progenitor cells in the bone marrow.[89,90] Recombinant human hematopoietic growth factors are commonly used to hasten the recovery of hematopoietic marrow from myelosuppressive chemotherapy or bone marrow failure syndromes.

***Imaging.*** In those treated with G-CSF or GM-CSF, MRI will show signal intensity changes associated with reconversion of fatty marrow to hypercellular hematopoietic marrow that coincide temporally with increases in the absolute neutrophil count. These changes may be observed incidentally on routine imaging studies or on imaging studies prompted by bone pain accompanying G-CSF administration.[26] As in other instances of marrow hyperplasia, the imaging changes follow signal intensity similar to that of red marrow. GRE out-of-phase sequences designed to detect altered proportions of fat and water may be the most sensitive for the effects of G-CSF therapy. The peak of hematopoietic marrow hyperplasia observed by MRI occurs about 2 weeks after discontinuation of G-CSF administration, and the bone marrow alterations normalize in most patients within 6 weeks after treatment. The marrow changes may be diffuse, patchy, or have a masslike appearance, and they can be asymmetric and simulate bone marrow involvement by leukemia, metastatic disease, or other infiltrative process.[72] The masslike appearance of red marrow on T1-weighted images may have well-defined margins rather than the wisplike, feathery appearance of residual red marrow (see Fig. 141.5). Marrow changes as a result of G-CSF may not follow the typical red marrow pattern of reconversion seen in patients who are anemic. For instance, diaphyseal red marrow islands may appear before metaphyseal red marrow changes. The changes can also obscure underlying marrow lesions.[91] Masslike marrow replacement owing to G-CSF is usually not associated with juxtacortical soft tissue edema at the same level of the lesion, which is more likely with metastatic marrow replacement. Consideration of the timing of the therapy and imaging is necessary to avoid misinterpretation of the marrow changes (see Fig. 141.7).

Similarly, FDG-PET, $^{99}$mTc sulfur colloid scintigraphy, gallium-67 scintigraphy, and thallium-201 scintigraphy can show elevated radiopharmaceutical uptake by the stimulated hematopoietic marrow (Fig. 141.33). Large interindividual variability is seen in marrow FDG uptake induced by hematopoietic growth factors. FDG marrow uptake returns to normal within 1 month after the discontinuation of G-CSF treatment in most individuals.[91]

The anemia of end-stage renal disease can be treated with recombinant human erythropoietin, which induces an increase in the erythropoietic marrow that manifests as decreased signal intensity on T1-weighted sequences. Erythropoietin also increases the bone marrow uptake of FDG.

## Radiation Therapy

***Etiology, Pathophysiology, and Clinical Presentation.*** In the acute phase, radiation therapy causes depression of the marrow cellularity and vascular sinusoid injury with edema and hemorrhage.[92] In the chronic phase, the vascular sinusoids are obliterated, and hematopoietic marrow is replaced by fat and fibrosis.[93]

The process of fatty marrow replacement is largely irreversible for doses higher than 30 to 40 Gy, because destruction of the vascular sinusoids prevents migration of hematopoietic cells into the irradiated marrow.[6] For doses less than 30 to 40 Gy, the fatty marrow replacement is less complete, and regeneration of the hematopoietic marrow may occur. This regeneration of hematopoietic marrow manifests as a mottled or band pattern in the vertebrae of children between 11 and 30 months after spinal irradiation of doses no greater than 40 Gy, and similar findings have been observed in the marrow of the long bones after irradiation. Marrow regeneration is more likely to occur with larger volumes of irradiated marrow, suggesting that partial spinal irradiation may not provide enough stimulation to induce regeneration, because the nonirradiated marrow is sufficient to meet hematopoietic demands.

***Imaging.*** STIR sequences are the most sensitive conventional MRI technique for depicting early postradiation changes in the marrow, and they can detect the effects of radiation therapy within a few days after initiation of treatment.[6] Areas of increased signal intensity in the marrow on STIR sequences peak 9 days after therapy and reflect edema, hemorrhage, and early influx of nonirradiated cells.[4,26,91] T1-weighted sequences in the acute phase show a corresponding decrease in the signal intensity of the bone marrow and a corresponding increased signal intensity on STIR sequences indicative of marrow edema. From 2 to 6 weeks after irradiation, the signal intensity of the bone marrow begins to increase on T1-weighted sequences and decrease on STIR sequences (Fig. 141.34).[91] After 6 weeks, the marrow pattern either becomes more homogeneous, with high signal intensity on T1-weighted sequences

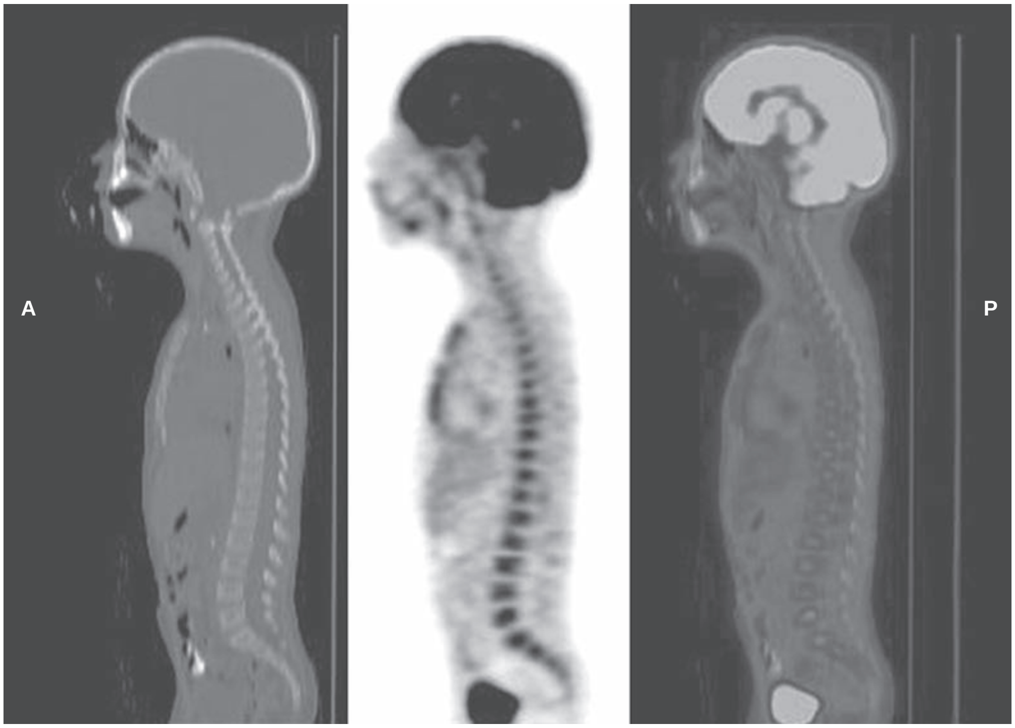

**Figure 141.33. Fluorodeoxyglucose positron-emission tomography (FDG-PET) and computed tomographic images of a 4-year-old boy on granulocyte-colony stimulating factor therapy to mitigate the myelosuppressive effects of Wilms tumor treatment.** Diffuse increased uptake of FDG by the bone marrow of the spine and sternum reflects the increased metabolic demand from stimulation of granulopoiesis in the marrow. *(Courtesy Dr. Barry Shulkin, St. Jude Children's Research Hospital, Memphis, TN.)*

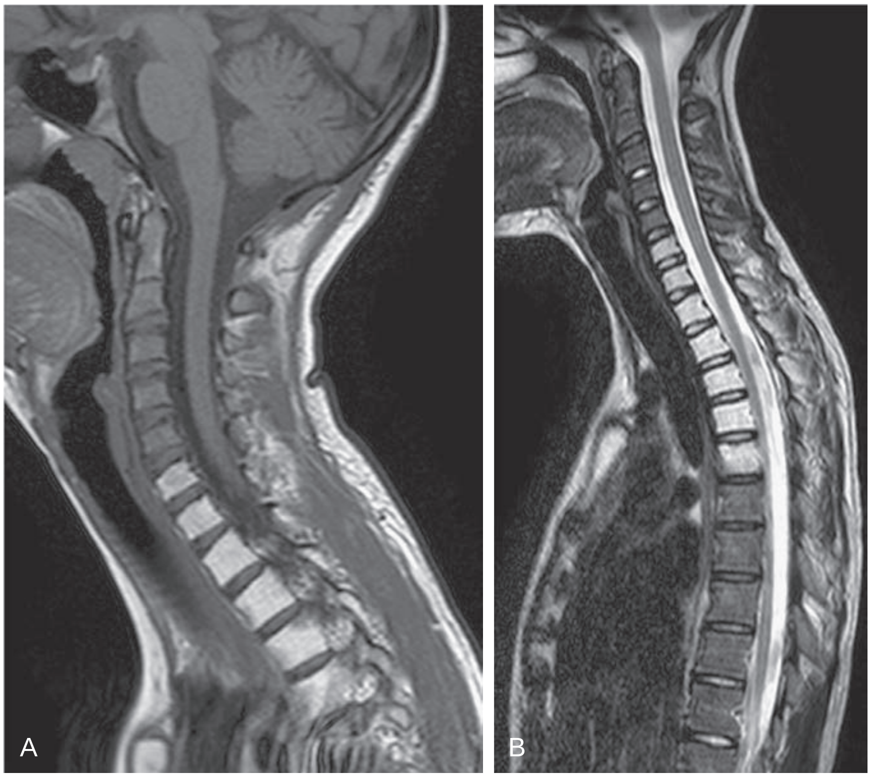

**Figure 141.34. Fifteen-year-old girl with a history of local radiation therapy for an extraosseous Ewing sarcoma in the left supraclavicular region.** Sagittal T1-weighted (A) and turbo spin echo T2-weighted (B) MR imaging of the upper spine reveals sharply demarcated, homogeneous high signal intensity of the marrow of the lower cervical spine, upper thoracic spine, and upper sternum that corresponds to fatty transformation of the marrow within the irradiated field.

and low signal intensity on STIR sequences, or it develops a band pattern of peripheral intermediate signal intensity surrounding central high signal intensity on T1-weighted sequences and produces reciprocal changes on STIR sequences.[91] In the chronic phase, the marrow also shows a marked decrease in contrast enhancement, reflecting vascular obliteration.[26,92] Additional late changes after radiation therapy include osteonecrosis and radiation-induced osteochondromas.[26]

## Bone Marrow Transplantation

***Etiology, Pathophysiology, and Clinical Presentation.*** Bone marrow transplantation is used in the treatment of numerous pediatric malignancies, as well as severe aplastic anemia, hereditary hemoglobinopathies, inborn errors of metabolism, and certain immunodeficiency and autoimmune syndromes. In preparation for bone marrow transplantation, the host marrow is ablated and conditioned by chemotherapy and possibly also by fractionated total-body irradiation to induce immune suppression and eliminate residual malignant cells, if applicable. Stem cells are then infused intravenously and engraft in the marrow within 2 to 4 weeks. Typical fatty and hematopoietic bone marrow is usually seen within 90 days after transplantation.[4]

***Imaging.*** In the interval after bone marrow transplantation, until the recovery of hematopoiesis, hematopoietic growth factors and multiple blood transfusions may be given, and the appearance of the marrow on MRI during this time will reflect the combined effects of marrow necrosis, early hematopoietic reconstitution, and possibly iron overload.[94,95]

Within 40 to 90 days after transplantation, a band pattern in the vertebral bodies may develop, consisting of a peripheral zone of intermediate signal intensity and a central zone of high signal intensity on T1-weighted sequences with reciprocal signal intensities on STIR sequences.[94] This pattern corresponds to regenerating hematopoietic marrow peripherally and fatty marrow centrally. The band pattern may gradually evolve into a more homogeneous appearance.[6] However, the hematopoietic marrow recovery after bone marrow transplantation may not achieve full reconstitution, corroborated by the observation that the fat fraction in the vertebral and pelvic marrow determined by chemical-shift MRI is higher in transplanted patients for several years after transplantation.[26]

### KEY POINTS

- MRI is the primary imaging modality for evaluating bone marrow. A combination of T1-weighted and fat-saturated T2-weighted or STIR sequences are sufficient for the detection and characterization of most marrow lesions. Contrast-enhanced MRI is reserved for when findings are unclear on precontrast images.
- Conversion from hematopoietic to fatty marrow in the axial skeleton occurs in a distal-to-proximal direction and from diaphyses to metaphyses in the long bones. Fatty conversion in the epiphyses and apophyses begins soon after ossification, and marrow reconversion occurs in the reverse order of marrow conversion.
- The MRI appearance of marrow in thalassemia and sickle cell disease reflects the combined effects of red marrow hyperplasia, iron deposition, iron chelation therapy, and in the case of sickle cell disease, medullary infarcts. Acute medullary infarcts are often indistinguishable from acute osteomyelitis on MRI.
- Treatment-related marrow changes, particularly with hematopoietic growth factors, cause bone marrow changes that can simulate involvement by leukemia, metastatic disease, and other infiltrative processes. Knowledge of the timing of therapy and imaging is necessary for accurate image interpretation.

# Skeletal Trauma

Deepa R. Pai and Peter J. Strouse

## GENERAL OVERVIEW

The dictum "Children are not small adults" is especially true regarding skeletal trauma. Fracture patterns, fracture healing, and fracture complications differ between children and adults.[1,2] Fortunately, fracture complications are relatively uncommon. In healthy children, the process of fracture healing and remodeling is rapid, particularly in the vascularized metaphysis.[3] Most posttraumatic deformities readily correct with healing and remodeling.[1,2] The composition of a child's bones and the presence of the growth process both predispose children to types and complications of fractures that are different from those seen in adults.[1,2,4]

## GENERAL ETIOLOGIES, PATHOPHYSIOLOGY, AND CLINICAL PRESENTATION (MECHANISM, HEALING, COMPLICATIONS)

***Mechanism.*** Falls, injuries at play, and motor vehicle accidents account for a majority of childhood fractures.[5] Unfortunately, children may suffer fractures as a consequence of nonaccidental trauma (child abuse). These injuries may have characteristic patterns and are covered in Chapter 143. Children are increasingly involved in athletics and competitive sports. Certain types of injuries, including stress injuries, are often associated with sporting activities (see Chapter 144). Pathologic fractures may be seen with underlying bone tumors, and insufficiency fractures may be seen with metabolic bone disease (see Chapters 138 and 139).

***Fracture Description and Nomenclature.*** Understanding basic fracture nomenclature is important for effective communication. Fractures are subdivided into two basic categories: (1) incomplete (plastic) and (2) complete. Incomplete fractures include *greenstick* and *buckle* fractures. Complete fractures should be described based on orientation: *transverse*, *oblique*, *longitudinal*, and *spiral*. Spiral fractures are defined by an approximately 180-degree or greater twist in the fracture plane. For any fracture, angulation, displacement, diastasis, comminution, and impaction must be described. On follow-up radiographs, any change, in addition to the presence or absence of fracture healing, should be described. Involvement of an open physis and articular surface also should be described. For physeal fractures, it is acceptable to describe the fracture using the Salter-Harris classification.

***Fracture Healing.*** Fracture healing in children has been described in three phases: (1) inflammatory, (2) reparative, and (3) remodeling (e-Fig. 142.1).[6] At the time of fracture, bone and periosteum are disrupted. An inflammatory response is initiated (inflammatory phase), and the organization of a hematoma begins. Bone resorption occurs at areas of necrosis.[7] This peaks 2 to 3 weeks after injury and appears as a poorly defined fracture line.[8] Initial callus is formed during the reparative phase.[6] Callus forming within the hematoma envelops the fracture fragments, joining and stabilizing them. Endosteal callus also forms within the fracture fragments and is seen as increased density on radiographs. Devitalized portions of bone at the margin of the fracture fragments may undergo resorption and appear demineralized on radiographs. An injury that is less than 5 to 7 days old will not show any of these described radiographic features.[7] In time, the woven bone of callus is replaced by organized lamellar bone during the remodeling phase. Remodeling lasts months and occasionally years.[6,7] The healing process is more rapid and complete in children than in adults. Most childhood fractures heal completely and without residual deformity.

***Complications.*** Complications may occur at the time of fracture, during treatment, or as a failure of normal, complete fracture healing. Box 142.1 lists potential complications of pediatric fractures. The incidence of a particular complication varies, depending on many factors, including the site and severity of the fracture, complicating factors (i.e., open fracture), the age and overall health of the patient, associated injuries, and the adequacy of therapy.[9]

In *nonunion*, healing stops before osseous continuity of the fracture fragments occurs. The fracture fragments may form a pseudoarthrosis. Pseudoarthrosis is most common in the clavicle, humerus, and tibia. Nonunion and pseudoarthroses are uncommon in normal children but may be seen with underlying abnormalities such as neurofibromatosis or congenital insensitivity to pain.[10,11] Nonunion is suggested when there is lack of progression to union greater than 6 months after injury when there are corresponding clinical signs and symptoms. The incidence of nonunion is increased with greater injury, comminution, and distraction, and with open fractures complicated by substantial soft tissue injury, infection, or both.[11] Mild degrees of malalignment are well tolerated and usually result in no permanent deformity and resolve over time because of remodeling. Surgical interruption of the healing process to correct residual malalignment is occasionally necessary. Posttraumatic synostoses are most common in the paired bones of the forearm and leg. Infection may occur due to an open fracture or as a complication of surgery or percutaneous pinning.[11]

Fracture at certain sites may result in neurovascular injury; however, such injuries are rare and usually only seen with substantial displacement and deformity, as may occur with supracondylar fractures of the distal humerus.[9] Compartment syndrome is an uncommon complication of extremity fractures, most commonly in the leg or with supracondylar elbow fractures, and may lead to Volkmann contracture caused by ischemia.[9]

Premature fusion occurs in approximately 15% of physeal fractures.[12] A bony "bridge" or "bar" forms across the physis.[13] Prognosis depends on the involved bone, the extent and location of the physeal bar (central versus eccentric), and the amount of remaining growth.[11,12] Morbidity is greater when the remaining growth potential is higher. The phalanges and distal radius are the most common sites of physeal fracture; however, growth arrest is rare in these locations.[12] The distal femur and proximal tibia have a high incidence of posttraumatic physeal fusion but are less common sites for physeal fracture.[12] Premature fusion in the distal femur and tibia is also of greater clinical importance because of possible resultant leg length discrepancy or angular deformity.[12] Indirect physeal insult such as burns, frostbite, and electrical injury, which are discussed later in this chapter, and other processes such as infection, ischemic insult, metabolic bone disease, and iatrogenic causes can also lead to premature physeal fusion (Box 142.2).

Central fusions cause longitudinal growth disturbances. Central fusions can result in a cupped appearance of the physis, with the epiphysis and physis invaginating into the center of the metaphysis

## Abstract:

Fracture patterns, fracture healing, and fracture complications differ between children and adults. Fracture complications are relatively uncommon in healthy children, in whom traumatic deformities typically heal and remodel rapidly. However, the presence of growth processes both predisposes children to types and complications of fractures that are seen in adults. This chapter reviews the imaging of skeletal trauma in children.

**e-Figure 142.1. Stages of fracture healing.** (A) Hematoma under the periosteum surrounding the fracture, communicating through the fracture with blood clot within the medullary cavity. (B) Subperiosteal and endosteal cellular proliferation encroaching on the hematoma. Islands of cartilage may be present. Bone at the margins of the fracture has been devitalized. (C) Fibroblasts, chondroblasts, and osteoblasts are all present at different stages replacing the hematoma with their characteristic extracellular matrix. Callus formation continues from osteoblastic cells in the proliferating cellular masses. The intracellular substance becomes calcified to form woven bone. The dead bone at the margins of the fracture undergoes resorption. (D) Replacement of woven bone by lamellar bone with bone continuity across the fractured area. (E) Remodeling. Cortical bone is organized to conform to the cortex. Resorption of excess bone results in recanalization of the medullary cavity. *(From Bleck EE, Nagel DA.* Physically Handicapped Children*. ### **BOX 142.1** Complications of Fracture

**ACUTE**

- Neurovascular injury
- Hemorrhage
- Fat embolism
- Compartment syndrome

**SUBACUTE OR CHRONIC**

- Premature growth plate fusion
- Delayed union
- Nonunion or pseudoarthrosis
- Malunion or deformity
- Synostosis (cross-union)
- Heterotopic ossification or myositis ossificans
- Overgrowth
- Refracture
- Premature degenerative joint disease (osteoarthritis)
- Osteomyelitis or septic arthritis
- Posttraumatic osteolysis
- Avascular necrosis
- Posttraumatic cyst
- Osteochondroma
- Fibrous cortical defect
- Aneurysmal bone cyst
- Reflex sympathetic dystrophy syndrome (Complex regional pain syndrome)

**IATROGENIC**

- Soft tissue infection
- Hardware misplacement, migration, or infection
- Casting complications
- Hypocalcemia of immobilization
- Superior mesenteric artery syndrome (cast syndrome)
- Deep venous thrombosis or pulmonary embolism

### **BOX 142.2** Causes of Physeal Arrest

- Injuries
    - Fractures involving the physis (Salter-Harris I–IV)
    - Physeal crush injuries (Salter-Harris V)
    - Overuse injuries
    - Electrical injuries
- Burns
- Frostbite
- Infection
- Ischemia and osteochondroses
- Neuropathic (i.e., myelodysplasia)
- Tumor
- Congenital/developmental deformities
- Metabolic bone diseases
- Iatrogenic causes
- Radiation therapy
- Medications (vitamin A analogues)
- Surgical epiphysiodesis

due to tethering.[11,12] Peripheral fusions result in angular deformities.[11,12] Premature physeal fusion usually occurs approximately 3 months after injury.[12] Radiographs may show obliteration of the physeal clear space. Comparison views are often helpful, particularly when evaluating an older child in whom the time of normal physeal closure is near. A secondary sign of premature physeal fusion is tethering of growth lines.[12] Growth lines normally form during the healing process. Normal growth lines parallel the physis, whereas with premature fusion, growth lines are angled toward a bony bar.[12]

Both computed tomography (CT) and magnetic resonance imaging (MRI) have been used to diagnose premature fusion. A limited CT scan with narrow collimation obtained through the physis can depict physeal bridges, which are best seen on sagittal and coronal reformatted images. Small bars may be seen as a sclerotic band across the physis, whereas with larger areas of fusion, continuity of the marrow space across the fusion is seen.[11,12,14] MRI can accurately depict physeal bridges on multiple sequences. The small bridges may appear as low-signal intensity on all sequences, however, if there are stress changes, edema-like signal may be present on T2-weighted sequences. Larger bridges often show signal following fatty marrow on all sequences. A thin-slice sequence with bright physeal cartilage and dark bone (e.g., three-dimensional [3D] spoiled gradient recalled echo with fat saturation) should be performed when evaluating bridges on MRI (Fig. 142.2). Reformatting this sequence into a maximum intensity projection (MIP) image of the physis can be used to create a "physeal map". On this reformatted image, the physeal cartilage is bright while a bridge across the physis is low-signal intensity.[12,15] This allows the radiologist to obtain the area of the bridge and the total area of the physis to obtain the percentage of the physis occupied by the bridge (area of bridge total area of physis = percent of physis occupied by bridge). This percentage is important to the orthopedic surgeon considering bar resection, as discussed later. MRI can also detect the potential fracture complication of trapped periosteum within the physis.[16]

Bar resection is considered when a deformity is present or developing from a physeal bridge, which occupies *less than* 50% of the area of the physis, *and* the child has at least 2 cm or 2 years of expected remaining growth.[11,17] Direct and indirect (metaphyseal) resection approaches can be used and an interposition material is placed in the resection site.[17] Bridges occupying greater than 50% of the physis are not resected because of poor outcomes, and very small bridges may resolve with physiologic growth. Depending on the deformity and growth potential of the patient, other orthopedic techniques may be utilized to minimize morbidity from the premature fusion, including osteotomies, lengthening and realignment procedures, and contralateral epiphysiodesis.[11]

***Imaging.*** Radiographs are the mainstay of imaging of traumatic injuries to the pediatric skeleton. As a general rule, two orthogonal views are obtained to assess for fracture at nonosteoarticular locations and an additional oblique view is added at osteoarticular locations. At some locations, normal anatomy limits the value of orthogonal projections (i.e., the pelvis). At other locations, unique projections are helpful for delineation of anatomy (i.e., an axillary view of the shoulder). When imaging a long bone, both the proximal and distal joints must be included.

Contralateral comparison views are not routinely obtained but frequently aid in differentiating normal developmental variation from pathology.[18] Comparison views are most helpful in areas of complex anatomy such as the elbow. Normal variants are common and may mimic fracture.

At certain sites and with complex patterns of injury, CT is very helpful in diagnosing fractures and delineating the anatomy of fracture planes, resultant deformity, and the extent and type of articular involvement. Occasionally, MRI or ultrasonography can be used to diagnose fractures in children; however, these modalities excel in delineating associated soft tissue injury rather than osseous injury. Ultrasonography, however, may be particularly helpful in infants whose epiphyses are not yet ossified. The cartilaginous epiphysis is well seen with ultrasound and its relationship and continuity with an adjacent metaphysis can be readily assessed. It also can be used to detect lipohemarthrosis as an indirect sign of fracture or to aid in diagnosis of an occult fracture.[19]

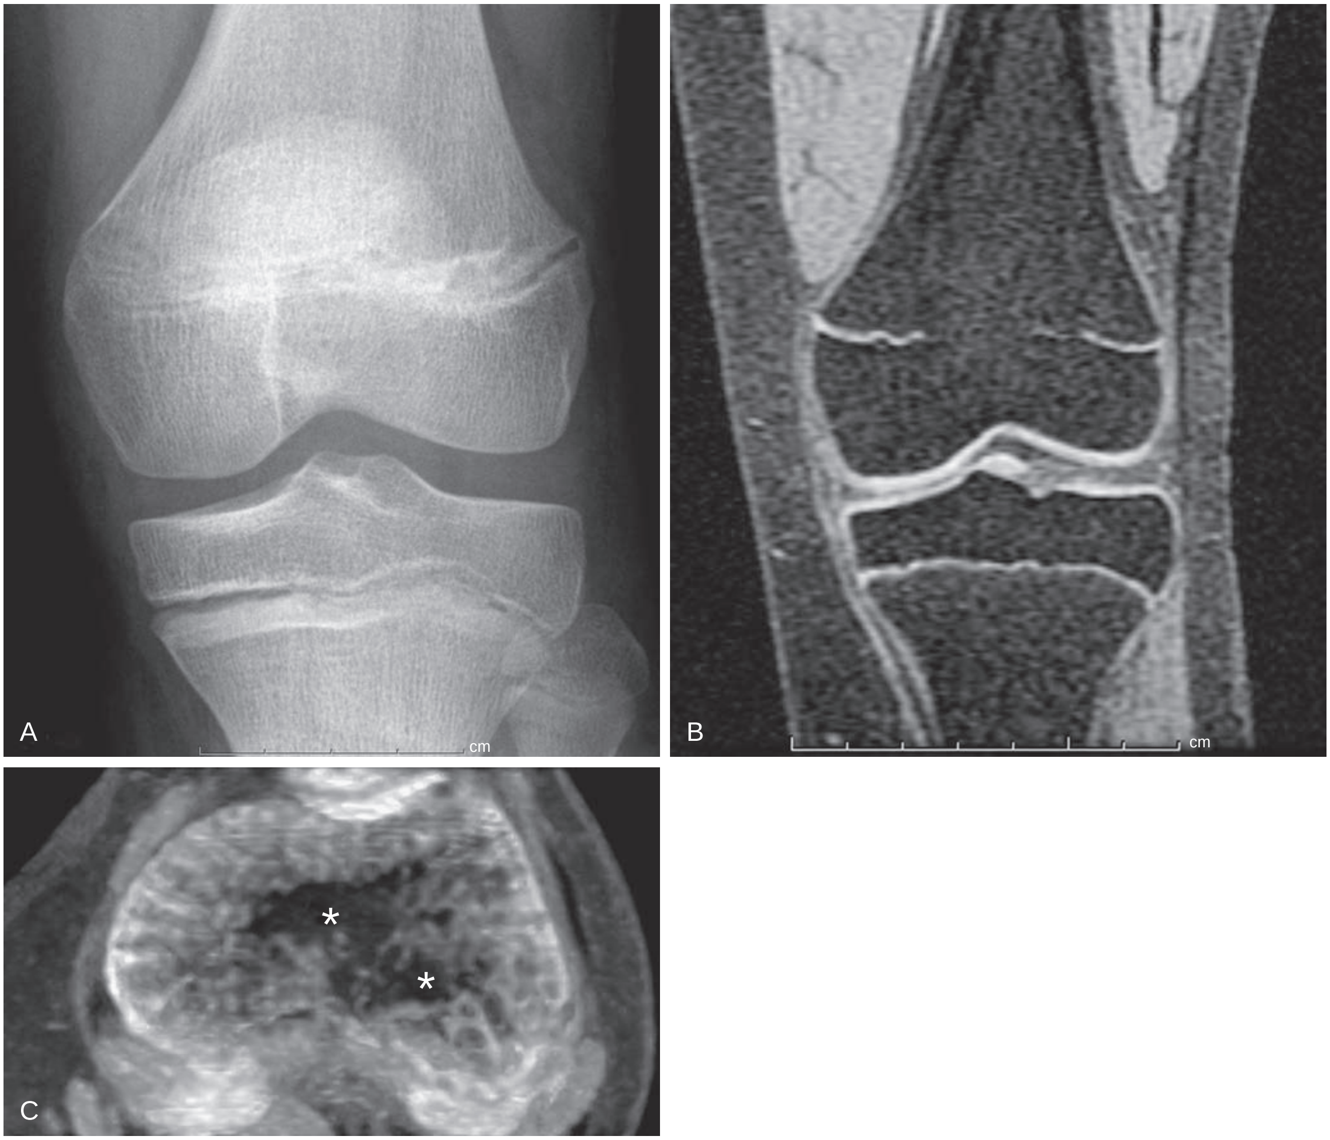

**Figure 142.2. Premature growth plate fusion.** (A) On radiography, the central portion of the distal femoral growth plate is poorly defined; however, the extent of fusion is poorly delineated. (B) Coronal spoiled gradient recalled echo magnetic resonance (MR) image with fat saturation. There is a central physeal bridge, seen as low signal extending across the bright physeal cartilage. (C) Axial maximum intensity projection (MIP) image constructed from the stack of coronal spoiled gradient recalled echo with fat saturation images. The area of the bridge *(asterisks)* and the total area of the physis can be obtained on this MIP image. *(Courtesy of Dr. K. Ecklund, Boston, MA.)*

## PLASTIC FRACTURES

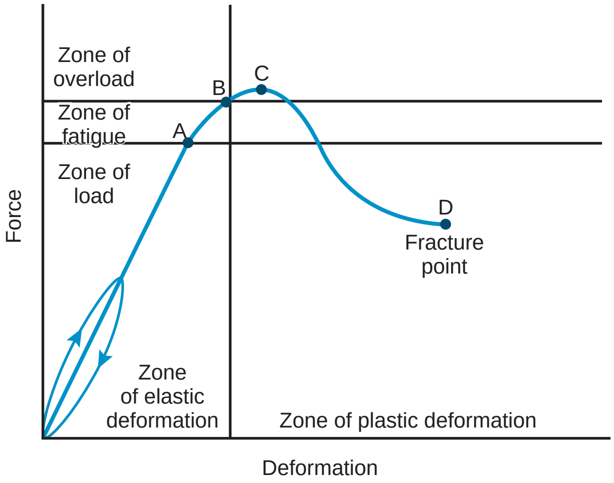
***Etiology, Pathophysiology, and Clinical Presentation.*** The composition of bones in a child is different from that of the bones in an adult.[20] The most apparent anatomic differences in the pediatric skeleton are the presence of the physis and a thick periosteum.[21] The plasticity of a child's bones allows for substantial deformity before fracture (e-Fig. 142.3).[2] Bone may give way and may become permanently deformed before a complete break. The result is an "incomplete fracture" or a "plastic fracture."

A *greenstick fracture* occurs when a cortical fracture occurs on the tension side of bone with intact cortex on the loading side of bone. A torus or buckle fracture is a cortical fracture occurring on the loading side of bone with intact cortex on the tension side. A bowing deformity does not have a radiographically identifiable fracture line on either the tension or loading side of bone.

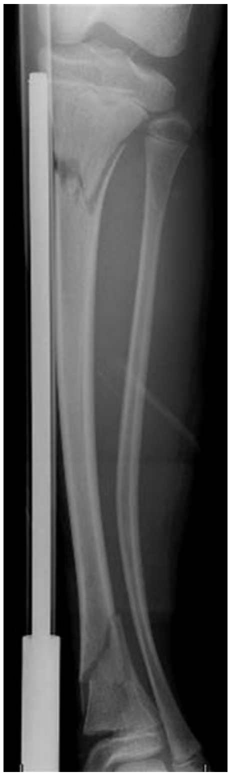
Greenstick fractures most commonly occur in long bones, particularly the radius and ulna.[2] These fractures are most common in the first decade of life, are uncommon in the second decade of life, and are not seen in normally developed and mineralized bones of adults.[2] *Buckle fractures* most commonly affect the distal radius and ulna, tibia, and proximal first metatarsal bone.

***Imaging.*** Radiographs are the standard method of evaluation and advanced imaging is usually not indicated. Subtypes of incomplete fractures are buckle or torus fractures (Fig. 142.4), lead pipe fractures (part transverse fracture or part buckle fracture), greenstick fractures (Fig. 142.5), and bowing deformities (e-Fig. 142.6). With incomplete fractures, the periosteum is intact wherever the cortex is intact.[2]

***Treatment.*** Cast and splinting is usually performed for pain control because most of these fractures are stable. Plastic fractures usually heal completely and have a good prognosis. Rarely, it may



**e-Figure 142.3. Graphic relation of bony deformation (bowing) and force (longitudinal compression).** The limit of an elastic response is not a fracture but plastic deformation. If the force continues, a fracture results. (A) Reversible bowing with stress. (B) Microfractures occur. (C) Point of maximal strength, between (C) and (D) bowing fractures. (D) Linear fracture occurs. *(Modified from Borden S IV. Roentgen recognition of acute plastic bowing of the forearm in children.* Am J Roentgenol Radium Ther Nucl Med. *1975;125:524–530.)*



**e-Figure 142.6. Bowing fracture of the fibula in a 12-year-old boy.** The fibula is bowed, without a fracture line or cortical buckle. Complete fractures of the proximal and distal tibia are present.

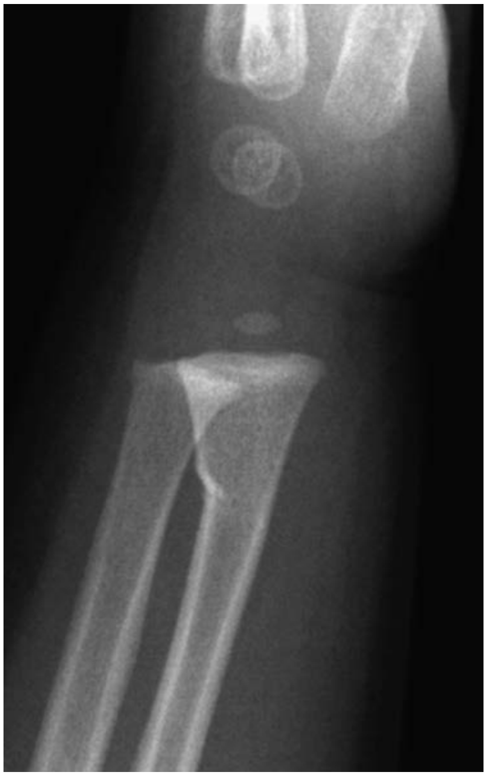


**Figure 142.4. Buckle fracture of the distal radius in a 19-month-old boy.** The dorsal aspect of the distal radius is slightly angulated.

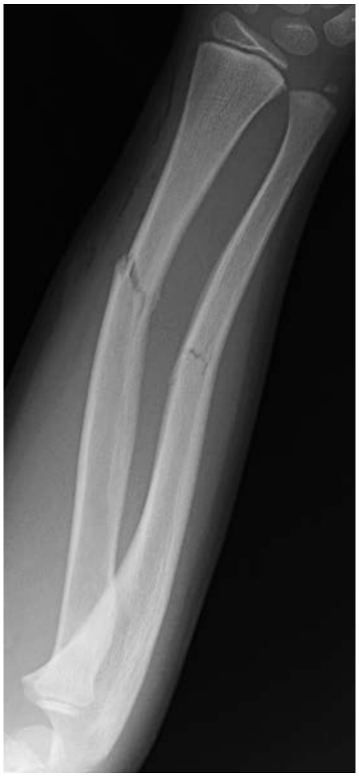

**Figure 142.5. Greenstick fractures of the radial and ulnar diaphyses in an 8-year-old boy.** The fracture lines only extend through part of the cortex.

be necessary to operatively "complete" the fracture for reduction of severe angular deformity. Mild angular deformities (<15 degrees) usually do not need to be reduced and will remodel nicely without permanent sequelae.

## PHYSEAL (SALTER-HARRIS) FRACTURES

***Etiology, Pathophysiology, and Clinical Presentation.*** For the musculoskeletal unit of the child, the physis and physeal equivalent regions are points of relative weakness and are thus predisposed to mechanical failure leading to fractures.[22] The physis usually fails before ligamentous or tendinous soft tissue structures fail after biomechanical stress. Once the physis fuses, ligamentous and tendon soft tissue injuries become more frequent, as do metadiaphyseal fractures. Fracture patterns in skeletally mature adolescents are similar to fracture patterns seen in adults.

Approximately 18% of pediatric fractures involve the physes.[23] Physeal fractures are classified by the system of Salter and Harris (Fig. 142.7). This well-accepted classification scheme for describing physeal fractures facilitates efficient communication between clinicians and radiologists.

***Imaging.*** Most physeal fractures are adequately delineated by radiography. The Salter-Harris classification, the degree of displacement and angulation, and intraarticular involvement should be described.

Fractures may pass solely through the physis (Salter-Harris I; e-Fig. 142.8), involve the physis and metaphysis (Salter-Harris II; Fig. 142.9), involve the physis and epiphysis (Salter-Harris III; e-Fig. 142.10), or cross the physis involving both epiphysis and metaphysis (Salter-Harris IV; e-Fig. 142.11). Crush injury of the physis (Salter-Harris V) is rare as an isolated injury to the bone and are typically diagnosed retrospectively.

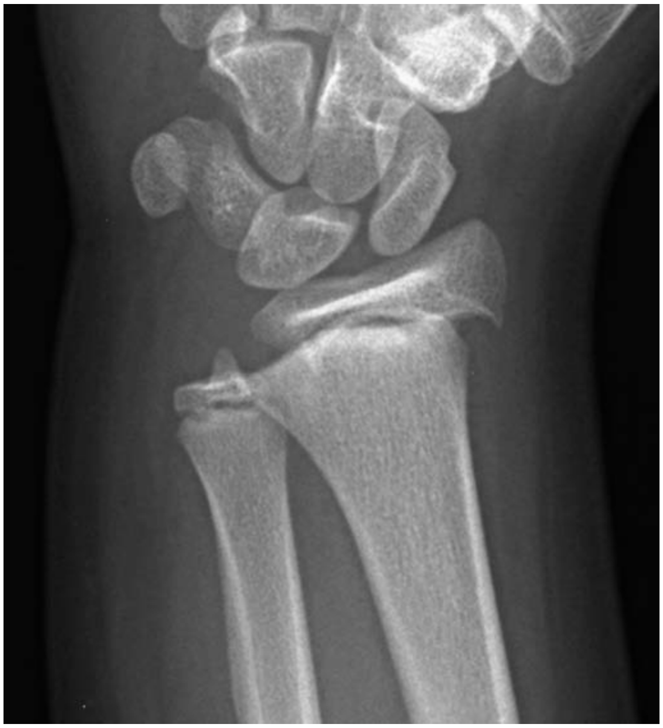
The Salter-Harris classification serves to assign prognosis. Higher grade Salter-Harris fractures have a higher incidence of premature physeal fusion. Most physeal fractures, however, are either Salter-Harris I (approximately 10%) or Salter-Harris II (approximately 75%). Thus although premature physeal fusion is more likely to occur with a higher grade Salter-Harris fracture, this complication is probably more commonly the result of the more common lower grade Salter-Harris fractures. Lesser grades of Salter-Harris fractures that proceed to premature physeal fusion may have a component of crush (Salter-Harris V) injury.

At certain locations, CT or MRI may be used to confirm or further delineate fractures, especially for defining exact measurements of fracture diastasis and whether involvement of an articular surface exists. On MRI, physeal fractures are diagnosed by widening and increased T2-weighted signal within the physis, adjacent bone marrow edema, associated metaphyseal (Salter-Harris II or IV) or epiphyseal (Salter-Harris III or IV) fracture lines, and periosteal disruption.[24] The most significant complication of physeal injuries is growth arrest (see Fig. 142.2), which can lead to deformity and longitudinal growth arrest, potentially with limb length discrepancies.[25] A rare complication of physeal fracture diagnosed by MRI is entrapment of periosteum within the fracture (Fig. 142.12). The entrapped periosteum will prevent complete reduction of the fracture.

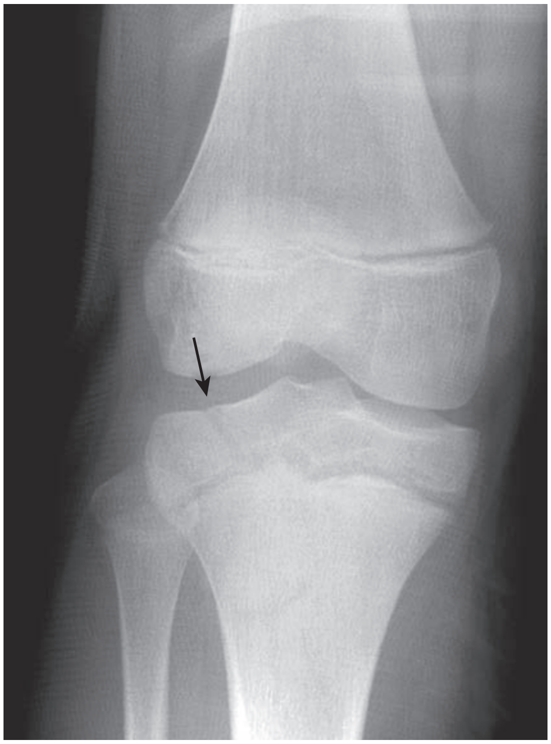
***Treatment.*** Salter-Harris I and II fractures are usually treated by closed manipulation followed by casting. Salter-Harris type III and IV fractures usually require open reduction and internal fixation, as these types of fractures often are displaced and extend to the joint. To prevent posttraumatic osteoarthritis, it is important to create a smooth articular surface; therefore Salter-Harris fractures with epiphyseal involvement and greater than 2 mm of diastasis or significant angulation usually require surgical fixation.

## TRAUMATIC INJURIES OF THE HUMERUS

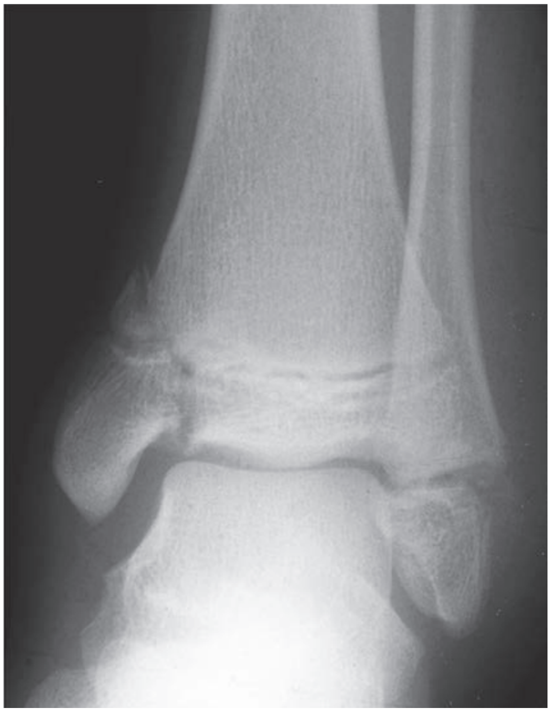
***Etiology, Pathophysiology, and Clinical Presentation.*** Infants and toddlers are likely to have a Salter-Harris I fracture of the proximal



**e-Figure 142.8. Apparent Salter-Harris I fracture of the distal radius in an 11-year-old girl.** The distal radial epiphysis is displaced laterally. No metaphyseal component was seen on this anteroposterior view or on the lateral view *(not shown)*. However, this may represent a Salter-Harris II fracture with a small metaphyseal component, which is radiographically occult, which is much more common in this location.



**e-Figure 142.10. Salter-Harris III fracture of the proximal tibia in a 10-year-old girl.** The proximal tibial physis is wide. The *arrow* shows the vertical epiphyseal fracture line.



**e-Figure 142.11. Salter-Harris IV fracture of the distal tibia in a 13-year-old boy who fell from a tree.** A Salter-Harris I fracture of the distal fibula with overlying soft tissue swelling is also present.

Premature closure

**Figure 142.7. Injuries to the cartilage plate classified according to Salter and Harris.** *Type I,* Fracture involving only the physis. The fracture does not involve the ossified portions of the bone. *Type II,* Fracture involves the physis and metaphysis with a triangular fragment of metaphysis attached to the displaced epiphysis. The prognosis is good. *Type III,* Partial transverse fracture of the physis with a longitudinal or oblique component extending through the epiphyseal ossification center to the articular surface. The prognosis is poor if the epiphyseal fracture is not reduced with smooth joint surfaces. *Type IV,* Oblique longitudinal fracture extending from the articular cartilage through the epiphyseal ossification center, across the physis, and through a segment of the metaphysis. These fractures frequently require open reduction for proper alignment. *Type V,* Compression (crush) injury of the physis, often followed by premature physeal closure and growth arrest. *(From Salter RE, Harris WR. Injuries involving the epiphyseal plate.* J Bone Joint Surg Am. *1963;45:587–622.)*

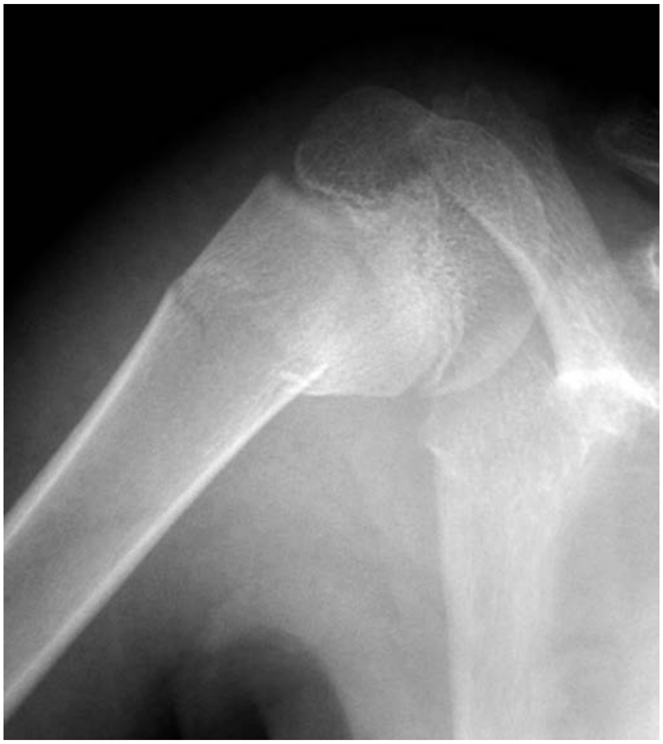
humeral physis. From 5 to 10 years of age, buckle fractures of the proximal humeral metaphysis are most prevalent (e-Fig. 142.13). In older children, Salter-Harris II fractures predominate (e-Fig. 142.14). Fractures of the humeral diaphysis are also common.[26]

The proximal humeral physis can be a site of birth trauma (e-Fig. 142.15).[27] Similar injuries can also be seen with child abuse.

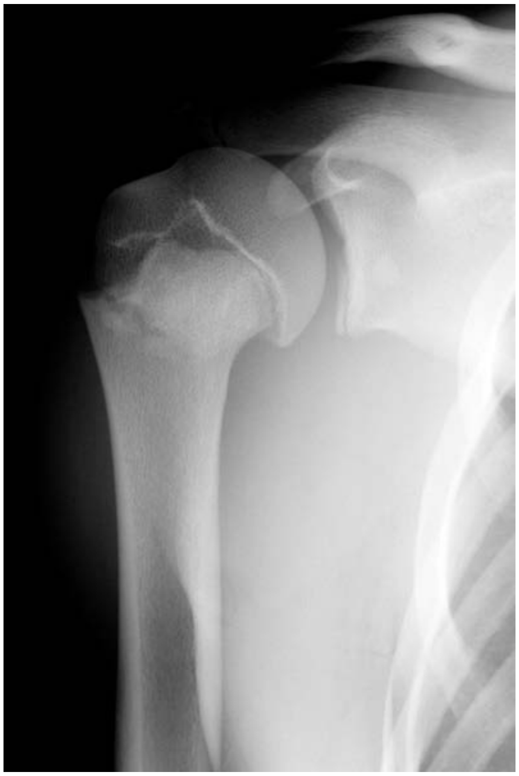
***Imaging.*** Anteroposterior and lateral radiographs of the humerus should be obtained to initially evaluate a fracture. If the fracture is near or involves the glenohumeral joint, an additional axillary view is recommended. If a Salter-Harris type I fracture is suspected in the neonate, evaluation with ultrasonography is preferable, as the proximal humeral epiphysis is cartilaginous readily seen. For older patients or those with complex proximal humeral fractures, CT or MRI may be useful to evaluate for intraarticular extension and for involvement of the greater and lesser tuberosities.

Radiographically, because the humeral head is usually not ossified or only slightly ossified at birth, fracture through the physis mimics dislocation of the shoulder (see e-Fig. 142.15). The humeral metaphysis may appear to align inferior to the glenoid. In the newborn, Salter-Harris I fracture of the proximal humerus is much more common than glenohumeral dislocation.[28] Ultrasound may be used to diagnose the fracture by showing malalignment of the cartilaginous humeral head with the proximal humeral metaphysis and showing motion at the physis (e-Fig. 142.16).[28,29]

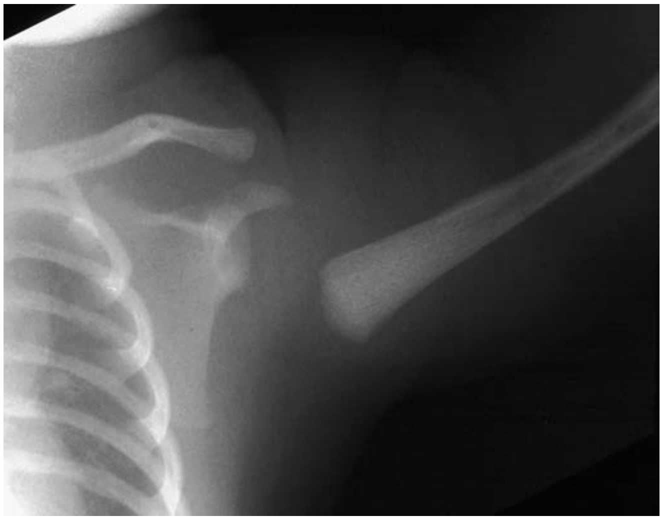
Salter-Harris fractures of the proximal humerus in older children are usually Salter-Harris II fractures, although the metaphyseal fragment is often very small. Occasionally, no metaphyseal fragment exists. Such Salter-Harris I fractures are sometimes called *slipped capital humeral epiphysis*. Typically, with a Salter-Harris I or II fracture of the proximal humerus, the epiphyseal fragment rotates medially because of unopposed pull by the rotator cuff.[27] Salter-Harris III and IV fractures of the proximal humerus are extraordinarily rare. Avulsion of the greater tuberosity is a Salter-Harris III fracture. Avulsions of the lesser tuberosity caused by hyperextension with avulsion of the subscapularis tendon are rare, often delayed in diagnosis, and are best delineated by an axillary view.[30,31]



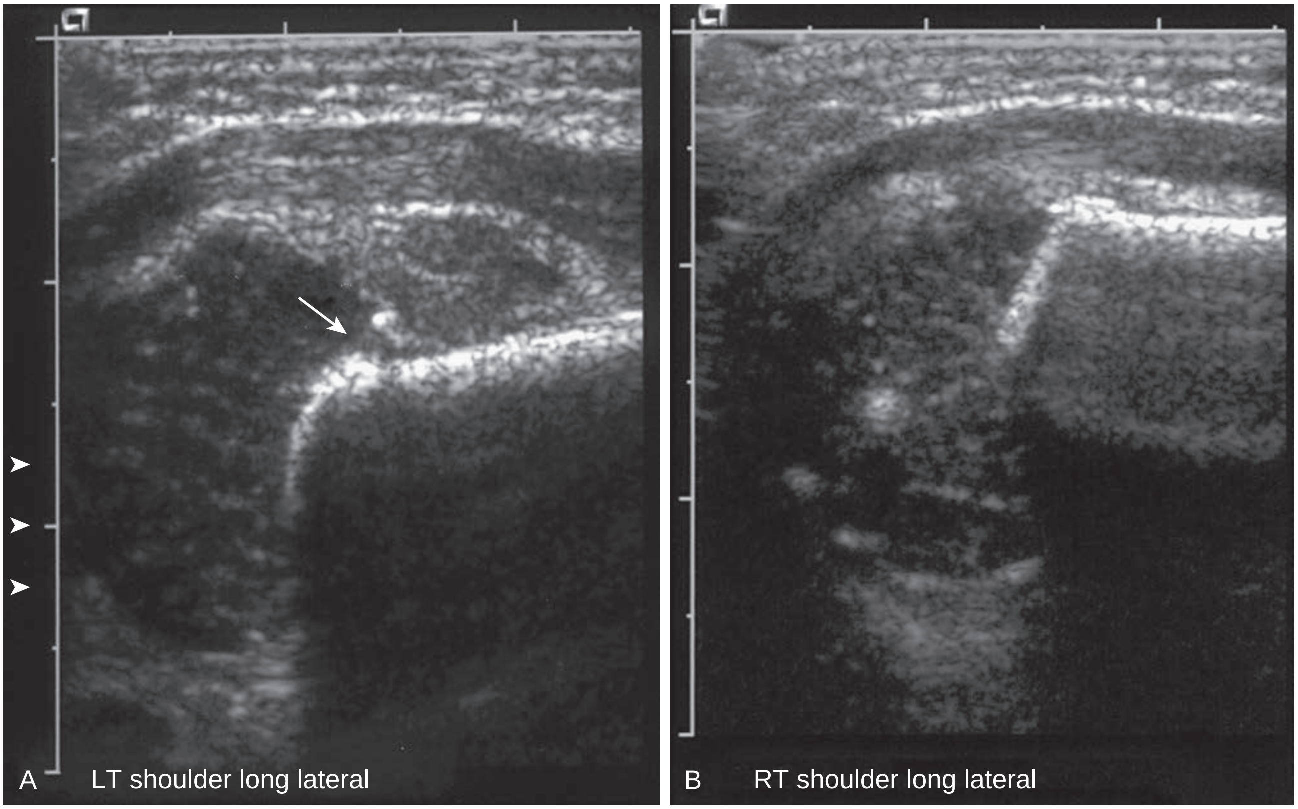
**e-Figure 142.13.** **Incomplete fracture of the proximal humeral metaphysis in a 9-year-old girl.**



**e-Figure 142.14.** **Salter-Harris II fracture of the proximal humerus in an adolescent.** The fracture involves the proximal humeral physis with a small metaphyseal fragment. There is slight medial rotation of the humeral head due to pull of the rotator cuff tendons on the greater tuberosity.



**e-Figure 142.15.** **Proximal humeral Salter-Harris I fracture in a newborn caused by birth trauma.** The proximal humeral metaphysis appears malaligned with the glenoid. The humeral head is not ossified. In an infant, this finding is more likely from epiphyseal fracture and separation than dislocation.



**e-Figure 142.16. Proximal left humeral fracture in a 16-day-old girl with decreased arm movement and normal radiograph.** Sonographic images of the shoulders were obtained in the coronal plane with lateral transducer positioning. (A) In the left shoulder, the cartilaginous epiphysis is displaced laterally from the metaphysis *(arrow)*. There is soft tissue swelling adjacent to the fracture site. (B) Normal right shoulder for comparison.

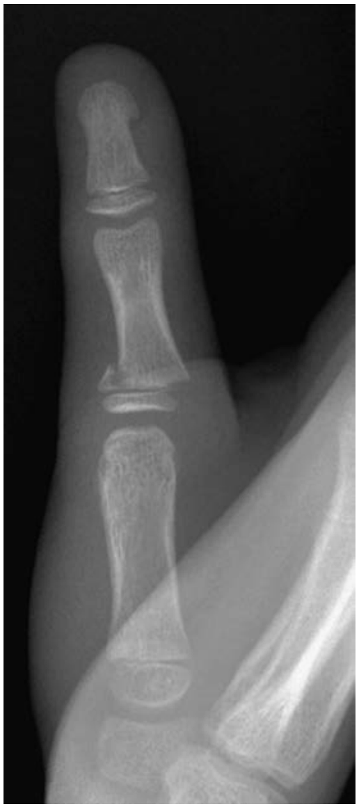


**Figure 142.9. Salter-Harris II fracture of the proximal phalanx of the thumb in a 10-year-old boy.** There is mild ulnar displacement of the distal fragment.

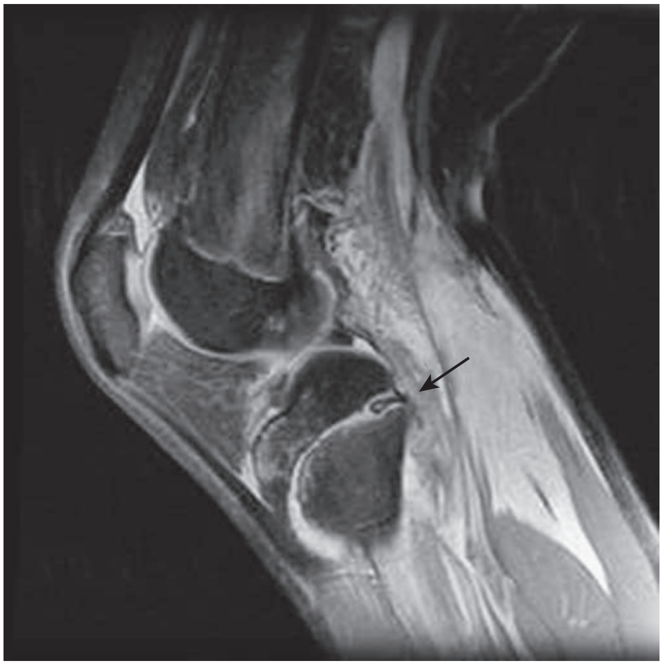

**Figure 142.12. Salter-Harris I fracture of the proximal tibia with trapped periosteum in an adolescent.** Proton density weighted sagittal MR image with fat saturation shows disrupted periosteum is trapped within the physeal fracture *(arrow)*. Abundant soft tissue edema is seen posteriorly. *(Courtesy of Dr. D. Grattan-Smith, Atlanta, GA.)*

In very young children, fractures of the humeral diaphysis may be incomplete fractures; however, beyond the toddler years, most fractures of the humeral diaphysis are complete fractures. The humerus is one of the more common sites for a pathologic fracture because of its propensity to develop solitary bone cysts.[32] The positioning and alignment of the fragments of a humeral fracture are dependent on the site of fracture and its relationship to the deltoid and pectoral muscular insertions.

***Management.*** Proximal humeral fractures are usually treated nonsurgically, including those with significant angulation and displacement. Fractures will heal and remodel without long-term orthopedic sequelae. However, some advocate operative management in certain situations.[33,34] Reduction may be necessary in patients near skeletal maturity if the fracture has more than 50 to 70 degrees of angulation in the coronal or sagittal plane.[35] Operative intervention also is indicated in those patients with associated neurovascular injury or who have intraarticular or open fractures.

## TRAUMATIC INJURIES OF THE ELBOW

### Overview

The complex anatomy of the elbow joint and the immaturity of the pediatric skeleton make this joint particularly susceptible to injury.[36] Complications, although uncommon, include neurovascular injury, malunion, and compartment syndrome.[37]

### Ossification Centers

The normal, orderly progression of the appearance of the ossification of the six major ossifications centers of the elbow (Fig. 142.17) is as follows: capitellum (~1–2 years), radial head (~2–4 years), medial (internal) epicondyle (~4–6 years), trochlea (~9–10 years), olecranon (~9–11 years), and lateral (external) epicondyle (~9.5–11.5 years).[38] This can be remembered by the mnemonics CRMTOL or CRITOE. With very rare exceptions, the medial epicondyle ossifies before the trochlea. If the trochlea is ossified, so should be the medial epicondyle. Fusion of the elbow ossification centers is less orderly, occurring after puberty.

### Joint Effusion

Patients with acute fractures at the elbow that extend into the synovial cavity will usually have an elbow joint effusion.[39,40] The effusion causes displacement of the anterior and posterior fat pads of the elbow (Fig. 142.18). Although the anterior fat pad is seen normally, it may appear elevated by an effusion ("sail sign"). The posterior fat pad normally resides within the olecranon fossa and is not seen on radiographs unless a joint effusion is present causing posterior displacement. The presence of an elbow joint effusion is strong evidence for the presence of a fracture.[41,42] Usually, the fracture is obvious. In younger children, a subtle buckle or greenstick fracture of the supracondylar distal humerus may occur. In older children, a subtle fracture of the radial head or radial neck may occur. The presence of an effusion is not unequivocal evidence for a fracture.[43] However, as fractures are often subtle or occult, the presence of an effusion without an identifiable fracture usually prompts splinting of the arm with follow-up radiographs to assess for healing of an occult fracture.

### Alignment Lines

On a properly positioned lateral view, the anterior humeral cortical line is drawn along the anterior cortex of the humerus. This line should pass through the middle third of the capitellum. Disruption of this relationship aids in the detection of supracondylar fractures, which are usually posteriorly angulated and displaced. The

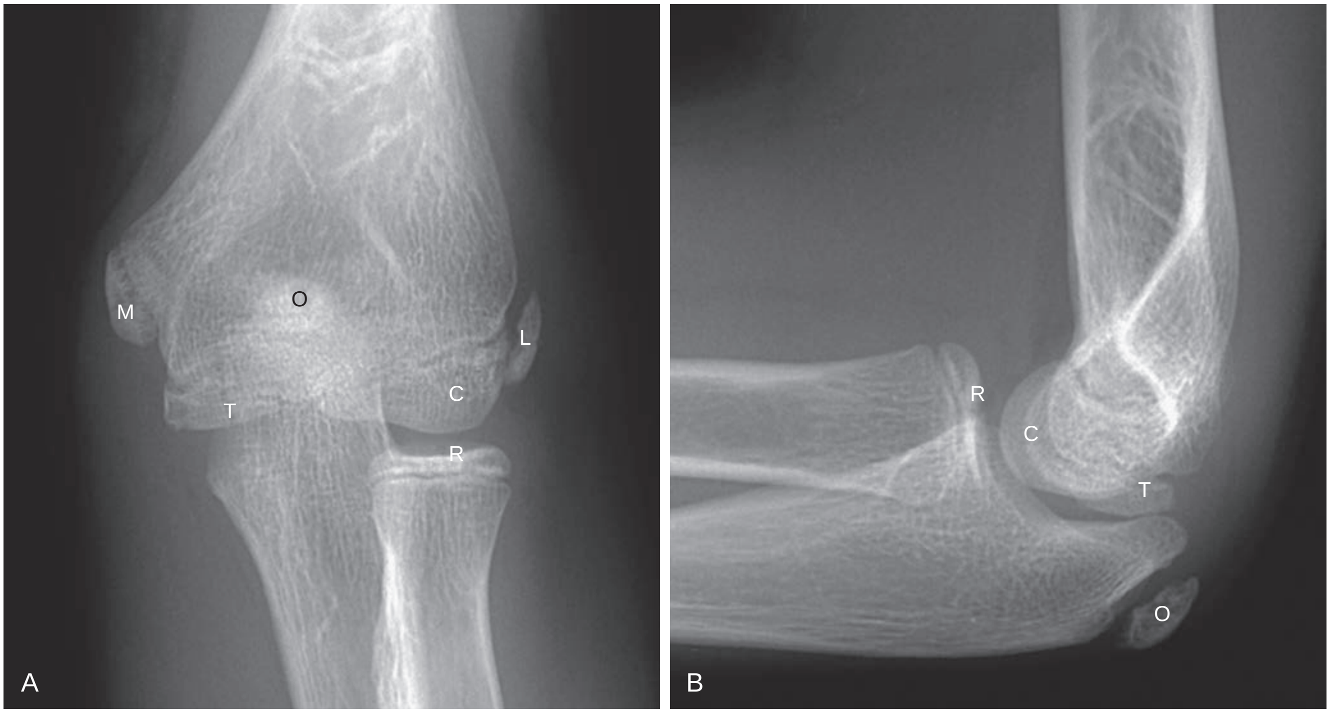

**Figure 142.17. Normal elbow in a 14-year-old boy.** Anteroposterior (A) and lateral (B) radiographs. *C,* Capitellum; *L*, lateral epicondyle; *M*, medial epicondyle; *O*, olecranon; *R*, radial head; *T*, trochlea.

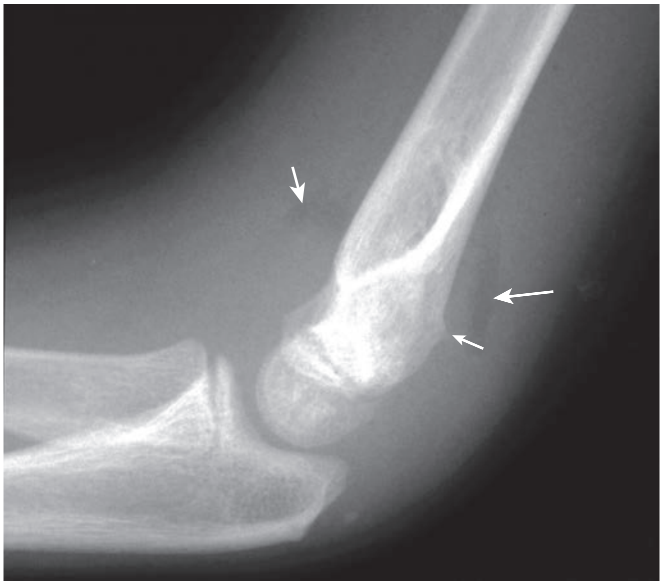

**Figure 142.18. Buckle-type supracondylar fracture *(small arrow)* in a 6-year-old boy.** The anterior and posterior fat pads *(large arrows)* are displaced by an elbow joint effusion. Note that the anterior humeral cortical line passes along the anterior margin of the capitellum, indicating posterior angulation of the distal fragment.

radiocapitellar line is drawn along the axis of the radius. Regardless of patient positioning or projection, this line should pass through the capitellum (Fig. 142.19). Disruption of this relationship aids in detection of radiocapitellar dislocation.[44] Other reasons for radiocapitellar line disruption include lateral condylar, radial neck, and Monteggia fractures.[45]

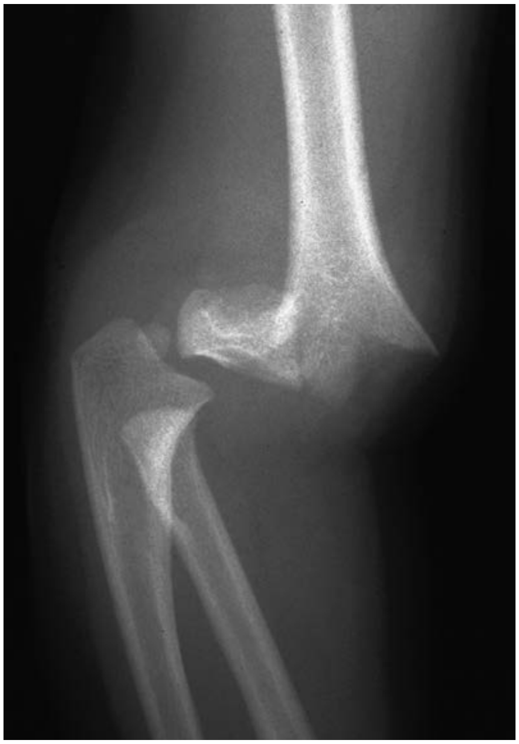
## SUPRACONDYLAR FRACTURES

***Etiology, Pathophysiology, and Clinical Presentation.*** Supracondylar fractures of the distal humerus account for 60% of pediatric elbow fractures.[46] The usual mechanism of injury is hyperextension with impingement of the olecranon on the posterior distal humerus.[47]

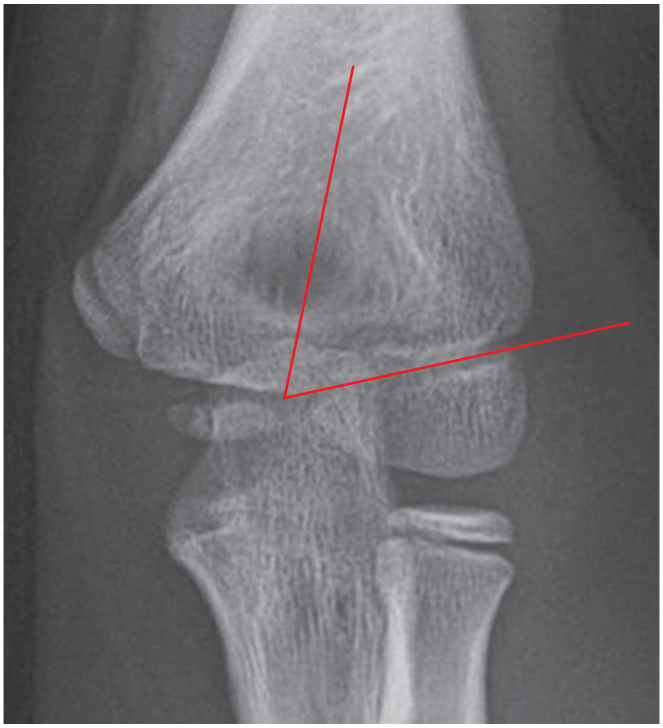
***Imaging.*** The distal fragment of a supracondylar fracture is often displaced or angulated posteriorly. As a result, the anterior humeral cortical line will not bisect the capitellum. If this line passes through the anterior third of the capitellar ossification center or anterior to it, then a supracondylar fracture is likely present.[45]

The modified Gartland classification system of supracondylar fractures is the most commonly used to succinctly describe the fracture and for treatment planning.[48] Type I supracondylar fractures are nondisplaced or minimally displaced less than 2 mm and have an intact anterior humeral line (see Fig. 142.18). Type II fractures are displaced greater than 2 mm with angulation and disruption of the anterior humeral line, but with an intact posterior cortex. Type III fractures are displaced with no cortical continuity (e-Fig. 142.20). Most type II and all type III fractures are treated surgically.[47] The risk of developing trochlear epiphyseal osteonecrosis increases with delayed reduction.[49] Neurovascular injury may occur with displaced supracondylar fractures.

Inadequately reduced supracondylar fractures may cause clinically significant limitations in elbow flexion.[50] After reduction, supracondylar fractures often demonstrate a mild degree of posterior displacement or angulation. This will not adversely affect functional outcome; however, fusion with loss of normal cubitus valgus will potentially inhibit the range of motion of the elbow. Normally, slight lateral angulation of the radius exists relative to the humerus (cubitus valgus) and is greater in females. The Baumann angle is created by the intersection of the humeral axis with a line tangent to the physis of the capitellum (e-Fig. 142.21). This angle can be used to reliably predict the final carrying angle of the elbow after



**e-Figure 142.20. Supracondylar fracture in a 2-year-old boy.** The distal fragment is displaced and angulated posteriorly.



**e-Figure 142.21. Normal elbow of a 10-year-old boy demonstrating a normal Bauman's angle.** On the frontal radiograph the Baumann angle is created by the intersection of the humeral axis with a line tangent to the physis of the capitellum. The normal range is 64 to 81 degrees, but increase in the angle compared with the contralateral side is more predictive of abnormality.

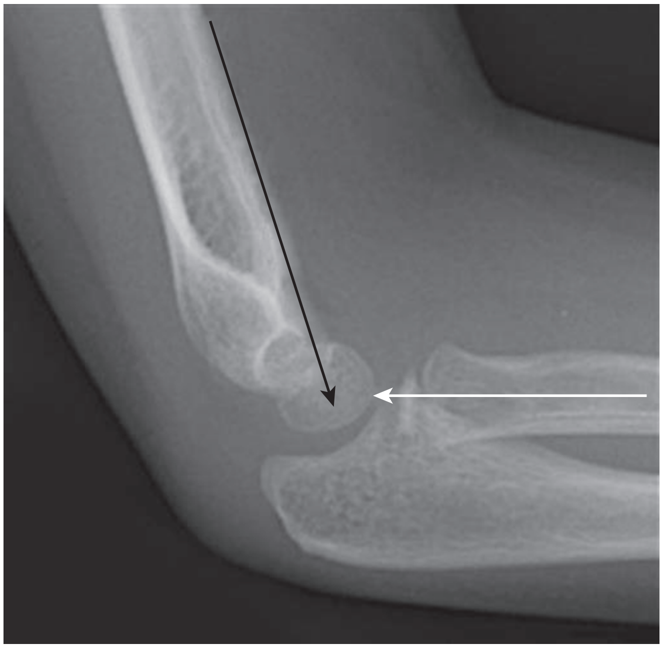


**Figure 142.19. Normal elbow alignment on a lateral radiograph.** The anterior humeral line *(black arrow)* is drawn along the anterior cortex of the humerus and should intersect the middle third of the capitellum. The radiocapitellar line *(white arrow)* is drawn along the axis of the radius. Regardless of patient positioning or projection, this line should pass through the capitellum.

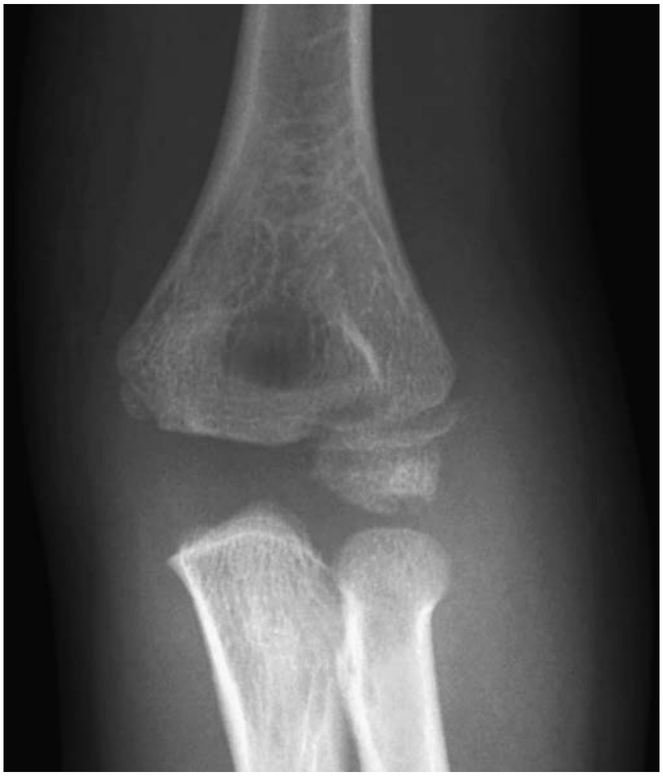

**Figure 142.23. Nondisplaced lateral condylar fracture in a 6-year-old boy.**

supracondylar fractures. The normal angle ranges from 64 to 81 degrees. With posttraumatic cubitus varus, the Baumann angle is increased.[51,52] An increase in the Bauman angle compared with the contralateral, unaffected elbow is more reliable than using an exact number to predict cubitus varus.

***Treatment.*** Conservative versus operative management depends on the degree of displacement, age of the patient, location and stability of the fracture, and associated injuries. Most type I or nondisplaced supracondylar fractures can be treated conservatively in a long arm cast. Most type II and III supracondylar fractures are treated operatively with closed reduction and percutaneous pinning.[53,54]

## LATERAL CONDYLAR FRACTURES

***Etiology, Pathophysiology, and Clinical Presentation.*** Lateral condylar fractures are the second most common type of fracture of the pediatric elbow, accounting for 12% to 20% of pediatric elbow fractures.[55] The mechanism is hyperextension with varus stress.[46] Lateral condylar fractures which extend through the distal humeral epiphysis are Salter-Harris IV fractures.

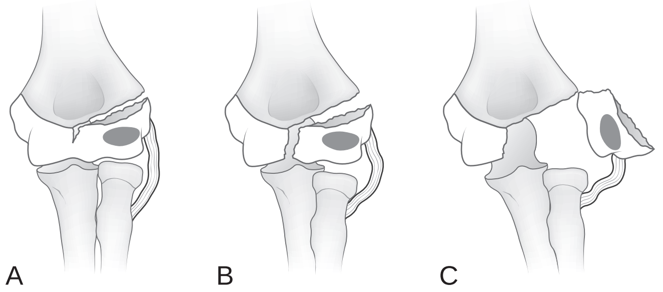
***Imaging.*** An internal oblique view may better delineate the lateral condylar fracture.[56] The fracture may or may not extend through the unossified portion of the distal humeral epiphysis (e-Fig. 142.22). “Stable” lateral condylar fractures (type I) do not traverse the cartilaginous epiphysis and are incomplete and thus nondisplaced or minimally displaced (Fig. 142.23). Type II lateral condylar fractures are complete and thus “unstable” but with little or no displacement. The lateral condylar fracture line may be quite subtle, often paralleling the adjacent metaphyseal margin. Both MRI and ultrasonography have proven capable of demonstrating the fracture through epiphyseal cartilage indicating a Salter-Harris IV fracture.[57] Type III fractures are complete and “unstable”, and the lateral condylar fragment is displaced and rotated; e-Fig. 142.24.

***Treatment.*** Lateral condylar fractures that are nondisplaced (stable) or are displaced 2 mm or less are managed with cast immobilization. Those that are displaced greater than 2 mm (unstable) are treated with surgical fixation with lateral entry pins.[55] Physeal growth arrest and posttraumatic osteoarthritis are more common complications of lateral condylar fractures compared with supracondylar fractures. The most common long-term deformity is relative lateral overgrowth with subsequent cubitus varus.[58]

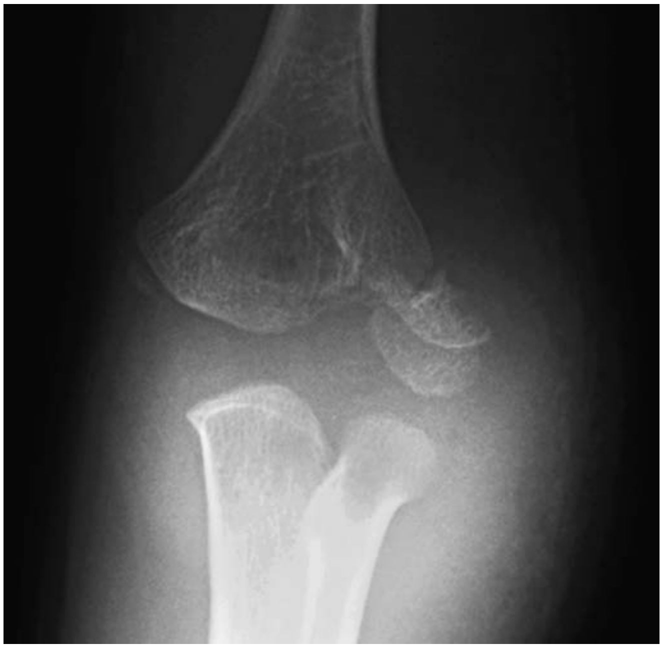
## MEDIAL EPICONDYLE AVULSION

***Etiology, Pathophysiology, and Clinical Presentation.*** The medial epicondyle ossifies by around age 7 years and fuses by around age 16 years.[59] The medial epicondyle is the origin of the forearm flexor mechanism and ulnar collateral ligament. Avulsions thus occur within this age range, although rare avulsions of the unossified medial epicondyle have been reported.[60] Medial epicondyle avulsions may occur secondary to a single acute injury, including elbow dislocations, or from chronic repetitive stress, as is seen in skeletally immature throwing atheletes.[59,61,62] The avulsion occurs because of hyperextension, with valgus stress producing traction on the apophysis by the flexor tendons and pronators. In the setting of an acute avulsion, the child will experience sudden-onset medial elbow pain and have point tenderness over the medial epicondyle.[62] Rarely, the avulsed medial epicondyle may displace into the joint mimicking a trochlear ossification center. This occurs because the valgus stress temporarily widens the joint.

***Imaging.*** Initial assessment should include anteroposterior, oblique, and lateral radiographs of the elbow (Fig. 142.25). With elbow dislocation in the skeletally immature patient, the medial epicondyle is often avulsed from its normal location. When assessing



**e-Figure 142.22. Classification of lateral condylar fractures according to the amount of displacement.** (A) Type I (incomplete) fracture. Note that the fracture line enters the cartilaginous surface of the distal humerus between the capitellum and trochlea. However, the fracture is not complete and does not extend to the articular surface. And it is therefore nondisplaced. (B) Type II (complete) fracture. The fracture extends completely through the cartilaginous distal humerus to the articular surface but has little to no displacement. (C) Type III (complete, displaced) fracture. The fracture extends completely through the cartilaginous distal humerus to the articular surface and is displaced. *(From Green NE, Swinotowski MF.* Skeletal Trauma in Children*, 3rd ed. Philadelphia, PA: Saunders; 2003.)*



**e-Figure 142.24. Displaced lateral condylar fracture in a 6-year-old boy.** Marked soft tissue swelling is present.

the images of a dislocated elbow, the status of the medial epicondyle should be specifically addressed (e-Fig. 142.26).

Some cases of medial epicondyle avulsion fracture occur with a transient, unrecognized dislocation. When an elbow dislocation is reduced, the medial epicondyle may be trapped in the elbow joint (Fig. 142.27). A trapped medial epicondyle may superficially mimic a trochlear ossification center in the first decade of life. However, absence of the medial epicondyle at its normal location should prompt a search for it within the joint. If the trochlea is ossified, the medial epicondyle should be as well. This illustrates the importance of the mnemonics CRMTOL or CRITOE for remembering that the medial (internal) epicondyle typically ossifies before the trochlea.

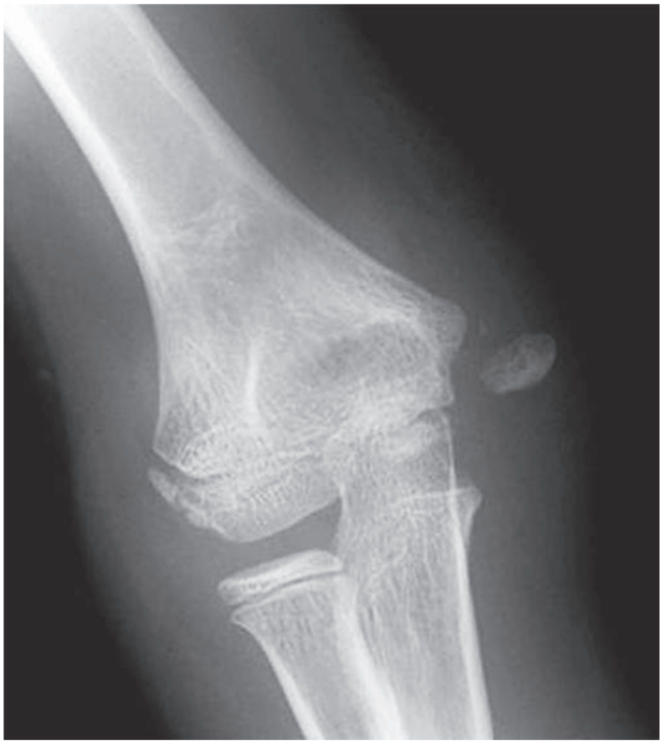


**Figure 142.25. Avulsed medial epicondyle in an adolescent boy.**

Comparison views may be helpful in confirming mildly displaced medial epicondylar avulsion injuries at the level of the medial epicondyle physeal equivalent region; however, they are usually not necessary. Avulsion of the medial epicondyle before its ossification is distinctly rare but has been reported. Ultrasonography, CT, or MRI can be used for fracture delineation.[63]

***Treatment.*** Medial epicondyle avulsion fractures can be treated conservatively if the avulsed fragment is not intraarticular, if the child is less than 5 years of age or the degree of displacement is less than 4 mm. Generally, the need for intervention increases with the age of the child, degree of dislocation, and athletic activity.[64]

## DISTAL HUMERAL SALTER-HARRIS I FRACTURE (TRANSCONDYLAR)

***Etiology, Pathophysiology, and Clinical Presentation.*** Distal humeral Salter-Harris I fracture is an uncommon fracture that occurs from birth to approximately age 7 years, peaking at age 2.5 years. It is typically an injury of infants and young toddlers, and is caused by child abuse in half of the cases or by a rare birth injury.[46,65,66]

***Imaging.*** Radiographically, the fracture may be mistaken for a dislocation of the elbow, as the bones do not appear to align. However, the radial axis will be normally aligned with the capitellum, but the capitellum itself will be abnormally related to the distal humeral metaphysis (e-Figs. 142.28–142.30). The radius, ulna, and humeral epiphysis will be medially displaced. Fractures may occur before capitellar ossification.[67]

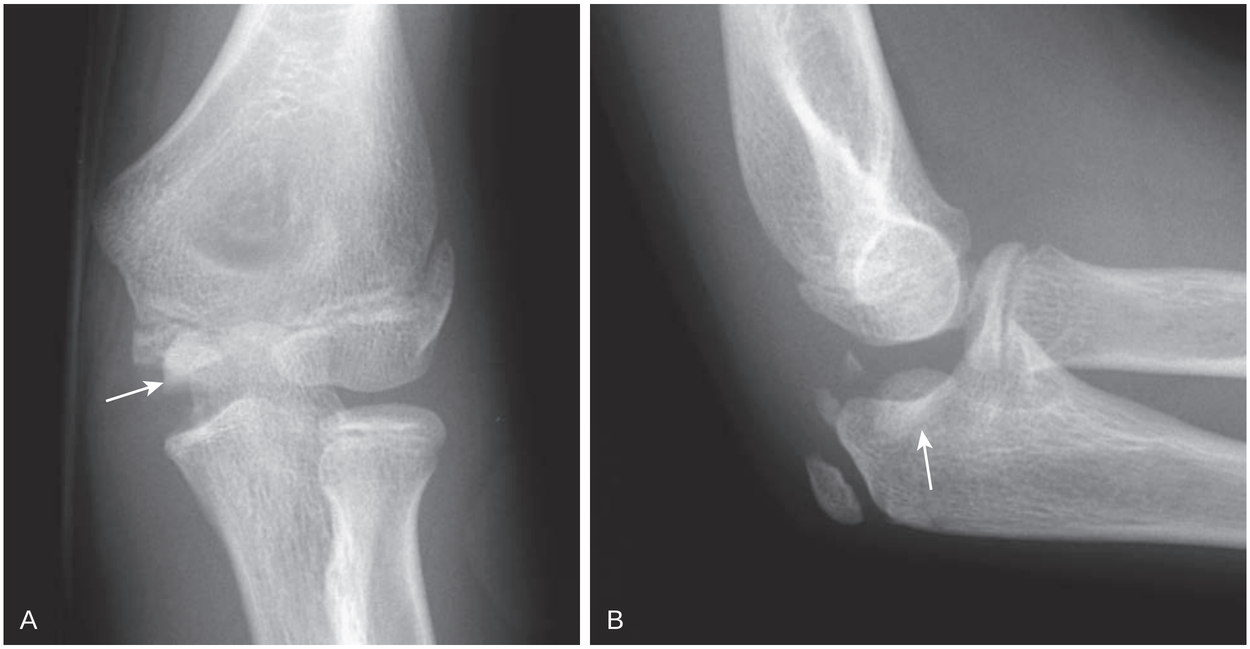

**Figure 142.27. Avulsed medial epicondylar entrapment.** Anteroposterior (A) and lateral (B) radiographs after reduction of a dislocated elbow in a 10-year-old girl show an avulsed medial epicondyle *(arrows)* trapped in the elbow joint.

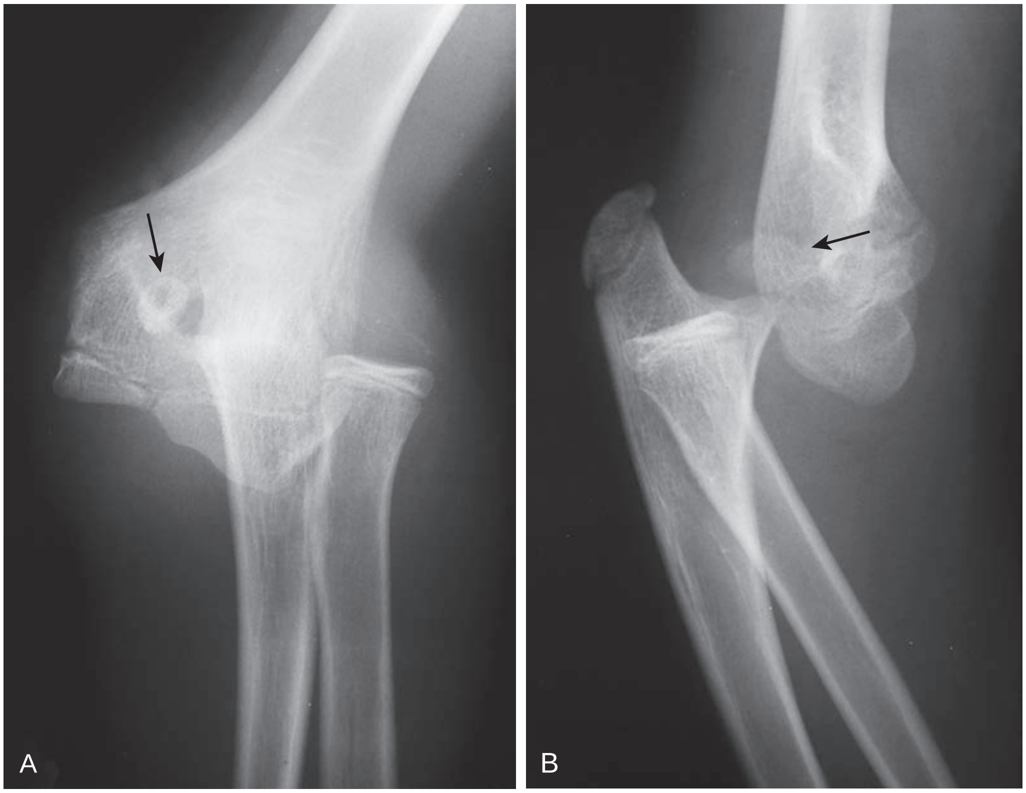
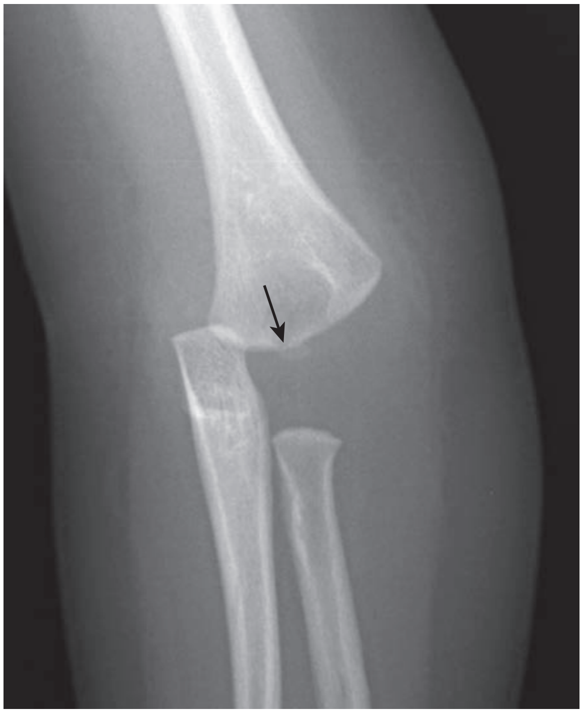
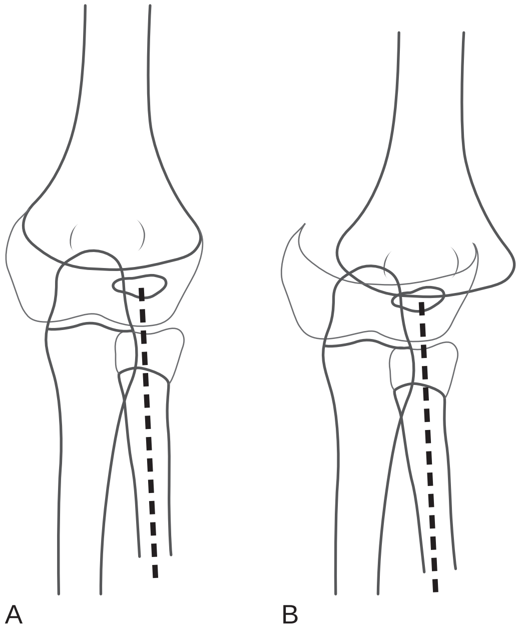


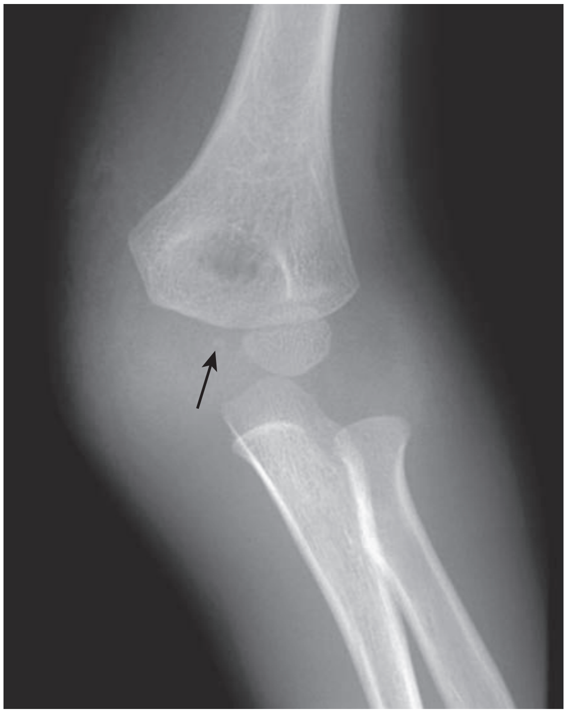
**e-Figure 142.26. Elbow dislocation in a 12-year-old boy.** Anteroposterior (A) and lateral (B) radiographs show an avulsed medial epicondyle *(arrows)* displaced into the joint space.



**e-Figure 142.28. Salter-Harris I fracture (transcondylar fracture) of the distal humerus in a 16-month-old boy.** The capitellum *(arrow)* is not properly aligned with the distal humeral metaphysis, and the whole forearm is shifted medially relative to the humerus. Note that the radial head ossification center is normally aligned with the capitellum.



**e-Figure 142.29. Separation of the entire distal humeral epiphysis.** (A) Normal elbow of a 2-year-old child. Heavy lines represent cortex, and fine lines represent the margin of the cartilaginous epiphysis of the humerus and radius. The radiocapitellar line *(dashed line)* defines the normal relationship of the radius and the capitellum. (B) Salter-Harris type I separation of the entire distal humeral epiphysis. Note the medial displacement of the radius, ulna, and humeral epiphysis. The normal relationship of the radius and capitellum is maintained. *(From Rogers LF.* Radiology of Skeletal Trauma*, 3rd ed. New York: Churchill Livingstone; 2002.)*



**e-Figure 142.30. Elbow dislocation in a 5-year-old boy.** The capitellum is normally aligned with the distal humerus; however, the radius is not properly aligned with the capitellum. Marked soft tissue swelling is seen medially. The medial epicondyle is undoubtedly avulsed and may be represented by a small ossific density *(arrow)*.

***Treatment.*** Nondisplaced fractures will be treated with splinting or percutaneous pinning. Displaced fractures usually are treated with open reduction and internal fixation.

## RADIAL HEAD AND NECK FRACTURES

***Etiology, Pathophysiology, and Clinical Presentation.*** Fractures of the radial head and neck account for 5% of pediatric elbow fractures.[46] Mechanism of injury is falling on an outstretched hand. Fractures in children often occur at or just distal to the physis; this is unlike the adult population where fractures typically involve the radial head.[46] Associated injuries include fracture of the olecranon, avulsion of the medial epicondyle, or medial collateral ligament injury.[46]

***Imaging.*** Radiographs are usually sufficient for diagnosis and follow-up. External oblique views best delineate the radial head and neck morphology. Radial neck fractures are usually buckle fractures or Salter-Harris II fractures. Isolated radial neck fractures as well as fractures with extension to the radial head are unusual. The radiocapitellar joint is often preserved even when radial neck fractures are displaced and angulated.

***Treatment.*** Most pediatric radial head and neck fractures can be treated nonoperatively with closed reduction and immobilization. If there is greater than 30 degrees of residual angulation, greater than 3 to 4 mm of displacement at the fracture site or less than 45 degrees of pronation or supination, then operative intervention is suggested.[68]

## OLECRANON FRACTURES

***Etiology, Pathophysiology, and Clinical Presentation.*** Olecranon fractures are relatively uncommon accounting for approximately 4% to 6% of elbow fractures in children.[46] Common mechanisms include falling on an outstretched hand, twisting injury, or direct trauma.[46] The olecranon is the insertion site of the triceps muscle and prone to avulsion fractures. Olecranon fractures commonly have associated injuries, including radial neck fractures, medial epicondylar fractures, coronoid fractures, and osteochondral injuries.[46]

***Imaging.*** Radiography is usually sufficient for defining olecranon fractures. Olecranon fractures may be transverse, oblique, or longitudinal. Buckle, bowing, or greenstick fractures are common in younger patients.

The olecranon physis and apophyseal ossification centers vary considerably in size, location, and degree of fragmentation.[69] The juxtaphyseal fragmentary appearance of the olecranon ossification center may be mistaken for fracture, and vice versa. Comparison views may be helpful. Olecranon ossifications are well corticated and appear oval or round. Olecranon fractures have a thin, sliver-like appearance, are usually not corticated, and are located near and parallel the olecranon metaphyseal equivalent zone (e-Fig. 142.31). Other olecranon injuries include stress fractures and sleeve fractures. An olecranon sleeve fracture is an avulsion of the triceps tendon from the olecranon process (e-Fig. 142.32). Stress fractures of the olecranon physis occur in adolescent baseball pitchers.[70] Nondisplaced stress fractures of the olecranon most commonly occur in adolescence and may require MRI for diagnosis.

***Treatment.*** Nondisplaced or minimally displaced olecranon fractures are treated conservatively with immobilization and splinting.[69] Displaced fractures are treated with tension wiring across the apophysis rather than screw fixation.[68]

## NURSEMAID'S ELBOW

***Etiology, Pathophysiology, and Clinical Presentation.*** *Nursemaid's elbow* occurs due to an upward pull on an extended elbow in pronation. The annular ligament of the proximal radius is disrupted or displaced, allowing the radial head to sublux or dislocate anteriorly relative to the capitellum (e-Fig. 142.33).[71] This injury most commonly occurs in the toddler years, up to age 5 years.[72]

***Imaging.*** An astute pediatrician will make the diagnosis clinically and reduce the radius without imaging. Often, when imaging is requested, the dislocation is reduced in the course of properly positioning the hand in supination for the anteroposterior view of the elbow. Ultrasonography may also play a role in detecting dislocation of the radial head with respect to the annular ligament.[73] The utility of radiography is not to make the diagnosis of nursemaid's elbow, but to exclude an underlying fracture. After nursemaid's elbow is successfully reduced, the only radiographic sequelae may be a joint effusion without underlying fracture.

When radiographs demonstrate a persistent anterior dislocation despite attempts at reduction, a congenital radial head dislocation should be considered, which has characteristic findings including a convex radial head, small capitellum, and concave shaped posterior margin of the olecranon.

MRI may be indicated when radiographs show persistent radial head dislocation despite attempted reduction to look for obstacles to reduction such as an entrapped annular ligament.

***Treatment.*** Supinating the child's forearm with the elbow in flexion will usually reduce the dislocation. Often, the dislocation is reduced at the time of imaging as previously described. A small percentage of children may have recurrent dislocations, with a higher risk the younger the first dislocation occurs.

## TRAUMATIC INJURIES OF THE FOREARM

***Etiology, Pathophysiology, and Clinical Presentation.*** Fractures of the distal radius and ulna are very common. The distal radius is the most common site of buckle fractures in children and usually occurs after a fall on an outstretched arm. Salter-Harris fractures of the distal radius (usually Salter-Harris II) and transverse fractures of the distal radial metadiaphysis are also common.[74] Stress injury to the distal radial physis is frequently seen in gymnasts. Fractures of the radial and ulnar shafts usually occur together. Often, the fracture in one bone is complete, whereas the other bone may be incomplete fracture.

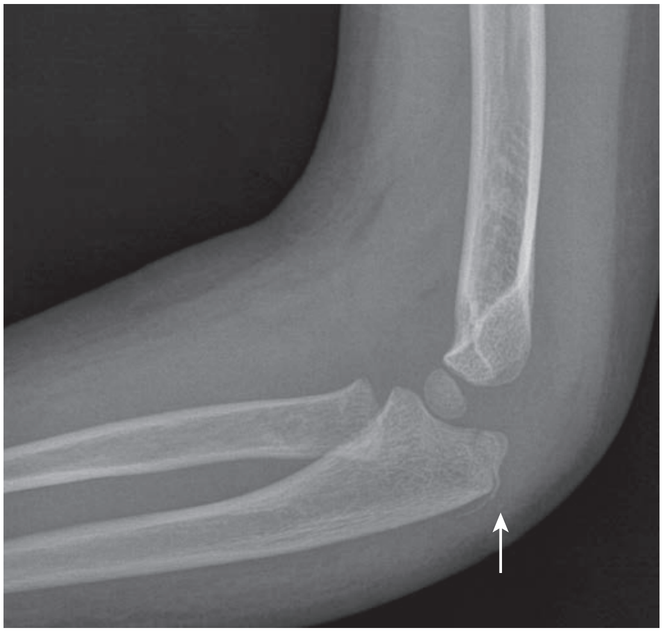
Forearm fractures may also be associated with dislocations. *Monteggia injury* is defined as a fracture of the proximal third of the ulna with dislocation of the radiocapitellar joint.

*Galeazzi injury* is a fracture of the distal radial shaft with a dislocation of the distal radioulnar joint. These injuries are rarely diagnosed in children, as distal radioulnar joint disruption is uncommon, perhaps because of underrecognition. The distal ulna is most commonly subluxed or dislocated in the direction opposite that of distal radial displacement.

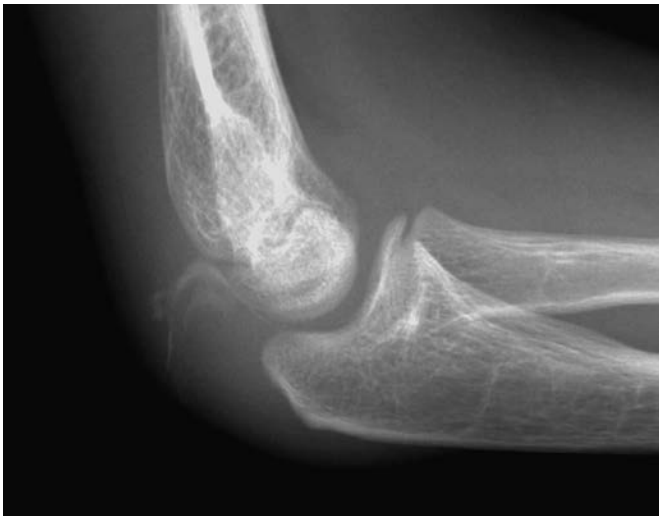
***Imaging.*** In radial buckle fractures, the cortex tends to buckle dorsally. A fracture line may be present volarly. It is important to look at all views for a subtle disruption of the normal smooth flared curve of the metadiaphyseal margin. Any extra angulation or "bump" is likely a fracture (see Fig. 142.4). An associated distal ulnar fracture may or may not be present. With a subtle distal radial fracture, the accompanying distal ulnar buckle fracture may be occult, often not identified until signs of healing are seen on follow-up radiographs. Distal radial buckle fractures may also be associated with triangular fibrocartilage injuries and fractures of the ulnar styloid process. Associated carpal injuries are uncommon.[75]

As with buckle fractures, Salter-Harris fractures of the distal radius and transverse fractures of the distal radial metadiaphysis often occur from falling on an outstretched arm. The distal fragment is usually dorsally displaced or angulated, or both.

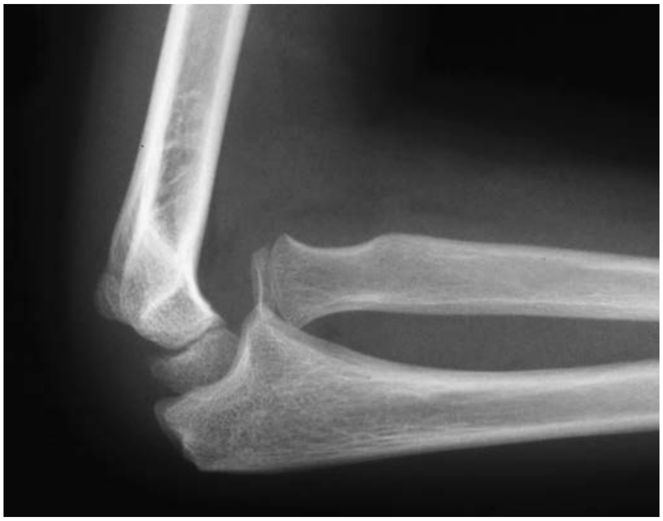
Several subtypes of Monteggia fractures are determined on the basis of the anatomy of the ulnar fracture and the direction of radial head dislocation.[76–78] The most common direction of radial head dislocation is anterior with respect to the capitellum (Fig. 142.34).



**e-Figure 142.31. Olecranon fracture involving the metaphyseal equivalent region *(arrow)* in a 4-year-old boy.** The olecranon epiphyseal equivalent is cartilaginous in a 4 year old.



**e-Figure 142.32. Olecranon sleeve fracture in an 11-year-old boy.** A shell of bone is avulsed from the olecranon process and displaced proximally related to the triceps muscle insertion.



**e-Figure 142.33.** Radial head dislocation in a 9-year-old girl.

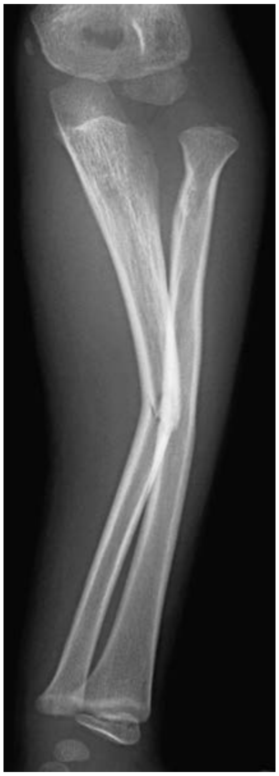


**Figure 142.34. Monteggia fracture–dislocation in a 6-year-old boy.** A greenstick fracture of the ulna is present with medial angulation of the distal ulna. The radial head is anteriorly dislocated.

***Treatment.*** Buckle fractures, including those with mild angulation, are usually treated with a splint. Nondisplaced, complete, nonphyseal fractures are casted. Fractures that involve the distal radial physis usually require closed reduction if displaced. The amount of accepted displacement depends on the type and location of the fracture, age of the child, and direction of angular deformity. In children older than age 10 years, fractures involving the proximal one-third of the radius and those with angulation appear to be at higher risk for failure when treated nonoperatively.[79] Surgical reduction is performed with pin fixation across the fracture. With Monteggia fractures, it is the nature of the ulnar fracture rather than the direction of radial head dislocation that is useful in determining optimal treatment for these injuries. Stable anatomic reduction of the ulnar fractures results in stable anatomic reduction of the radial head.[80] Nonsurgical management of Galeazzi fractures with anatomic reduction and immobilization in a long-arm cast has been successful in children.[81]

## TRAUMATIC INJURIES OF THE WRIST

***Etiology, Pathophysiology, and Clinical Presentation.*** Carpal bone fractures and intercarpal ligament injuries usually occur during the second decade, when children are near skeletal maturity, and follow an adult pattern of injury. Carpal fractures in the first decade are exceedingly rare because of two reasons: (1) the carpal bones have significant epiphyseal equivalent cartilage cushioning the primary carpal ossification centers from injury; and (2) the point of maximal weakness of the forearm and wrist is at the level of the radial and ulnar physes, leading to Salter-Harris fractures, as well as the level of metadiaphyseal cortex where buckle fractures occur. Therefore in the first decade, Salter-Harris fractures and buckle fractures are far more common than carpal bone fractures and ligamentous injuries.

The scaphoid is the most frequently fractured carpal bone. Scaphoid fractures most commonly are transverse and extend through the scaphoid waist. Fractures of the triquetrum are the next most reported carpal bone fracture, followed by the trapezium.[2]

***Imaging.*** Scaphoid views with ulnar deviation will better profile the scaphoid and can be added as a supplement to the standard three view wrist series. CT or MRI (e-Fig. 142.35) can be used to confirm the diagnosis and assess for alternative etiologies for wrist pain.[82] Alternatively, if clinical suspicion persists because of mechanism or physical examination findings (snuffbox tenderness), then splints may be applied, with follow-up radiographs obtained after 10 to 14 days or MRI to reassess for fracture.

The scaphoid artery enters from the distal pole and extends proximally to supply the proximal pole. As a result, proximal pole osteonecrosis may occur after midpole scaphoid fractures. Osteonecrosis is less frequent in the pediatric population compared with the adult population.[2] The affected proximal pole of the scaphoid will appear dense relative to the other bones of the wrist (Fig. 142.36). Nonunion of the scaphoid can occur with or without osteonecrosis. The incidence of nonunion is increased with delay in diagnosis.[83,84] Other complications of scaphoid fractures include humpback deformity, when there is abnormal angulation between the proximal and distal poles, and carpal instability.

Fractures of the triquetrum (e-Fig. 142.37) are seen as a small bony fragment projecting dorsally. Fractures of the hook of the hamate may occur in athletes. Carpal dislocations are rare in children. As in adults, these dislocations may involve a fracture of the scaphoid. Carpal instability rarely manifests in childhood.[83]

***Treatment.*** Scaphoid fractures usually heal with closed treatment and immobilization. Displaced fractures may require either open or closed reduction with internal fixation to minimize the risk of nonunion.[83] Triquetral fractures are usually treated nonoperatively.

## TRAUMATIC INJURIES OF THE HANDS

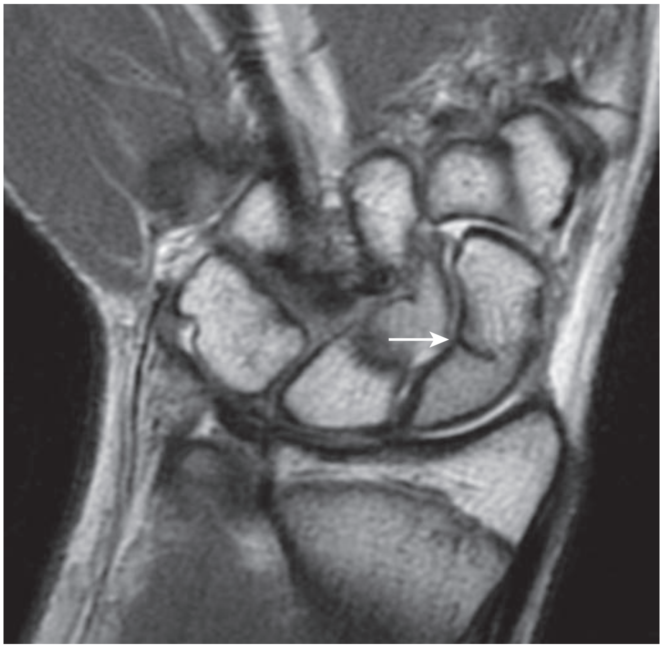
***Etiology, Pathophysiology, and Clinical Presentation.*** Fractures of the hand are common in children. The incidence peak is bimodal, the first peak being at age 1 to 2 years and the second at age 12 years. At age 1 to 2 years, the most common hand injury is a distal phalanx fracture with soft tissue laceration. At age 12 years, the most common hand injury is fracture of the proximal phalanx of the little finger, followed by metacarpal fractures.[85] In general, phalangeal fractures and interphalangeal dislocations are relatively common injuries. Fractures of the hand often involve the physis,[86] and Salter-Harris fractures are common. Growth disturbances in this region are relatively uncommon.[2]

***Imaging.*** Radiography with at least anteroposterior, oblique, and lateral views should be obtained tailored to the specific injured digit rather than imaging the entirety of the hand.

Avulsion injuries usually occur from hyperextension, hyperflexion, or “jamming” of the finger into an object. “Mallet finger” is the result of forced flexion of a distal interphalangeal joint leading to Salter-Harris III fracture–avulsion of the dorsal aspect of the terminal phalanx (e-Fig. 142.38).[86] Volar plate Salter-Harris III avulsion fractures occur along the volar side and may occur at either the terminal phalanx or middle phalanx insertion of the flexor digitorum tendons (e-Fig. 142.39).

Salter-Harris II fractures are common and frequently involve the proximal phalanx of the thumb.[86] Displacement is variable. The fractures may be very subtle with minimal physeal widening or a tiny metaphyseal fragment (e-Fig. 142.40). It may be difficult to distinguish between a Salter-Harris III fracture of the proximal phalanx and a bifid epiphysis, an uncommon normal variant. Salter-Harris I and III fractures occur occasionally in the digits.

Fracture of the fifth metacarpal (“boxer’s fracture”) is the most common metacarpal fracture in adolescents.[85] The fracture plane is transverse or oblique through the metaphysis at the distal aspect



**e-Figure 142.35. Scaphoid fracture.** A 15-year-old boy with T1-weighted coronal MR image demonstrating a nondisplaced incomplete scaphoid waist fracture *(arrow)*.

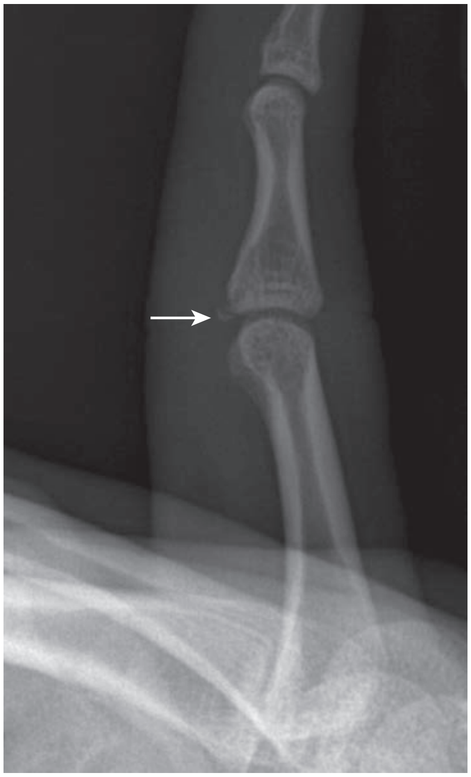
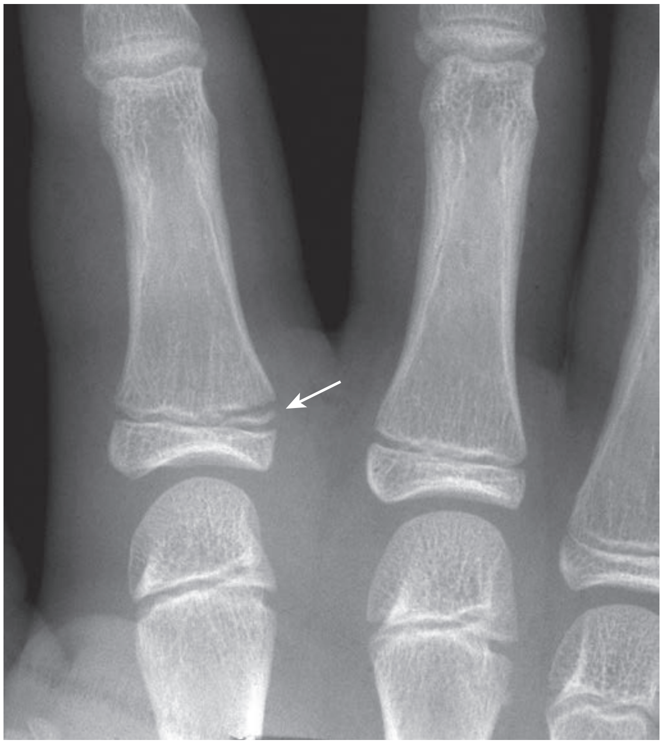
**e-Figure 142.38.** Mallet finger in a 13-year-old boy.



**e-Figure 142.39.** Phalangeal volar plate fracture *(arrow)* in a 15-year-old boy.



**e-Figure 142.40. Salter-Harris II fracture of the proximal phalanx of the index finger *(arrow)* of a 9-year-old girl.** The child was hit with a ball with the finger extended.

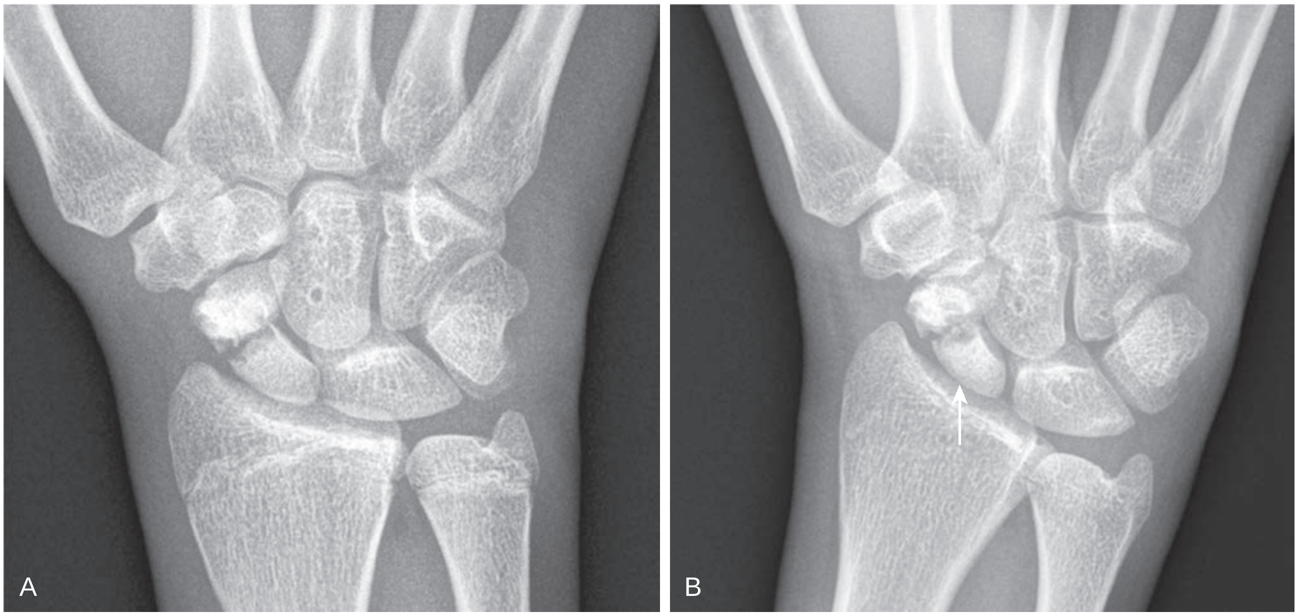


**Figure 142.36. Scaphoid waist fracture in a 16-year-old boy.** (A) Radiograph at presentation demonstrates a mildly displaced scaphoid waist fracture. (B) Repeat radiograph 6 months later shows lack of healing at the fracture site, and subtle increased proximal pole radiodensity *(arrow)* without collapse, suggestive of nonunion and early osteonecrosis.

of the fifth metacarpal. The distal fragment is angulated toward the palm (e-Fig. 142.41).

Salter-Harris III fractures of the first metacarpal bone are analogous to a Bennett fracture occurring after skeletal maturity (e-Fig. 142.42). A Bennett fracture is an intraarticular fracture at the base of the first metacarpal with first carpometacarpal subluxation. A Rolando fracture is a comminuted version of the Bennett fracture. These injuries are rare in children.

"Gamekeeper's thumb" (e-Fig. 142.43) is a traumatic avulsion fracture at the first proximal phalangeal insertion of the ulnar collateral ligament. This injury can be seen in children from a ski pole injury.[87] An avulsion may be seen at the ulnar volar base of the proximal phalanx of the thumb or a Salter-Harris III fracture if the physis is not yet fused. Radial subluxation of the proximal phalanx may be evident, but stress views may be required to show instability in the absence of fracture. Ulnar collateral ligament avulsion may also cause a Stener lesion with the adductor aponeurosis interposed between the torn ulnar collateral ligament and its insertion, preventing approximation, which can be diagnosed on MRI.

***Treatment.*** Nearly all metacarpal and phalangeal fractures are treated nonsurgically with 3 to 4 weeks of immobilization.[2] Surgical pinning is required for intraarticular fractures, particularly those involving the interphalangeal and metacarpophalangeal joints. Nondisplaced avulsion fractures are typically treated by brace taping or buddy taping the injured digit to its neighbor. Stener lesions are managed operatively.[86]

## TRAUMATIC INJURIES OF THE PELVIS AND HIP

### Pelvic Fractures

***Overview.*** Pelvic fractures are not common in children.[88] Pedestrian–motor vehicle collisions account for the majority of cases, followed by falls. The majority of victims are boys.[88,89] A pelvic injury in a child is a marker of severe injury and should alert the clinician to search for additional injury.[89,90] Apophyseal avulsion injuries of the pelvis are covered in Chapter 144.

***Etiology, Pathophysiology, and Clinical Presentation.*** Once a patient has reached skeletal maturity, pelvic ring fracture patterns follow the adult fracture pattern and classification.[91] Several classifications schemes have been applied to pediatric pelvic fractures such as the classification scheme of Torode and Zieg (e-Fig. 142.44).[92] Disruption of the sacroiliac joints or pubic symphysis may accompany pelvic fractures. Plastic or incomplete fractures may be seen in children. Usually, if a break in the obturator ring or pelvic ring is present, another break is also present. Younger children, however, may not follow this rule because of the plasticity of their bones.[93,94]

Fractures involving the acetabulum of young children are fortunately rare. Acetabular fractures become more common in the later teen years because of motor vehicle accidents[93] and follow patterns similar to those in adults. Most occur in association with hip dislocations.[94]

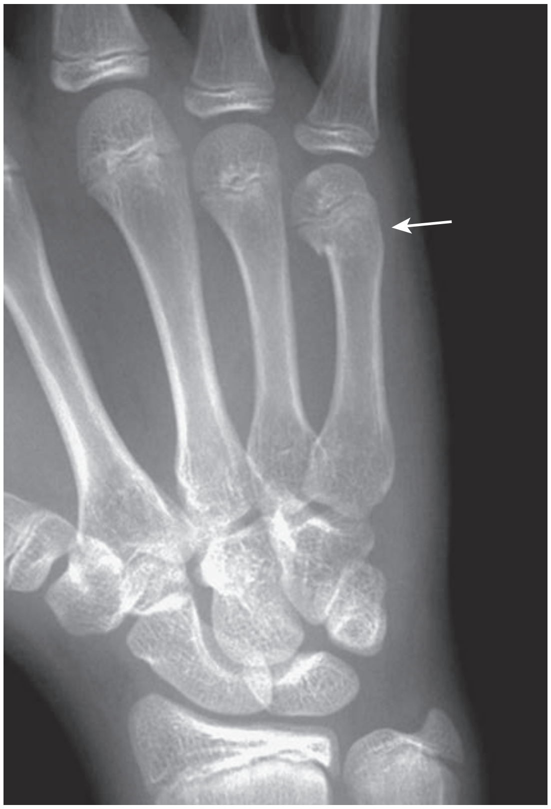
***Imaging.*** CT is the preferred modality for delineation of unstable pelvic fractures. Although most fractures are seen on radiography, CT better delineates the full extent of fracture.[95] Radiography is not necessary if CT will be performed to evaluate for other injuries.[96]

Asymmetric widening of the triradiate cartilage may be noted in acetabular fractures (e-Figs. 142.45 and 142.46). In younger children, fractures involving the triradiate cartilage are prone to complications, particularly when displaced fragments are present. Premature fusion of the triradiate cartilage may lead to a shallow acetabulum and progressive hip instability.[93] This complication is more common in children under age 10 years at the time of fracture.

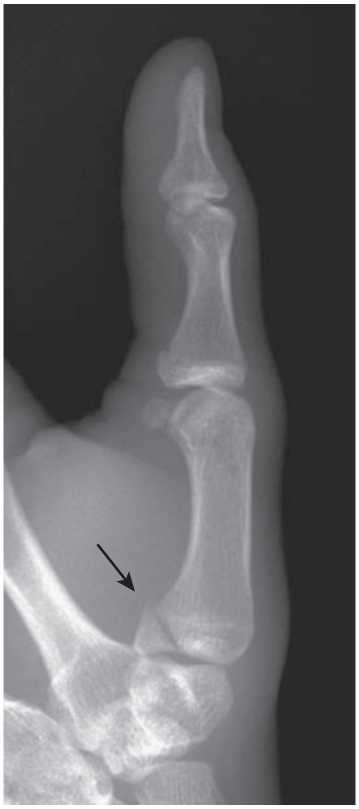
***Treatment.*** The majority of pelvic fractures can be treated nonsurgically.[89,97,98] Surgical intervention is needed for unstable fractures or fracture-dislocations.

### Hip Dislocation

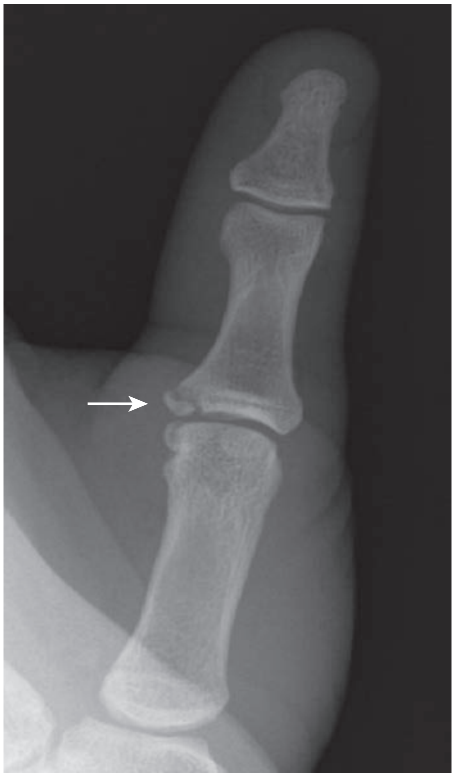
***Overview.*** Traumatic hip dislocations are more common in adolescence. The hip usually dislocates posteriorly. Compared with adults, these injuries are less commonly associated with acetabular fractures.[94]



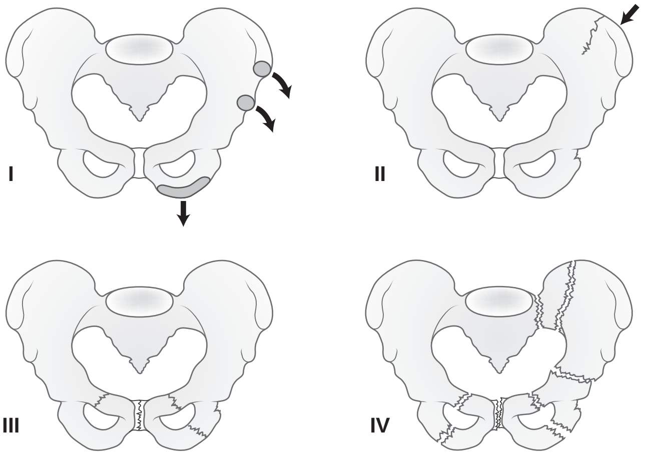
**e-Figure 142.41. Boxer's fracture of the fifth metacarpal *(arrow)* in a 17-year-old boy who punched a wall.** Slight palmar angulation of the distal fracture fragment is seen distally.



**e-Figure 142.42. Salter-Harris III fracture of the base of the thumb metacarpal *(arrow)* in a 16-year-old boy.** The injury occurred when the boy's thumb caught on another player's equipment while playing football.



**e-Figure 142.43. Gamekeeper's thumb fracture *(arrow)* in a 14-year-old boy.**



**e-Figure 142.44. Pelvic fractures in children—Torode and Zieg classification.** *Type I,* Avulsion fracture. *Type II,* Iliac wing fracture. *Type III,* Simple ring fracture. *Type IV*, Ring disruption fracture. *(Modified from Beaty JH, Kasser JR.* Rockwood and Wilkins' Fractures in Children*, 6th ed. (A) Anteroposterior radiograph of the pelvis shows left pubic fractures and widening of the left triradiate cartilage. (B) Axial CT image shows the superior pubic ramus fracture to extend to involve the triradiate cartilage.

**e-Figure 142.46. Types of triradiate cartilage fractures.** (A) Normal triradiate cartilage. (B) Salter-Harris I fracture. (C) Salter-Harris II fracture. (D) Salter-Harris V (compression) fracture. *(From Scuderi G, Bronson MJ. Triradiate cartilage injury: report of two cases and review of the literature.* Clin Orthop Relat Res*. 1987;217:179–189.)*

***Etiology, Pathophysiology, and Clinical Presentation.*** In adolescents, hip dislocation is usually the sequela of significant trauma such as that sustained in motor vehicle accidents, whereas younger children may dislocate their hips with relatively minor trauma, usually falls.[99] Fractures of the acetabulum and femoral head can occur at the same time. When dislocations occur with minimal trauma, ligamentous laxity should be considered as a possible underlying condition such as that seen with Ehlers-Danlos syndrome, Larsen syndrome, and Down syndrome.

***Imaging.*** Initial imaging evaluation should be radiographs (Fig. 142.47). If asymmetry of the hip joint persists on radiography after reduction, then further evaluation with either CT or MRI (e-Fig. 142.48) should be considered to evaluate for labral entrapment or interposed osteochondral fragments. If a fracture of the acetabular wall or femoral head is suspected, CT or MRI should be obtained, as it could alter patient management.

***Treatment.*** Most hip dislocations in children are reducible with gentle manipulation; however, closed reduction of the hip in the adolescent population carries a risk of epiphyseal osteonecrosis. Open reduction is necessary when closed reduction fails or when interposition of soft tissue or bone exists. Additional complications of hip dislocations include premature osteoarthritis and sciatic nerve injury. If the delay in reduction is greater than 6 hours, the risk of osteonecrosis is significantly increased.[100,101]

## Slipped Capital Femoral Epiphysis

***Etiology, Pathophysiology, and Clinical Presentation.*** Slipped capital femoral epiphysis (SCFE) is the most common hip disorder affecting the adolescent population.[102] SCFE is essentially a Salter-Harris I fracture of the proximal femoral physis. SCFE occurs more frequently in boys than in girls, tends to occur earlier in age in girls compared with boys, and occurs more commonly in African Americans. SCFE is usually idiopathic with a higher incidence in children who are clinically obese.[102,103] Risk factors for SCFE include hypothyroidism, pituitary dysfunction, hypogonadism, and renal osteodystrophy.[104,105] Hips previously exposed to a radiation treatment field are at increased risk. When a child presents with bilateral symmetric SCFE or outside of the typical age range, an underlying disorder should be suspected.[106]

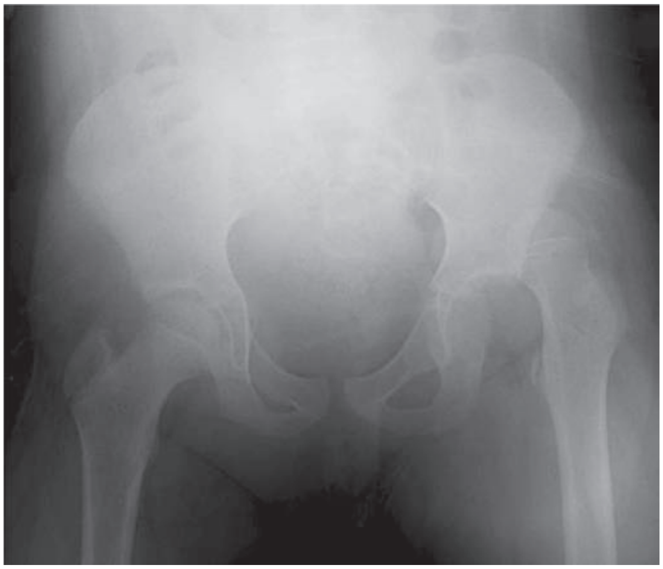

**Figure 142.47. Hip dislocation.** A single anteroposterior radiograph of the pelvis in a 9-year-old girl demonstrates superolateral position of the left femoral head compatible with a posterior hip dislocation.

Approximately 25% of patients will have bilateral SCFEs,[104,105] and approximately half of these present synchronously. Risk for contralateral SCFE is greatest in the first 2 years after initial diagnosis.[104]

Children with SCFE usually present with hip, groin, or thigh pain. Symptoms may first occur after minor trauma. Up to one-quarter of patients present with referred knee pain.[106] Hip radiographs are therefore recommended in the adolescent with unexplained knee pain. SCFE can be categorized as acute or chronic and stable or unstable.[107–110] By definition, patients with stable SCFE are able to bear weight.

***Imaging.*** Radiography for suspected SCFE should include a pelvic anteroposterior and "frogleg" lateral view. Both hips should be included. Epiphyseal slips may occur in the medial direction, posterior direction, or both. The frogleg lateral view is helpful, as most epiphyseal slips occur in the posterior direction, which can be subtle on the anteroposterior view (Fig. 142.49). The anteroposterior view best assesses the degree of medial displacement, which is often subtle. Klein's line is drawn parallel to the lateral margin of the femoral neck on the anteroposterior view. Normally, a small portion of the femoral head extends lateral to Klein's line. When the femoral head does not extend lateral to Klein's line, medial displacement should be suspected (see Fig. 142.49).[111] Theoretically, Klein's line can potentially be preserved if the SCFE is directly posterior without a medial component. The smaller the capital femoral epiphysis appears on the anteroposterior view, the greater is the degree of posterior slip.

With chronic slips, sclerosis may be seen in the medial femoral neck with bone remodeling ("buttressing") in response to altered mechanics (e-Fig. 142.50).

CT and MRI may also be used to make the diagnosis of SCFE; however, radiographs usually suffice. MRI can be used to detect a "pre-slip" state, as evidenced by physeal widening with adjacent bone marrow edema.[112] MRI may also be used in follow up to evaluate cartilage and labral abnormalities that can result as chronic sequelae of SCFE, the latter due to femoral acetabular impingement secondary to CAM-type deformities, which may form at the femoral head-neck junction.

***Treatment.*** In situ fixation with transphyseal screw is the treatment for SCFE. Prophylactic pinning of the contralateral hip may be performed in high-risk individuals. Timing of treatment is predicated on symptoms. Stable SCFEs can be electively pinned. Unstable SCFEs usually require urgent or emergent pinning, as they are at higher risk for epiphyseal osteonecrosis. Reduction of the capital femoral epiphysis is performed with extreme caution, because even minimal manipulation may disrupt the epiphyseal blood supply.

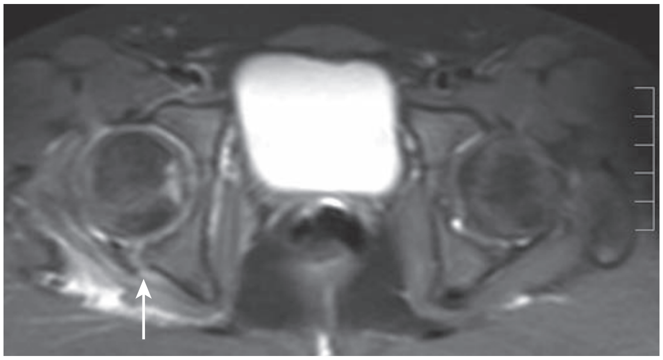
Complications after SCFE treatment include epiphyseal osteonecrosis (Fig. 142.51) and chondrolysis (e-Fig. 142.52). Epiphyseal osteonecrosis is more frequent after treatment of unstable SCFE. Chondrolysis used to complicate 5% to 10% of patients with SCFE, but the incidence has substantially lessened with newer fixation techniques.[113] Chondrolysis is now rarely seen without accompanying epiphyseal osteonecrosis. An additional complication of SCFE is cam-type femoroacetabular impingement related to abnormal offset of the femoral head and neck junction (see Chapter 144).

## TRAUMATIC INJURIES OF THE KNEE

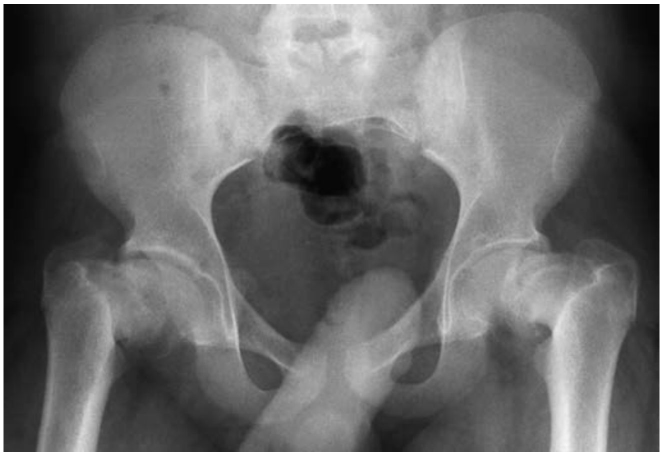
***Overview.*** Before physeal fusion, the physes are the usual site of traumatic injury at the knee.[114] Once the physes fuses, cruciate ligament injury becomes much more common.[115] Hemarthrosis of the knee joint may be the consequence of soft tissue injury and/or fracture.

## DISTAL FEMUR

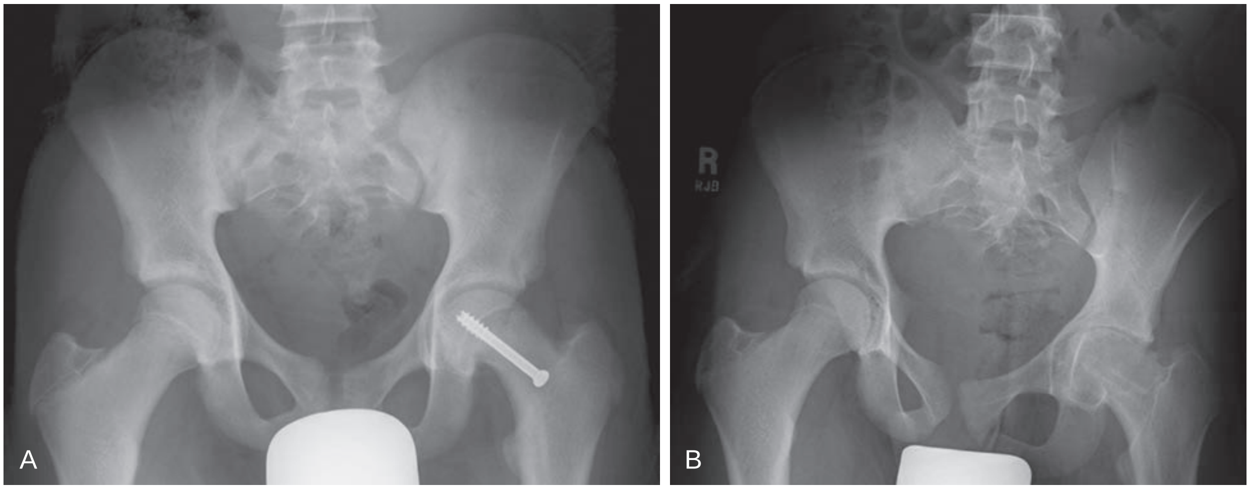
***Etiology, Pathophysiology, and Clinical Presentation.*** Two types of distal femoral fractures have been described. Juvenile type injuries



**e-Figure 142.48. Acetabular fracture.** A 10-year-old boy with posterior osteolabral acetabular wall fracture *(arrow)* on short tau inversion recovery axial magnetic resonance imaging after dashboard injury related to motor vehicle accident.



**e-Figure 142.50. Advanced, chronic bilateral slipped capital femoral epiphyses at presentation in a 16-year-old boy.** The femoral heads are rotated medially with varus deformity. The femoral necks are sclerotic with buttressing medially.



**e-Figure 142.52. Chondrolysis after treatment of slipped capital femoral epiphysis in a 15-year-old boy.** (A) Postoperative radiograph demonstrates pin fixation of left-sided SCFE with normal hip joint space. (B) One year later, uniform joint space narrowing of the left hip consistent with chondrolysis is seen.

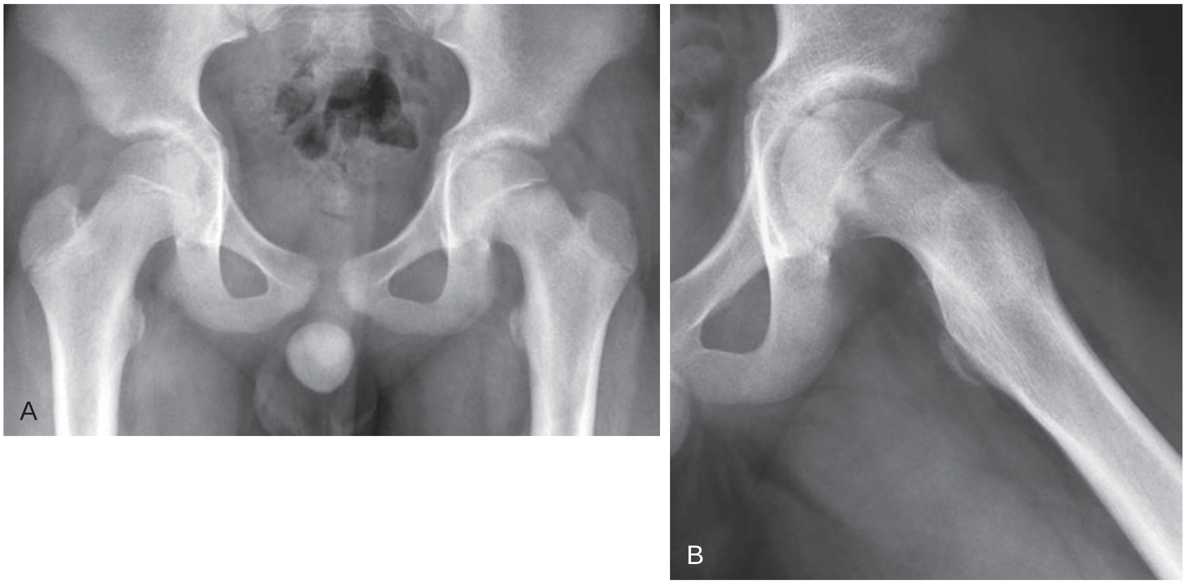


**Figure 142.49. Slipped capital femoral epiphysis in an 11-year-old boy with left hip pain.** (A) On the anteroposterior view, the growth plate of the left proximal femur is wide and indistinct. The left femoral epiphysis is slightly medially positioned on the metaphysis with no portion of the left femoral head projecting lateral to Klein's line. The right proximal femur is normal. (B) On the lateral view, malalignment of the femoral epiphysis is better seen. The femoral epiphysis is displaced posteromedially relative to the femoral metaphysis but is still in continuity.

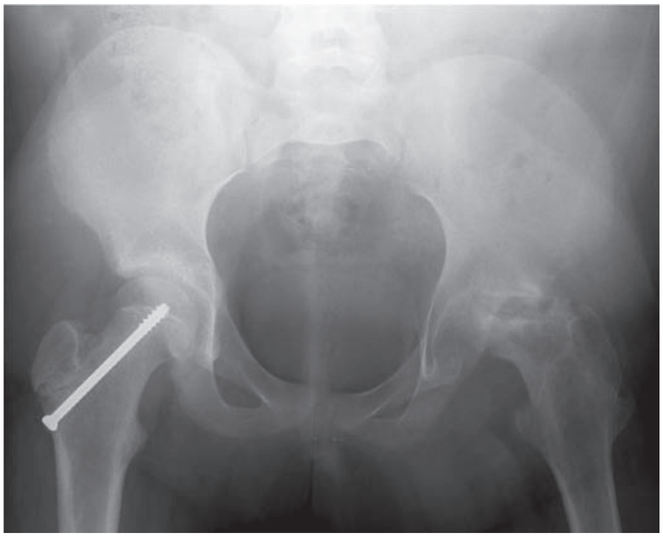

**Figure 142.51. Complication of slipped capital femoral epiphysis.** Single anteroposterior radiograph of the pelvis in a 14-year-old girl demonstrates left femoral head fragmentation and collapse consistent with osteonecrosis. There are postsurgical changes of the right femur.

(age 2–10 years) are most common secondary to high-energy trauma such as a motor vehicle accident, whereas adolescent type injuries are typically sports-related.[116] Salter-Harris type II fractures are the most common injury with usual displacement in the coronal plane, medial physeal separation, and associated medial collateral ligament sprain.[116] Salter-Harris type fractures are more common in the distal femur compared with ligamentous injuries of the knee, particularly during periods of rapid growth.

***Imaging.*** Initial evaluation begins typically with anteroposterior, lateral, and axial (e.g., merchant, sunrise) views of the knee. Axial views are usually not helpful in children under age 5 years, because the patella is undermineralized and patellar fractures are unusual in the first decade. Depending on the mechanism of injury, MRI or CT may be used in certain situations. MRI review must include specific attention to the unfused physes as part of the search pattern.[115] MRI is particularly useful in evaluating tendon and ligamentous injuries and bone contusions. With intraarticular fracture, lipohemarthrosis may be seen on cross-table lateral radiographs, MRI, or CT.[117] This indicates breech of the bone marrow due to fracture.

Most displaced Salter-Harris fractures of the distal femoral metaphysis are obvious on clinical examination and on radiographs; however, subtle distal femoral Salter-Harris injuries may be occult on radiography and not diagnosed until MRI is performed (e-Fig. 142.53). On follow-up imaging, close assessment of the physis should be performed due to the high incidence of physeal bridges that occur after distal femoral fractures involving the growth plate.

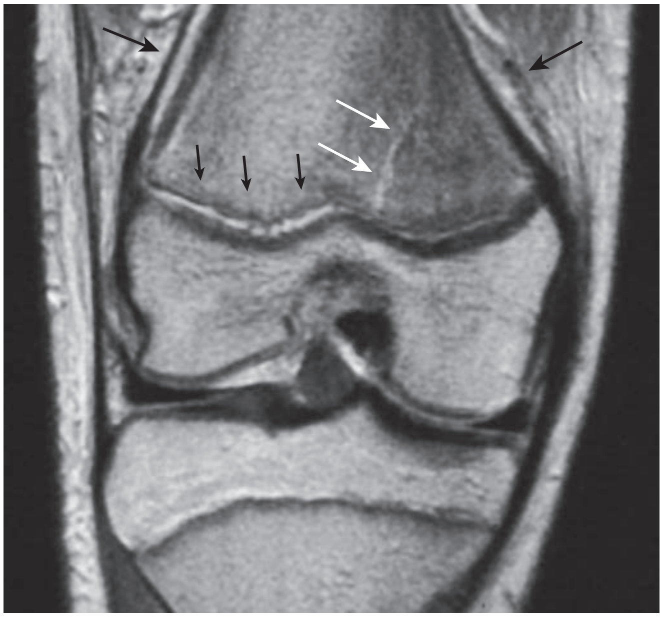
***Treatment.*** Distal femoral physeal fractures are treated conservatively with immobilization if nondisplaced and stable. Unstable, intraarticular, or displaced fractures are treated operatively with fixation.

## PATELLA

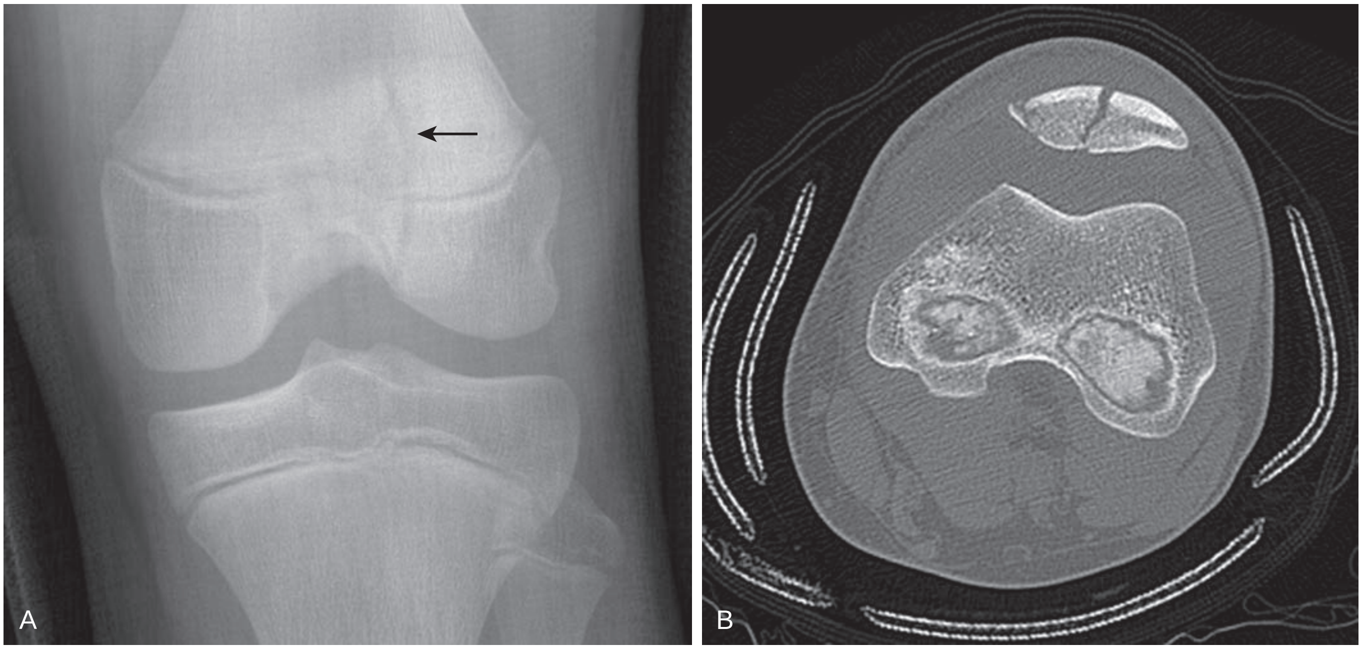
***Etiology, Pathophysiology, and Clinical Presentation.*** Fractures of the patella in skeletally immature patients are rare.[118] Osteochondral fractures and avulsions related to patellar dislocation and patellar sleeve avulsion fractures are discussed in Chapter 144.[119,120] Direct impaction injury is the most common cause of patellar fractures that are not related to sleeve avulsions of dislocations. Like the scaphoid, the patella has a recurrent blood supply. Avascular necrosis of the proximal fragment is a rare complication of transverse patellar fractures.

***Imaging.*** Initial evaluation begins with anteroposterior, lateral and axial (e.g., merchant, sunrise) radiographs of the knee.

Patellar fractures may be simple (e-Fig. 142.54) or comminuted. Intraarticular involvement is important to define for



**e-Figure 142.53. Salter-Harris II fracture of the distal femur in a 12-year-old girl.** Proton density MR image shows widening of the distal femoral growth plate *(small black arrows)* and bone marrow edema. A metaphyseal fracture line is also seen *(white arrows)*. Periosteum is elevated *(large black arrows)*.



**e-Figure 142.54. Intraarticular nondisplaced patellar fracture in a 13-year-old boy.** The fracture line is seen on the (A) anteroposterior radiograph *(arrow)* and (B) axial CT. CT also demonstrates a medial patellar fracture.

surgical planning, and CT and MRI may be obtained for further evaluation. These fractures should be differentiated from a bipartite patella, which may fracture at the synchondrosis between the patellar body and the smaller superolateral ossification center.

***Treatment.*** Patellar fractures are treated surgically, depending on several factors, including integrity of the extensor mechanism, degree of displacement, and articular extension. Patellar fractures are particularly difficult to treat conservatively because of issues with nonunion (from chronic traction related to the extensor mechanism), and premature osteoarthritis, when the articular surface is involved.

## TIBIAL TUBEROSITY AND PROXIMAL TIBIA

***Etiology, Pathophysiology, and Clinical Presentation.*** Tibial tuberosity acute and chronic avulsion injuries, physeal equivalent Salter-Harris injuries of the tibial tuberosity, and tibial eminence anterior cruciate ligament avulsion fractures are covered in detail in Chapter 144.

The proximal tibia has an upside-down L–shaped physis and epiphysis. Both the tibial epiphysis and tuberosity are a single entity that fuses to the underlying tibia at approximately age 15 years in girls and age 17 years in boys.[121,122] Therefore any proximal tibial fracture extending to the tibial physis or tibial tuberosity physeal equivalent region should be considered a Salter-Harris type fracture.

Tibial hyperextension toddler fractures (also referred to as *trampoline fractures*) occur in the upper tibial metadiaphysis. These occur secondary to anterior forces being applied to knee during hyperextension.[123,124]

Unlike in adult patients, tibial plateau fractures in children are less likely to be depressed because the epiphyseal cartilage is more resilient and acts as a cushion for the tibial epiphyseal bone.

***Imaging.*** Initial evaluation begins with anteroposterior and lateral radiographs of the knee. Transverse fractures of the proximal tibia may appear innocuous but are technically Salter-Harris II fractures if they extend to the tibial tuberosity physeal equivalent zone. Avulsion fractures that violate the tibial epiphysis or tibial tuberosity are Salter-Harris III fractures (e-Fig. 142.55).

CT and MRI are useful to determine the 3D orientation of the fracture and its involvement of the physis, with MRI allowing a more detailed assessment of potential injury to the extensor mechanism. Tibial plateau fractures are best evaluated with MRI to assess the articular cartilage injury as well as coexisting meniscal and ligamentous injury.

Hyperextension fractures can be subtle; typically a buckle deformity of the anterior cortex of the proximal tibial metaphysis can be seen (Fig. 142.56).

***Treatment.*** Salter-Harris fractures involving the proximal tibia weight-bearing zone (tibial plateau) and Salter-Harris fractures involving the physeal equivalent region of the tibial tuberosity have different biomechanical challenges related to management. The tibial tuberosity is the insertion of the knee extensor mechanism, and therefore tibial epiphyseal equivalent fractures in this region may be unstable with knee motion. Tibial plateau fractures are also unstable, but because these are loadbearing surfaces, when the overlying cartilage is violated, it should cause concern for posttraumatic osteoarthritis and coexisting internal derangement and meniscal tears of the knee. For these reasons, a low threshold exists for surgical fixation and immobilization for both tibial tuberosity and tibial epiphyseal Salter-Harris fractures in children.

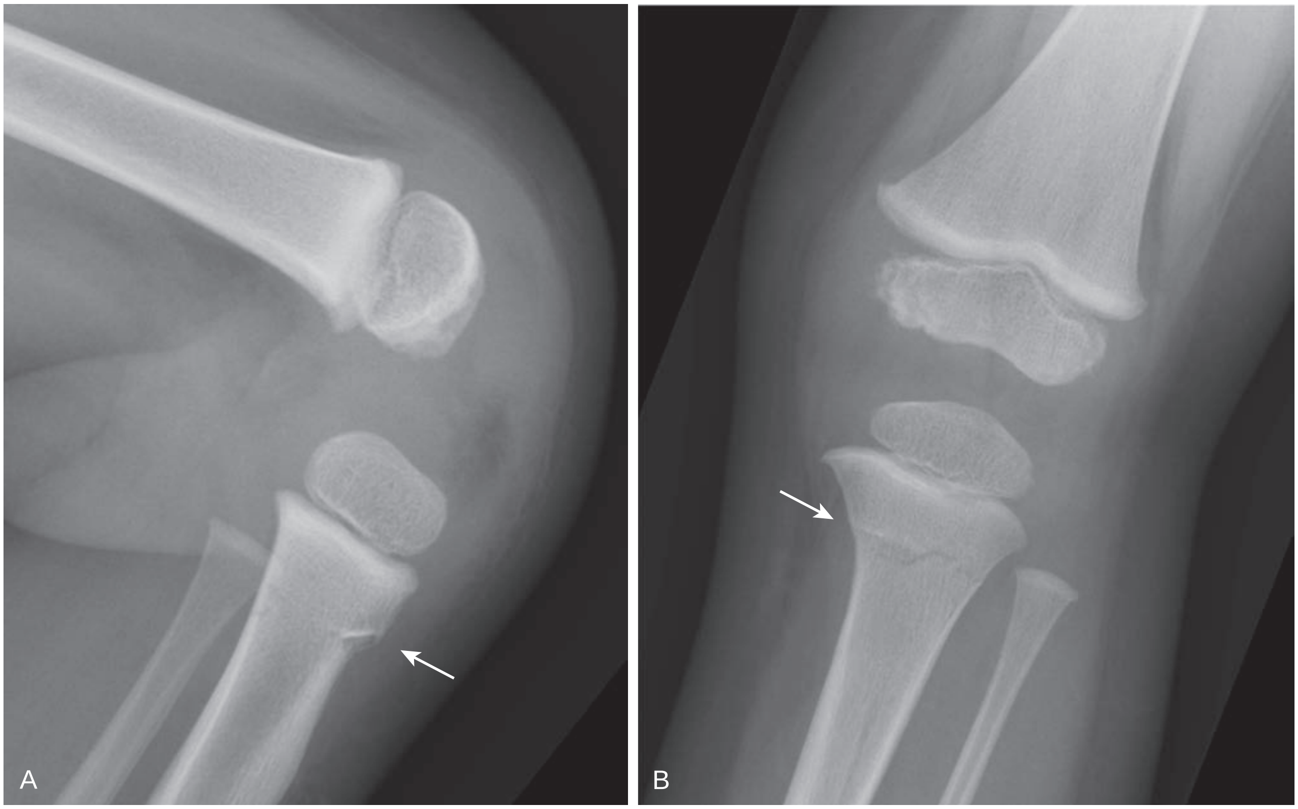


**Figure 142.56. Toddler's hyperextension fracture in a 23-month-old girl while jumping on a trampoline with an adult.** (A) Lateral radiograph shows a buckle fracture *(arrow)* of the anterior cortex of the proximal tibial metadiaphysis. Normally, the anterior proximal tibial cortex has a smooth appearance, which may be concave due to the unossified tibial tubercle. (B) Anteroposterior radiograph shows a faint transverse fracture line *(arrow)*.

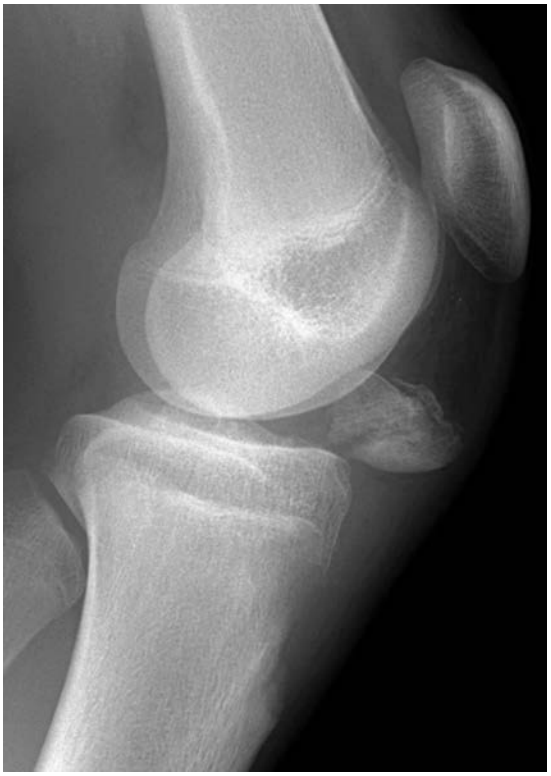

**e-Figure 142.55. Tibial tuberosity avulsion in a 16 year old after a bicycle accident.** The avulsed fragment is distracted proximally and rotated.

## TODDLER FRACTURES

***Etiology, Pathophysiology, and Clinical Presentation.*** Toddler fractures are typically seen between ages 9 months and 3 years. The term “toddler fracture” is used to describe any fracture of the leg or foot in the toddler. The tibia diaphysis is the most commonly fractured, followed by the fibula, femur, and cuboid bone.[125]

In the classic clinical toddler fracture history, the child’s leg is caught on an object, the leg twists, and the child falls. Other children present with pain and refusal to bear weight without a specific precipitating incident. On physical examination, the child will be point tender over the fracture.[126] Toddler fractures are common once children begin to cruise and walk.

***Imaging.*** Toddler fractures may occur anywhere within the proximal metadiaphysis, diaphysis, or distal metadiaphysis of the tibia. The fracture line is oblique or spiral usually with little to no distraction or displacement (Fig. 142.57). Acutely, the fracture line may be very subtle. In some patients, follow-up radiographs are necessary to confirm the fracture (e-Fig. 142.58). Similarly, acute toddler fractures of the fibula, femur, and cuboid (e-Fig. 142.59) may be subtle. The healing process, with sclerosis at the margins of the fracture line and development of periosteal new bone, may increase the conspicuity of the fracture.

Because the fracture line is oblique or spiral and because a particular event may not have led to the fracture, toddler fractures may erroneously be ascribed to child abuse. In the absence of other injury, however, the typical radiographic appearance of a toddler fracture in a child of appropriate age should not in itself raise suspicion.

***Treatment.*** Treatment is conservative, consisting of immobilization and casting, as well as avoidance of weight bearing.

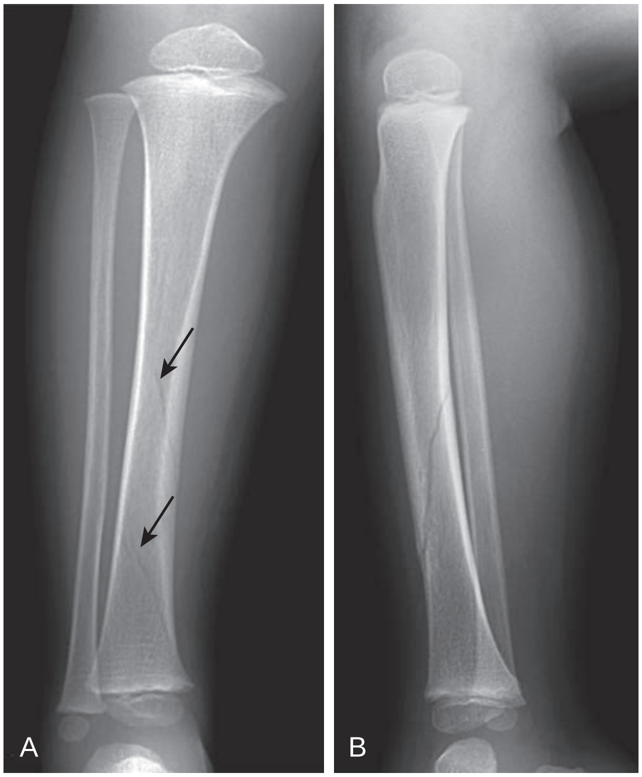

**Figure 142.57. Toddler fracture of the tibia in a 2-year-old girl.** Anteroposterior (A) and lateral (B) views of the tibia shows a spiral fracture line as shown by two apparent fracture lines on the anteroposterior view *(arrows)* and the intervening single fracture line on the lateral view. Slight soft tissue swelling is seen anterior to the fracture on the lateral view.

## OTHER TIBIAL AND FIBULAR FRACTURES

***Etiology, Pathophysiology, and Clinical Presentation.*** Most tibial fractures occur in the distal metadiaphysis,[127] which is a common site for buckle fractures in young children. Salter-Harris fractures are also very common at the distal tibia and are covered in detail in the section on ankle fractures (see later). In older children, fractures of the tibial shaft are usually complete with a transverse or oblique fracture plane. The fibula is commonly fractured when a complete fracture of the tibial diaphysis occurs.[128]

Maisonneuve fractures of the proximal fibula may occur with medial ligamentous injury or medial malleolar fracture at the ankle. The mechanism for Maisonneuve fractures is forced ankle valgus injury. These fractures may also occur with juvenile Tillaux or triplane fractures of the distal tibia. With a disruption of medial support at the ankle, the injury force may traverse the interosseous membrane up the leg and pass obliquely through the proximal fibular diaphysis. The presence of a Maisonneuve fracture thus indicates disruption of the interosseous membrane and potential instability if the ligamentous injury is not surgically addressed.

***Imaging.*** Nonphyseal and extra-articular fractures of the leg can be assessed with anteroposterior and lateral views. Once the physis of either end of the leg are involved, dedicated osteoarticular imaging is necessary to comprehensively characterize physeal and intraarticular involvement, if present.

Whenever a medially located fracture or ligamentous disruption of the ankle occurs, radiographs of the remainder of the leg should be obtained to rule out a Maisonneuve fracture (e-Fig. 142.60).[129]

Distal tibial Salter-Harris III fractures may be seen medially or laterally (juvenile Tillaux fracture; see later). The distal tibia is one of the more common locations of Salter-Harris IV fractures (see e-Fig. 142.11 and e-Fig. 142.61).

***Treatment.*** Treatment of tibial fractures depends on the age of the child, type and location of the fracture, and degree of fracture displacement and angulation. Most tibial fractures can be managed nonoperatively provided that they are purely extra-articular and do not involve a physis. Fibular fractures, including those that have physeal involvement, invariably are treated nonsurgically, because the fibula is a relatively non–load-bearing bone.

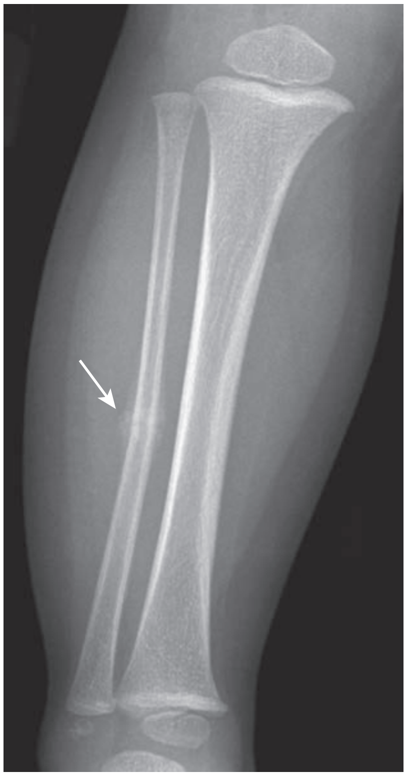
Maisonneuve fractures can be managed nonsurgically if the fracture is stable. With unstable fractures, the syndesmosis needs to be approximated and medial malleolus fixated. The associated proximal fibular fracture is treated conservatively, and the deltoid ligament need not be directly repaired.[130]

## TRAUMATIC INJURIES OF THE ANKLE

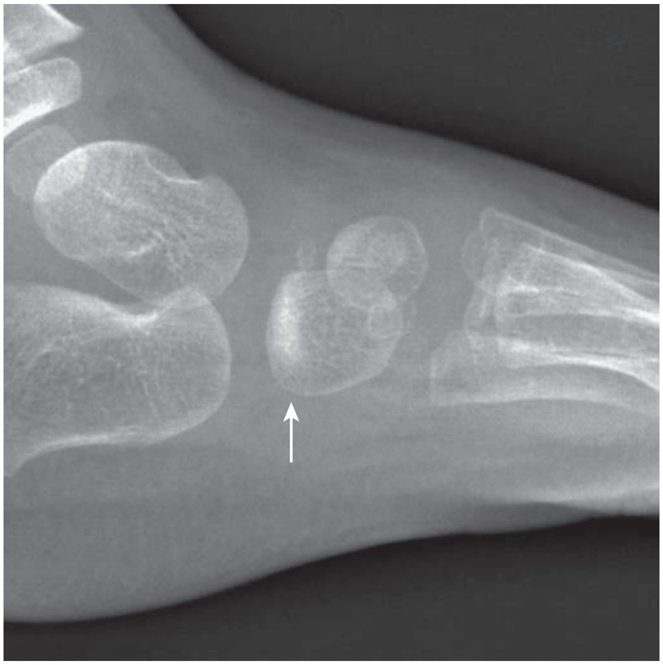
### Transitional Ankle Fractures (Juvenile Tillaux and Triplane)

***Etiology, Pathophysiology, and Clinical Presentation.*** “Transitional” fractures occur in the early teen years when the distal tibial physis is nearing the time of fusion or is already partially fused. The distal tibial physis begins to fuse in the medial central physis. Fusion then proceeds medially and posteriorly (e-Fig. 142.62). The anterolateral portion of the physis is the last portion of the physis to close and thus is the plane of least resistance to fracture.[131,132] The unique pattern of physeal fusion of the distal tibia leads to characteristic fracture patterns in the distal tibia.

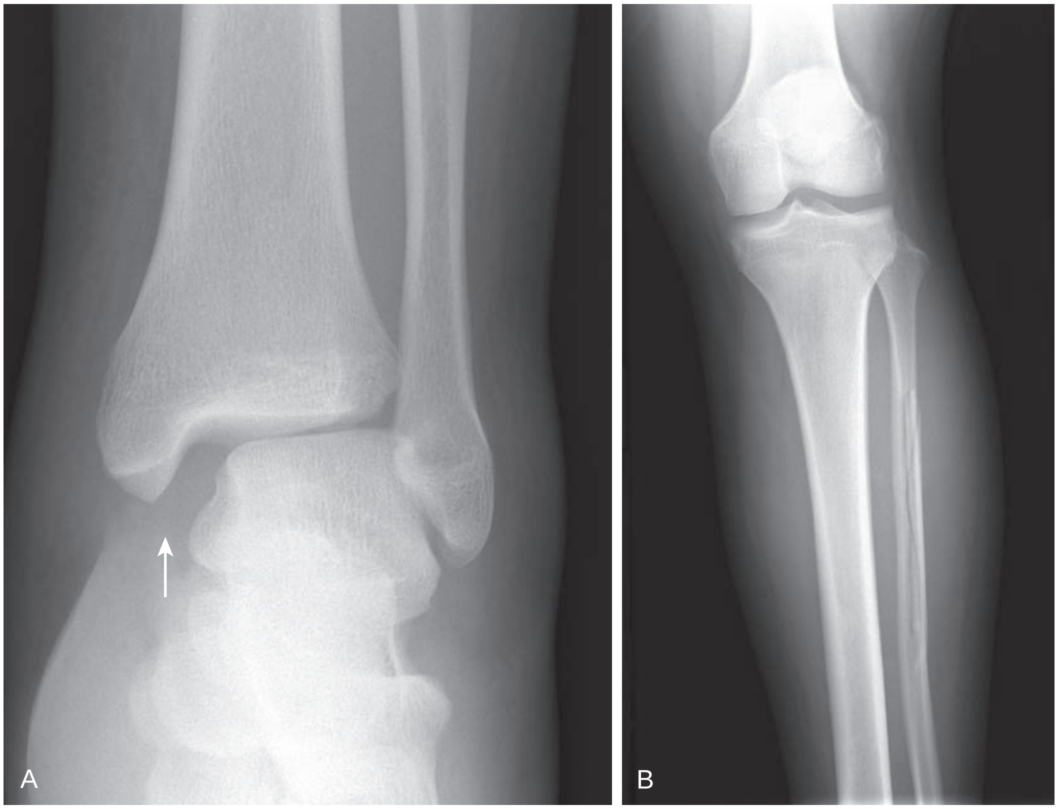
Juvenile Tillaux fracture is a Salter-Harris III fracture of the distal tibial physis and epiphysis. Juvenile Tillaux fractures probably represent an anterolateral avulsion of the distal tibial epiphysis pulled by the anterior tibiofibular ligament and anterior syndesmosis caused by forced external rotation.[133] Triplane fractures are closely related to juvenile Tillaux fractures; however, there is an additional fracture plane of the distal tibial metaphysis, usually coronal in orientation (Fig. 142.63). The three planes of a triplane fracture are thus: (1) a sagittal fracture through the epiphysis, (2) a transverse



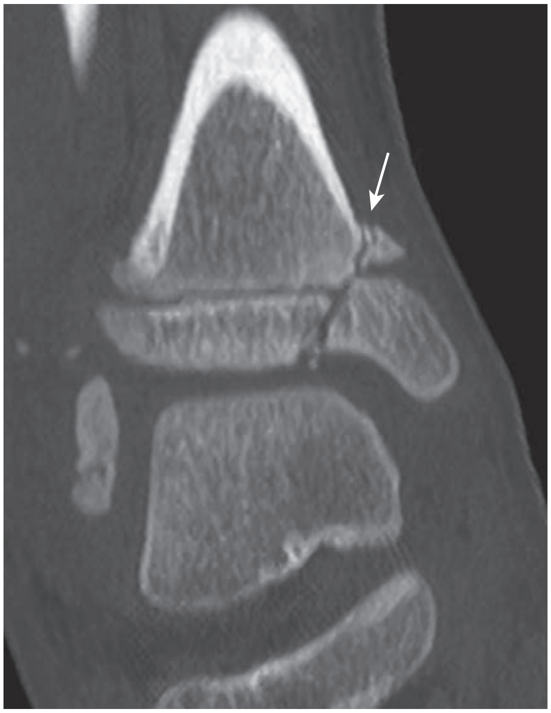
**e-Figure 142.58. Fibular toddler fracture in a 19-month-old boy.** Callus is present *(arrow)* with a faint transverse fracture line.



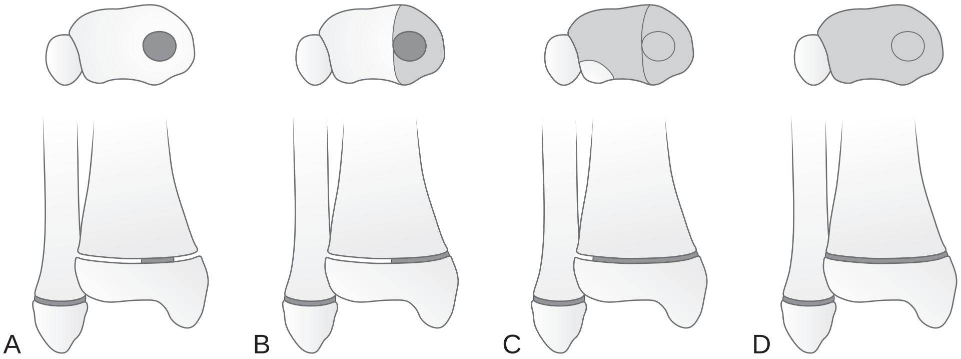
**e-Figure 142.59. Healing toddler fracture of the cuboid in a 19-month-old boy.** A band of sclerosis is seen within the proximal aspect of the cuboid *(arrow)*.



**e-Figure 142.60. Maisonneuve fracture in a 14-year-old boy.** (A) Anteroposterior radiograph of the ankle demonstrates medial tibiotalar widening consistent with deltoid ligament injury *(arrow)*. (B) Anteroposterior radiograph of the leg demonstrates a proximal fibular fracture.



**e-Figure 142.61. Salter-Harris IV fracture of the distal tibia in an 8-year-old boy.** Coronal CT reconstruction shows the course of the fracture *(arrow)*. Note the apposition of metaphysis and epiphysis across the fracture.



**e-Figure 142.62. Diagram of the path of distal tibial physeal closure.** Closure begins centrally (A) and proceeds medially (B) and then laterally (C) before fusion is complete (D). *(Modified from Beaty JH, Kasser JR.* Rockwood and Wilkins' Fractures in Children*, 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2006.)*

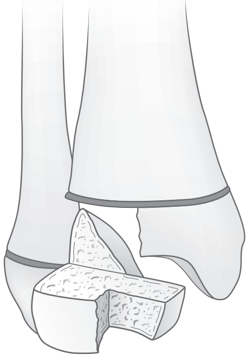


**Figure 142.63. Triplane fracture.** In a two-part triplane fracture, typically sagittal epiphyseal, transverse physeal, and coronal metaphyseal fracture lines are present. *(Modified from Beaty JH, Kasser JR.* Rockwood and Wilkins' Fractures in Children*, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)*

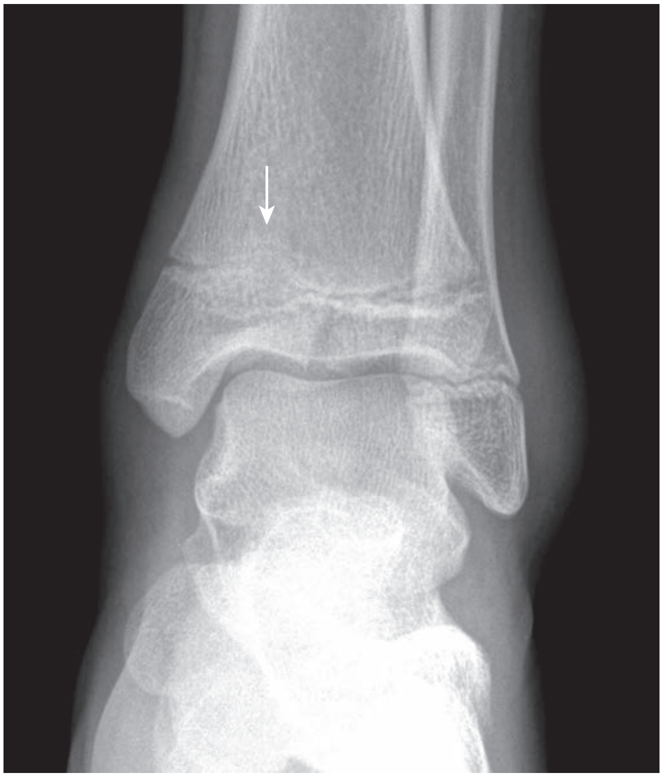

**Figure 142.64. Juvenile Tillaux fracture in a 15-year-old boy.** Note the Salter-Harris III vertical fracture line is lateral to Kump's bump *(arrow)*, the site of initial distal tibia physeal closure.

fracture through the physis, and (3) a coronal fracture through the metaphysis.[134,135]

***Imaging.*** The vertical fracture line in juvenile Tillaux fractures is invariably located lateral with respect to anteromedial tibial physeal fusion, which is called *Kump's bump* (Fig. 142.64). This should be distinguished from epiphyseal fractures that are medially located (see e-Fig. 142.61). The concern with juvenile Tillaux fracture of the distal tibia is not possible premature fusion of the physis, because the physis is already fusing, but rather involvement of the articular surface. A significant gap or incongruity of the fracture fragments at the articular surface may portend an early progression to degenerative disease in the ankle.

For triplane fractures, the epiphyseal and metaphyseal fracture planes may vary somewhat from true orthogonal orientation. A classic triplane fracture has two parts; however, three-part and four-part variants occasionally occur (Fig. 142.65).[136] Triplane fractures are complex fractures that some authors classify as Salter-Harris IV fractures and others as a combination of Salter-Harris type II and type III fractures; however, classification systems specific to triplane fractures (such as those developed by Von Laer, van Laarhoven, and Rapariz) provide a more useful classification.[137]

Superficially, triplane fractures on anteroposterior view may mimic juvenile Tillaux fracture (see Fig. 142.65A). If a Salter-Harris II fracture component is not visualized on the lateral view, CT may be helpful to distinguish these two fractures, as this will alter management.

Radiography is usually sufficient for detecting both juvenile Tillaux and triplane fractures. CT is often used in preoperative planning to measure displacement at the articular surface and to map the anatomy of the fracture planes (e-Fig. 142.66), and has been shown to impact the classification and treatment planning of triplane fractures.[137–142]

***Treatment.*** If the fracture line is wider than 2 mm, a transitional fracture will undergo operative fixation.[133] Widening of the medial joint space may be a sign of fracture displacement.[143] Nondisplaced fractures can be treated with immobilization.[144] Juvenile Tillaux fractures are surgically fixed at the level of the epiphysis. Displaced triplane fractures will require surgical fixation of both the epiphyseal and metaphyseal fracture components.

## TRAUMATIC INJURIES OF THE FOOT

***General Overview.*** Foot fractures account for approximately 5% to 8% of pediatric fractures.[145] These fractures are generally uncommon in infants and toddlers given the significant cartilaginous composition of the foot during this age; the incidence of fractures increases with age as the foot becomes more ossified.[145] The majority of pediatric foot fractures are isolated injuries.[145]

## Hindfoot Fractures

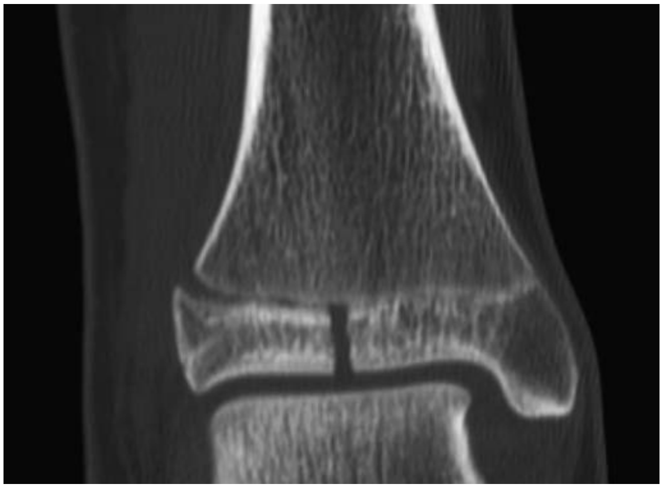
### Talar Fractures

***Etiology, Pathophysiology, and Clinical Presentation.*** Fractures of the talus are uncommon, compromising approximately 2% of pediatric foot fractures.[145] Avulsion fractures are the most common, followed by osteochondral fractures, talar neck, then talar body fractures.[146]

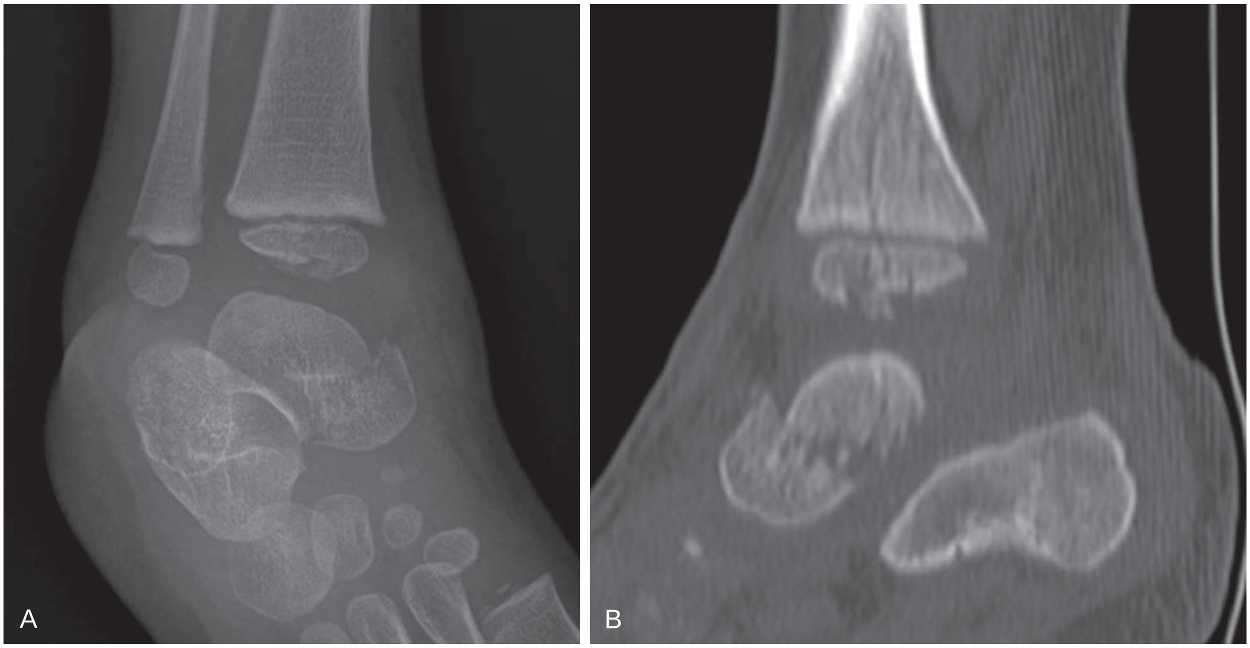
The majority of talar neck and body fractures occur with high-energy trauma, usually from a fall or a motor vehicle accident.[145] Complete fractures of the talar neck are seen in older children but are rare.

Younger children may have buckle fractures of the talar neck. The buckle is evident along the dorsal surface of the bone and may be very subtle.[147] The talus is one location of the so-called *tarsal toddler fracture*. These fractures occur from compression of the talar neck against the anterior margin of the tibia with forced dorsiflexion.[148]

***Imaging.*** Anteroposterior, oblique, and lateral radiographs of the ankle are initially obtained. Given the complexity of some talar fractures, CT can be used to delineate fracture anatomy and articular involvement (e-Fig. 142.67). Because of the recurrent blood supply of the body of the talus, fractures may be complicated by osteonecrosis of the proximal pole. The presence of a subchondral lucency in the talar dome (Hawkins sign) seen approximately 2 months after injury indicates that the talar dome has an adequate blood supply, and therefore the risk of developing osteonecrosis is low; loss of this sign is abnormal indicating osteonecrosis.[145] Other significant complications include post-traumatic arthritis caused by malalignment.[148]



**e-Figure 142.66. Juvenile Tillaux fracture in a 14-year-old boy.** Coronal CT reconstruction shows the Salter-Harris III fracture of the anterolateral distal tibial epiphysis.



**e-Figure 142.67. Talar neck fracture and a complex distal tibia Salter-Harris fracture in a 2-year-old girl.** (A) Radiographs show talar and distal tibial fractures that are better depicted on CT (B).

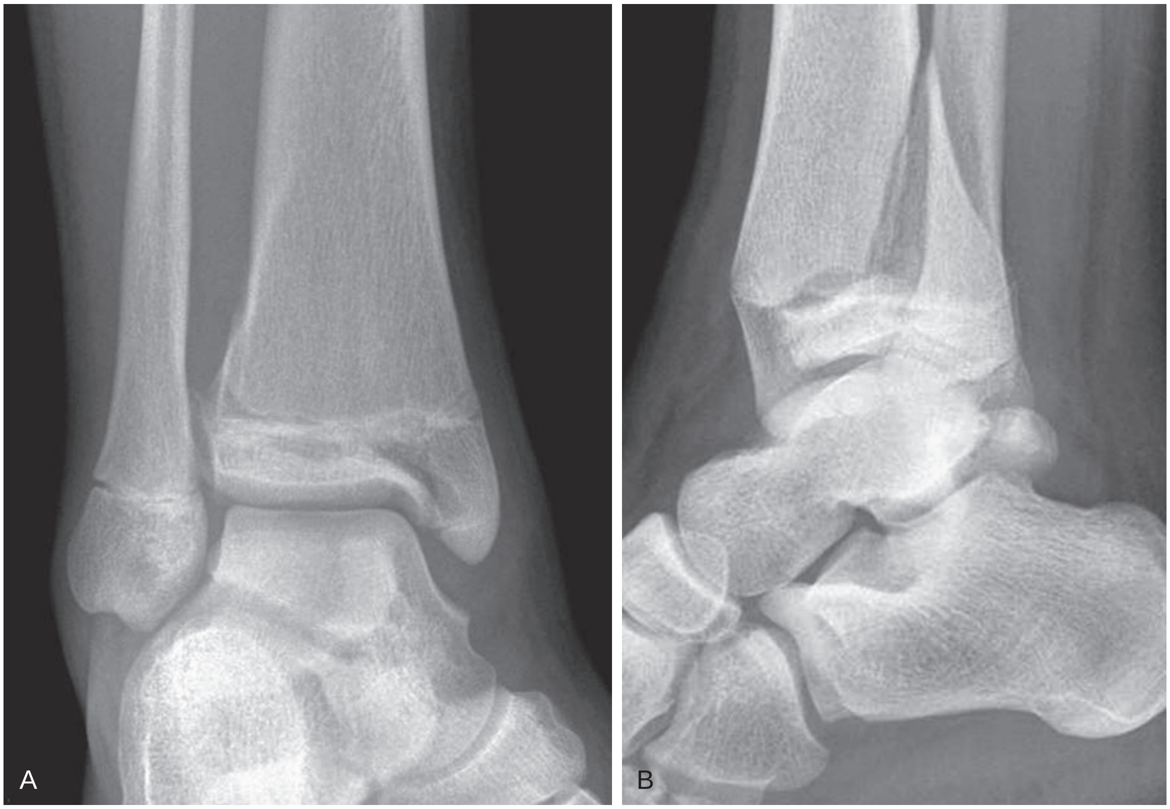


**Figure 142.65. Triplane fracture.** Anteroposterior (A) and lateral (B) radiographs of a triplane fracture in an adolescent. *(Courtesy of Dr. Brent H. Adler, Columbus, OH.)*

***Treatment.*** Treatment of nondisplaced talar fractures includes immobilization and casting, while either closed or open reduction is performed for displaced fractures.

### Calcaneal Fractures

***Overview.*** Calcaneal fractures are uncommon, comprising only 2% of all pediatric foot fractures. Associated injuries are common.[145] Toddler fractures of the calcaneus, which have been described in the literature, are uncommon.[149]

***Etiology, Pathophysiology, and Clinical Presentation.*** Calcaneal fractures most commonly occur with jumps or falls from a large height and from motor vehicle accidents.[145] The mechanism of injury is usually an axial loading force.[150] Prior to apophyseal fusion, the posterior calcaneus may experience fractures involving the apophyseal physis and apophysis that can be classified by the Salter-Harris system.[151]

***Imaging.*** Calcaneal fractures may have a variable degree of comminution and of depression of the superior margin of the calcaneus. The Böhler angle can be used to assess for calcaneal depression caused by the fracture. This angle is the posterior angle between two lines, one drawn tangent to the anterior process of the calcaneus and the highest point of the posterior facet, and the other drawn from the latter point to the superior margin of the posterior calcaneus. Normally, the Böhler angle measures around 25 to 40 degrees in adults but is less in children.[152] With depressed calcaneal fractures, the Böhler angle is decreased. Although the Essex-Lopresti classification system is widely used, it is important to differentiate between intraarticular and extra-articular fractures with reference to involvement of the subtalar joint (Fig. 142.68).[145]

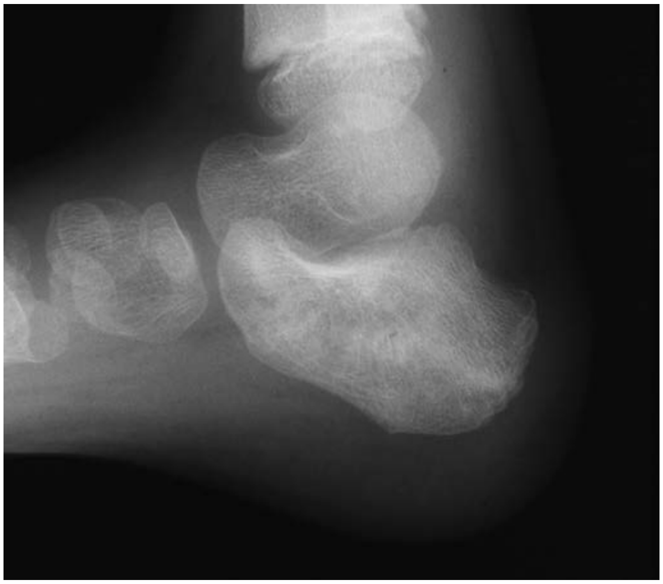
CT is utilized for full delineation of calcaneal fracture anatomy. Subtle compression fractures of the calcaneal body are not infrequent in younger children. These injuries may be virtually impossible to diagnose acutely from radiographs unless a buckle of the margin of the bone exists. Follow-up radiographs will show an oblique band of sclerosis within the midcalcaneal body (e-Fig. 142.69).

***Treatment.*** Displaced, intraarticular fractures of the calcaneus are typically treated surgically with open reduction and internal fixation.[153,154] Most patients have a good clinical outcome with few complications.[152]

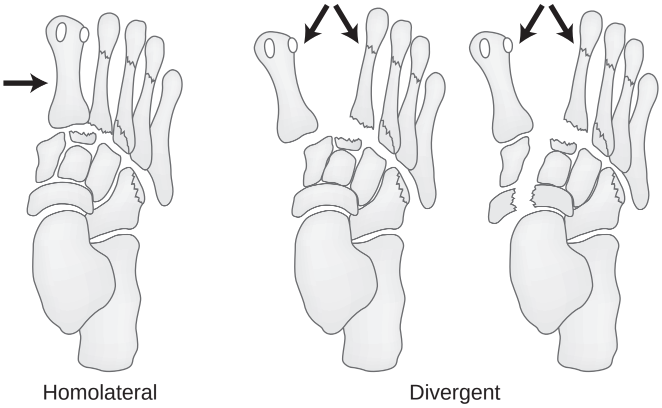
## Midfoot Injury

***Overview.*** Isolated fractures of the cuneiform bones are rare. “Bunk bed” fractures of the cuboid have been reported (see later). Lisfranc injuries may occur throughout childhood but become more common in older children.

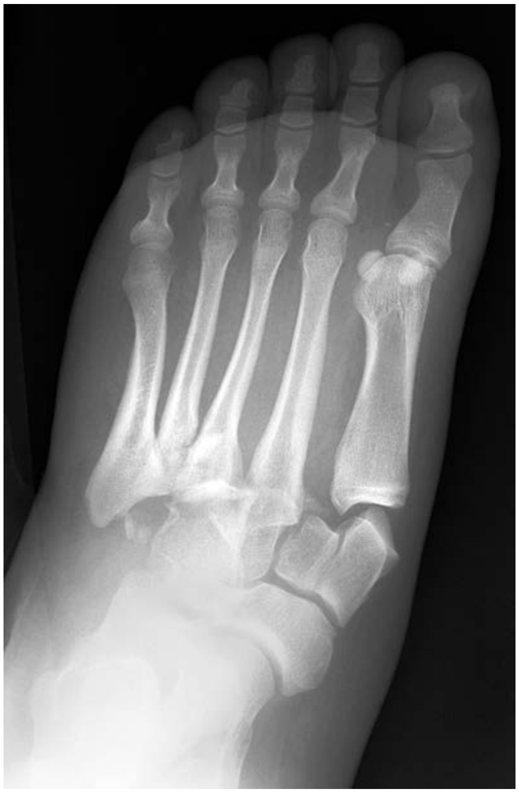
***Etiology, Pathophysiology, and Clinical Presentation.*** The mechanism may be direct, from a falling object, or indirect, from forced plantar flexion, abduction, or both.[145] Falls from a height account for the largest number of Lisfranc injuries in children.[145] The Lisfranc joint, which courses between the distal tarsals and the metatarsals, is disrupted. Fractures may be seen within the bases of the metatarsals or within the cuneiforms. Fracture at the base of the second metatarsal is a consistent finding. Multiple metatarsal fractures and midtarsal bone injuries are more likely in children.[2] These fractures may be chondro-osseous separations seen only as small slivers of bone but are often occult with radiographs. Lisfranc injuries can be classified as homolateral, with the first metatarsal displaced in the same direction as the other four metatarsals, or divergent, with the first metatarsal displaced medially and the other metatarsals displaced laterally (e-Figs. 142.70 and 142.71). A fracture of the cuboid with a fracture of the second metatarsal base is compatible with significant tarsometatarsal joint injury.



**e-Figure 142.69. Healing calcaneal fracture in a 6-year-old boy.** A horizontal band of sclerosis is seen within the body of the calcaneus.



**e-Figure 142.70. Lisfranc tarsometatarsal fracture–dislocations.** The two basic types are homolateral and divergent. A fracture is consistently seen at the base of the second metatarsal. Jagged lines represent additional potential sites of fracture. *(From Rogers LF.* Radiology of Skeletal Trauma*, 3rd ed. New York: Churchill Livingstone; 2002.)*



**e-Figure 142.71. Lisfranc fracture-dislocation in a 15-year-old morbidly obese boy from a motor vehicle accident.** The injury is homolateral. The space between the first and second metatarsals is widened. The tarsal-metatarsal joint is completely disrupted. A fracture is present at the base of the second metatarsal as well as other metatarsals.

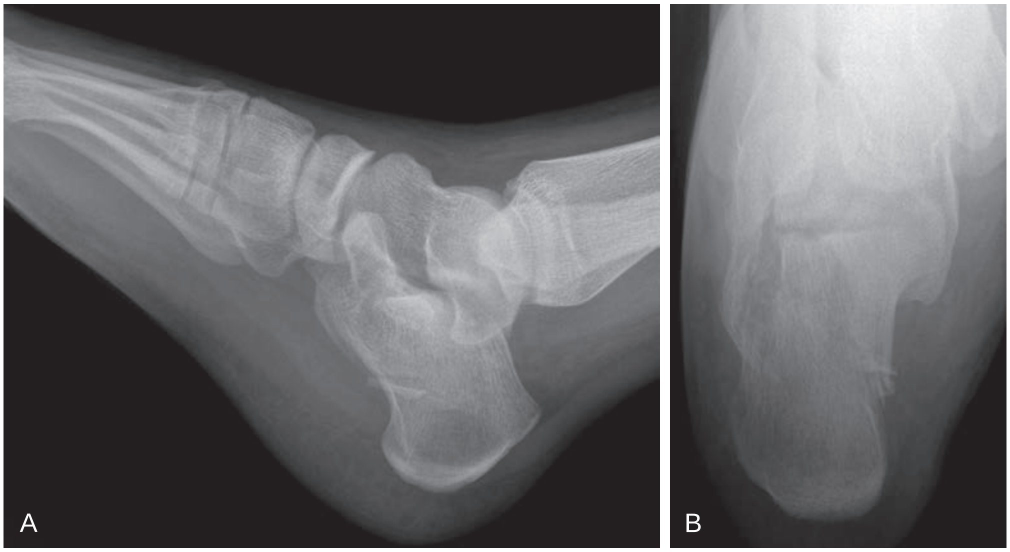


**Figure 142.68. Comminuted intra-articular fracture of the calcaneus in a 15-year-old boy.** (A) Lateral radiograph. (B) The subtalar involvement is best seen on the Harris view.

***Imaging.*** Radiographic abnormalities may be subtle. Weight-bearing views of the foot are necessary to accurately evaluate alignment of the forefoot and midfoot. Weight bearing will stress the tarsometatarsal joints and may bring out subtle Lisfranc injuries. Any malalignment between the bases of the metatarsals or with their corresponding tarsal bones on any view should be regarded with suspicion. The midfoot should be closely evaluated for possibility of avulsion fractures. CT is used for confirmation of diagnosis and delineation of comorbid anatomy. MRI and less commonly ultrasound are used to evaluate the Lisfranc ligament.[155]

***Treatment.*** Nondisplaced or minimally displaced tarsometatarsal dislocations may be treated conservatively. Patients with Lisfranc fracture–dislocations with more than minimal displacement are treated surgically.[145] If closed reduction is not successful, percutaneous pin fixation may be employed for stabilization. Stabilizing the fracture of the proximal second metatarsal is important.[2]

## Forefoot Fractures

***Overview.*** Metatarsal fractures are one of the most common pediatric foot fractures. Most are nondisplaced or minimally displaced.[156] If the fractures involve the base of the metatarsal, injury to the tarsometatarsal joint must be considered. Buckle fractures of the phalanges and metatarsals are common in younger children. The most commonly injured metatarsal in younger children is the first metatarsal and in older children the fifth.[156]

***Etiology, Pathophysiology, and Clinical Presentation.*** Phalangeal fractures usually occur from objects falling directly on the foot, particularly on the great toe.[150] Salter-Harris fractures may affect the physes of these bones. Salter-Harris III fractures at the base of the proximal phalanx of the great toe may be mistaken for a bifid epiphysis and vice versa. Buckle fractures of the phalanges and metatarsals are common in younger children. Often, adjacent bones are fractured together. Oblique or transverse fractures of the metatarsal shafts may be caused by dropped objects, falls, or twisting injuries. In severe twisting injuries in which the foot is caught, multiple adjacent metatarsals may be fractured.

***Imaging.*** Dedicated radiographs in three planes of the injured phalanx is preferred rather than imaging the foot in its entirety. True lateral radiographs of the isolated symptomatic toe are challenging to obtain because of overlap of adjacent toes but are nevertheless important to obtain for complete assessment and for identifying toe dislocations that may be missed on only anteroposterior and oblique views.

***Treatment.*** Displaced fractures need reduction and occasionally K-wire fixation.[150] Phalangeal fractures heal quickly and usually only buddy taping is required.[150]

## STUBBED GREAT TOE FRACTURE

***Overview.*** Stubbed great toe fractures are considered Salter-Harris I or II fractures of the base of the proximal or distal phalanx of the great toe until proven otherwise.[157] Fractures of the distal phalanx of the great toe are unique given the relationship of the nail bed to the physis, which increases the risk for osteomyelitis.

***Etiology, Pathophysiology, and Clinical Presentation.*** The nail bed of the great toe is closely apposed to the physis of the distal phalanx, with the skin directly attached to the juxtaphyseal periosteum. After an injury, this relationship is thought to allow contamination of the underlying bone and physis.[158] Therefore any nail bed injury with associated physeal fracture should be considered an open fracture.[159]

***Imaging.*** Physeal widening of the terminal phalanx is the most common finding seen with stubbed toe fractures (Fig. 142.72). Rarefaction and physeal widening can be related to the primary injury, related to superimposed osteomyelitis, or both and usually cannot be distinguished on the basis of radiography alone. If a high clinical concern for superimposed infection exists, MRI is necessary.

***Treatment.*** Prophylactic antibiotic therapy is recommended, as these are considered open fractures. The fracture is treated nonsurgically unless complicated by osteomyelitis with abscess formation.

## BUNK BED FRACTURE

***Etiologies, Pathophysiology, and Clinical Presentation.*** A bunk bed fracture is a buckle fracture of the first metatarsal. This is most commonly seen in children 3 to 6 years of age.[125,147]

These fractures occur with a fall or a jump from a height onto a hard surface, with the prototypical injury occurring with a jump from the top bunk of a bunk bed onto a hardwood floor,

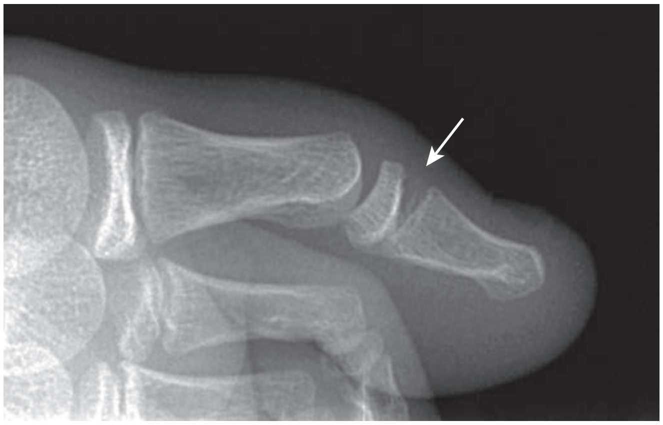

**Figure 142.72. Stubbed great toe fracture in a 12-year-old boy *(arrow)*.** A tiny metaphyseal fragment is present. The patient was prophylactically placed on antibiotics.

landing in a tiptoe position.[160] The child's entire weight is placed on the first metatarsal (axial loading injury), leading to a buckle fracture. The bunk bed fracture is associated with ligamentous injury at the tarsometatarsal junction and is considered a Lisfranc variant.

***Imaging.*** Radiography is the primary modality to evaluate these fractures (e-Fig. 142.73). Occasionally, the normal undulation of the physis of the first metatarsal may mimic a bunk bed fracture. This should not cause interruption or buckling of the metaphyseal cortex, however, as is seen with a fracture.

***Management.*** Bunk bed fractures are treated conservatively with immobilization; surgical intervention is rarely indicated unless significant displacement or articular involvement has occurred.

## FRACTURES OF THE FIFTH METATARSAL

***Overview.*** Fractures at the base of the fifth metatarsal are common.[161] The types of fifth metatarsal fractures described in children include apophyseal avulsions, intraarticular, proximal metadiaphyseal, diaphyseal, and neck fractures.

***Etiologies, Pathophysiology, and Clinical Presentation.*** The Jones fracture is a fracture of the proximal fifth metatarsal caused by repetitive inversion.[145] The fracture is transversely oriented and approximately 1.5 cm distal to the tip of the fifth metatarsal tuberosity and extends into the adjacent intermetatarsal facet (e-Fig. 142.74). This should be differentiated from fifth metatarsal stress fractures, which are located greater than 2 cm distal with respect to the fifth metatarsal tuberosity.

Jones and stress fractures of the fifth metatarsal should be differentiated from fifth metatarsal tuberosity avulsion fractures, which are tarsometatarsal fractures related to forced flexion and inversion, often due to an unexpected step or falling when on stairs. Tuberosity avulsion fractures were previously thought to be caused by avulsion at the insertion of the peroneus brevis but now appear to be an avulsion from the origin of the abductor digiti minimi.[145] In children, avulsions of the tuberosity are more common than true Jones fractures.

***Imaging.*** Initial evaluation should include anteroposterior, lateral, and oblique views. A comparison view of the opposite side obtained in the same position will be confirmatory particularly when apophyseal avulsions are a consideration. The physis of the avulsed apophysis will appear widened. The key is to differentiate base of the fifth metatarsal fractures from the normal fifth metatarsal apophysis. The fifth metatarsal apophysis is longitudinally oriented (e-Fig. 142.75) whereas metatarsal stress and avulsion fractures are horizontally oriented. To add to the confusion of the growing appendicular skeleton, the apophysis of the fifth metatarsal may rarely avulse (Fig. 142.76).

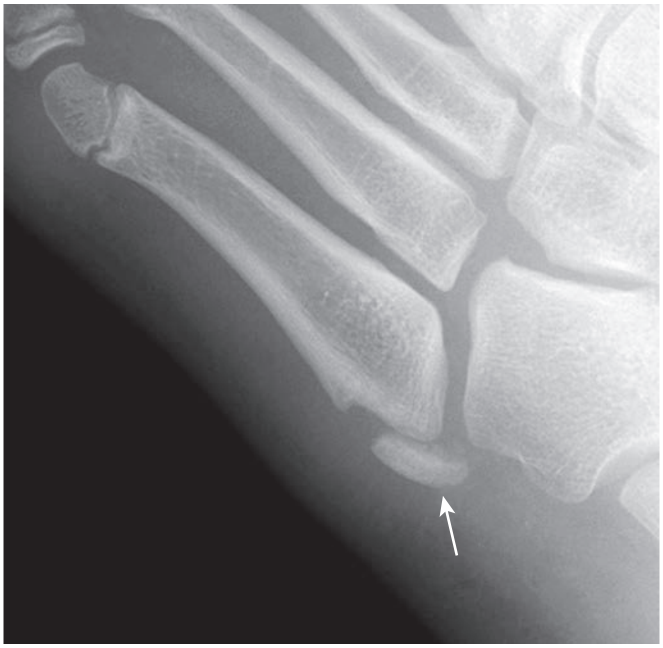

**Figure 142.76. Avulsion of the fifth metatarsal apophysis *(arrow)* in a 13-year-old boy.** The apophysis is displaced from the underlying bone and retracted proximally.

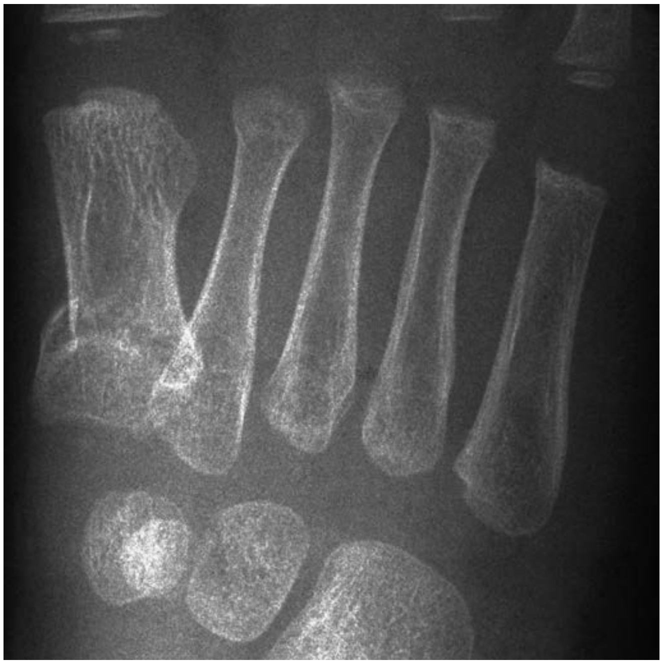
The transverse fracture line of a tuberosity avulsion may extend through the apophysis and its physis (e-Fig. 142.77). Injuries to the base of the metatarsal can extend into the fifth metatarsal–cuboid joint or into the region between the fourth and fifth metatarsal bases. These fractures should be differentiated from more distally located Jones or stress fractures (e-Fig. 142.78) of the fifth metatarsal shaft.

***Treatment.*** Apophyseal avulsions are treated conservatively with immobilization. Jones fractures have a higher rate of delayed union or nonunion and may need to be treated with longer immobilization or surgically management. The tenuous blood supply at the fracture site in Jones fractures has been implicated as a cause of delayed healing.[162]

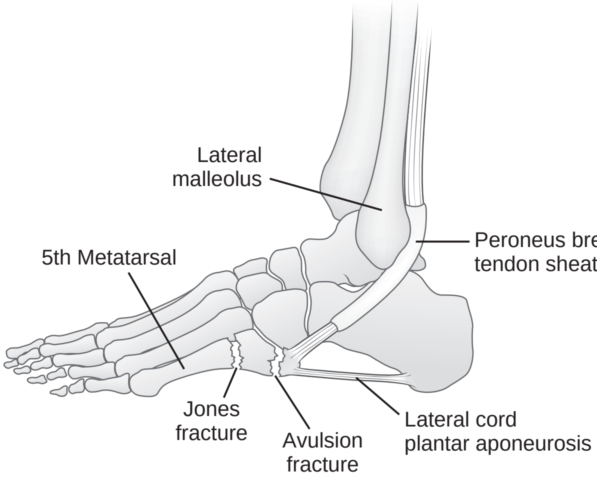
## NEUROPATHIC INJURY

***Etiologies, Pathophysiology, and Clinical Presentation.*** Causes of neuropathic injury in children include myelomeningocele, syrinx, congenital insensitivity to pain, and familial dysautonomia (Riley-Day syndrome).[163–166] Superimposed infection is common.[163] Neuropathic fractures and joints ("Charcot joints") are much less common in pediatric patients than in adults.

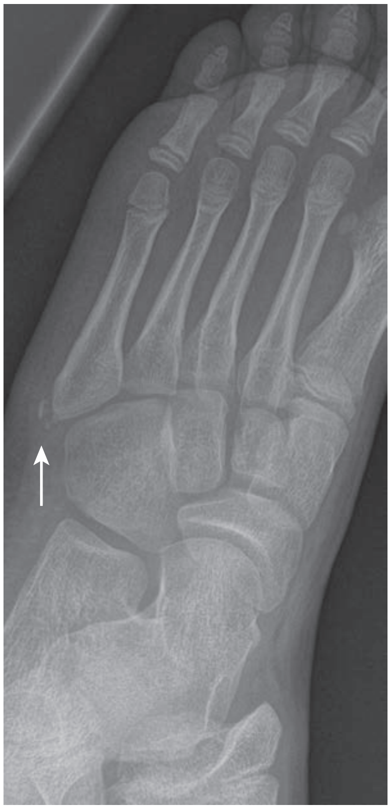
***Imaging.*** Neuropathic injury is characterized by the four Ds: (1) dislocation, (2) debris, (3) disorganization (deformity), and (4) density (sclerosis). Injuries fail to heal. Physeal fractures may occur and are often associated with subperiosteal hematoma and exuberant periosteal new bone. Findings may mimic tumor or infection. Repetitive trauma may lead to chronic physeal injury that may lead to premature fusion. Other sequelae include acro-osteolysis, joint deformity, joint dislocation, and epiphyseal osteonecrosis.[163] Neuropathic fractures are most common in the lower extremities in the diaphysis or metaphysis (e-Fig. 142.79). Injury to the fingertips is caused by crush, thermal damage, and chewing (e-Fig. 142.80).



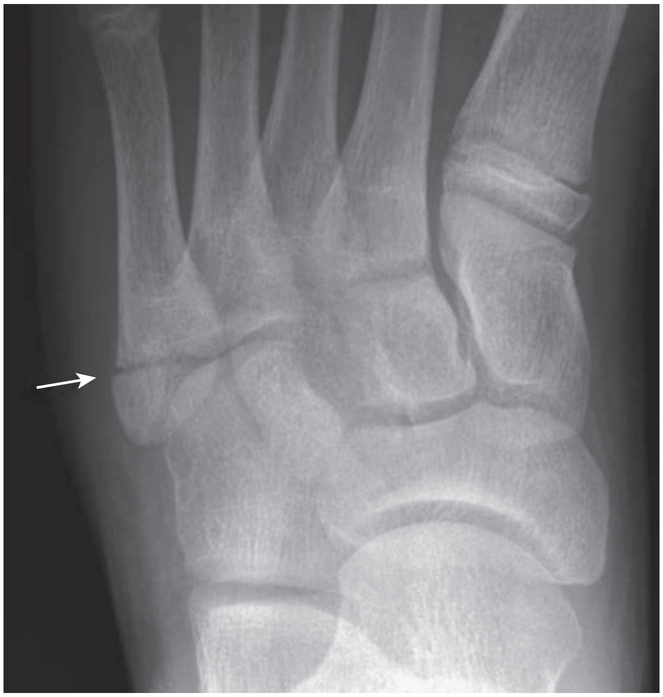
**e-Figure 142.73. Bunk bed first metatarsal fracture in a 3-year-old boy.** The cortex is buckled proximally.



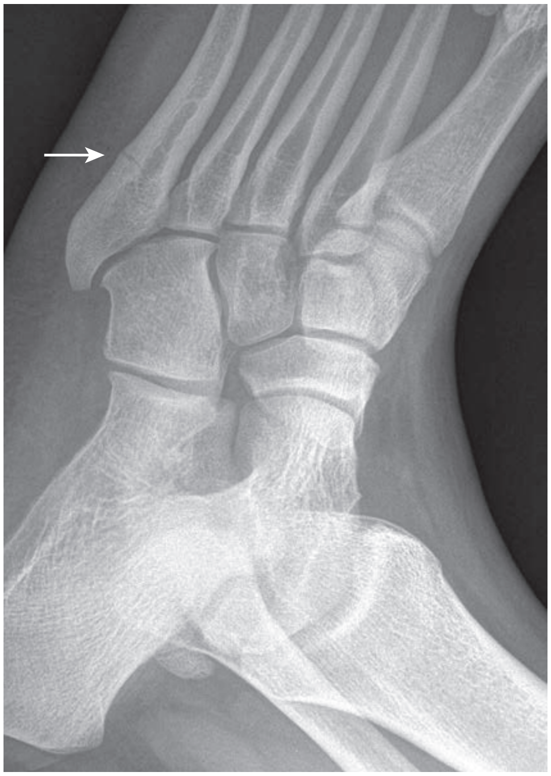
**e-Figure 142.74. Fractures at the base of the fifth metatarsal.** These fractures result from inversion of the foot, which places tension on the peroneus brevis tendon and the lateral cord of the plantar aponeurosis. An avulsion fracture of the proximal bulbous tip of the metatarsal is to be distinguished from the classic Jones fracture, a transverse fracture at the base of the metatarsal located 1.5 to 2 cm distal to the tip of the metatarsal. *(From Rogers LF.* Radiology of Skeletal Trauma*, 3rd ed. New York: Churchill Livingstone; 2002.)*



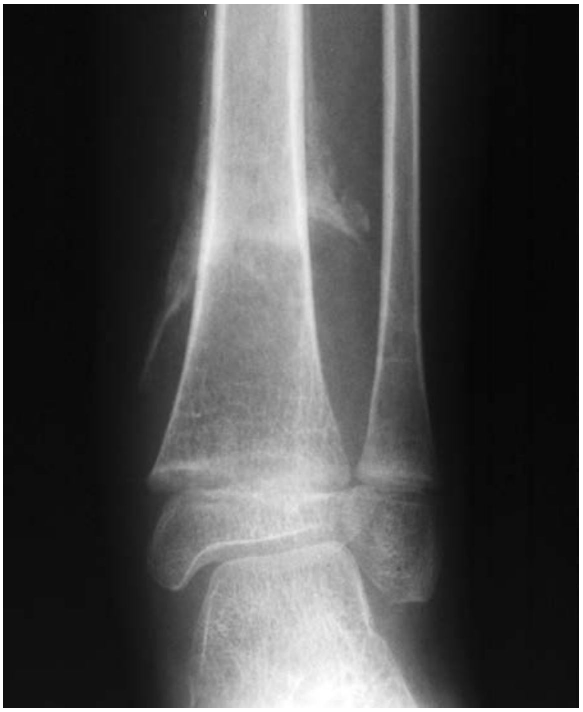
**e-Figure 142.75. Normal longitudinally oriented fifth metatarsal apophysis in a 9-year-old girl *(arrow)*.**



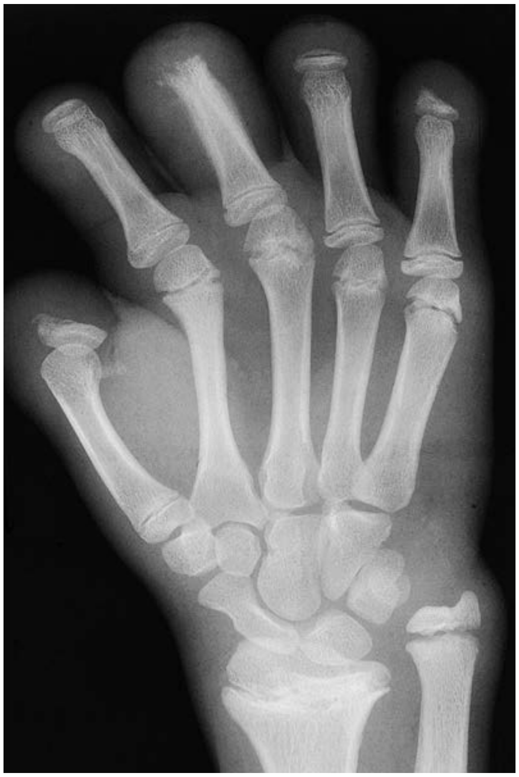
**e-Figure 142.77. Transverse fracture of the tuberosity of the fifth metatarsal *(arrow)* in a 12-year-old boy.**



**e-Figure 142.78. Fifth metatarsal stress fracture in a 17-year-old boy.** The fracture *(arrow)* is located approximately 3 cm distal to the fifth metatarsal tuberosity.



**e-Figure 142.79. Neuropathic fracture of the distal tibial growth plate in an 11-year-old girl with myelomeningocele.** The patient presented with swelling. The distal tibial growth plate is widened. Periosteal new bone is elevated and interrupted because of subperiosteal hemorrhage, which was caused by delayed diagnosis and lack of immobilization.



**e-Figure 142.80. Sequelae of congenital insensitivity to pain in a 16-year-old boy.** All of the fingers are amputated because of chronic injury. Premature fusion of the distal radial growth plate is noted with resultant shortening of the radius. The ulna is dislocated.

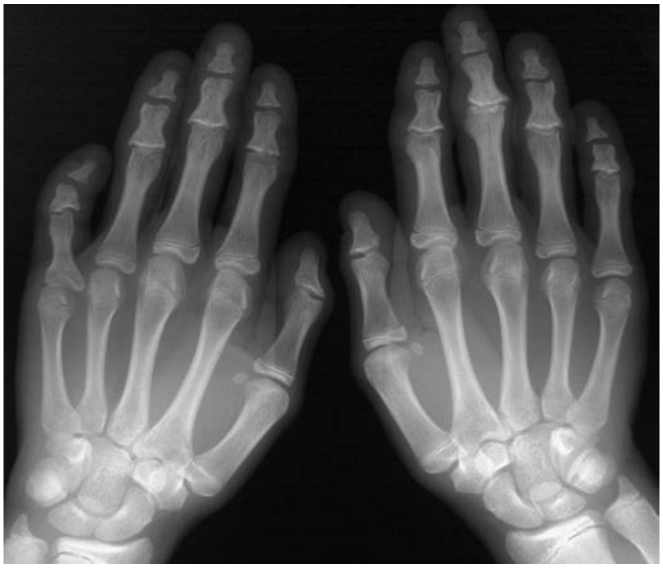


**Figure 142.81. Sequelae of frostbite in a 15-year-old girl.** Brachydactyly of the distal and middle phalanges was caused by premature growth plate closure. In this patient, the thumbs were not spared. The proximal phalanx of the right fifth finger is also shortened.

***Treatment.*** Treatment is variable and tailored to the underlying problem. Both nonsurgical management and surgical management are used for treating Charcot arthropathy. Nonsurgical treatment includes immobilization and reduction of stress. Examples of surgical management include removal of bony prominences, arthrodesis, plate and screw fixation, bone grafting, and reconstructive surgery.

## PHYSICAL AGENTS

### Frostbite

***Etiologies, Pathophysiology, and Clinical Presentation.*** Frostbite injury is most common in children ages 5 to 10 years. The pathophysiologic mechanism of frostbite is not well defined, but a direct injury to chondrocytes may occur within the physis.[167] The sequelae in children are premature fusion of the physis and shortening of the involved digits. Bone fragmentation may be caused by ischemic damage.[167] Secondary degenerative changes develop from direct articular injury and malapposition of joint surfaces in the affected digits.[168]

***Imaging.*** Immediate radiographic findings occurring 1 week after exposure include soft tissue swelling and soft tissue gas, which is a poor prognostic sign.[167] Radiographically identifiable osseous changes manifest weeks to months after injury. Characteristically, the thumb is spared as it is clenched at the time of exposure and covered by the other digits. Findings are most pronounced in the distal phalanges, occasionally affect the middle phalanges, and rarely involve the proximal phalanges or metacarpals (Fig. 142.81).[168]

***Treatment.*** Treatment is variable and depends on the degree of injury. Rewarming the extremity, surgical debridement of nonviable tissue and thrombolytics are potential treatments. Antibiotics are commonly used to prevent or treat superimposed infection.

## THERMAL AND ELECTRICAL INJURY

***Etiologies, Pathophysiology, and Clinical Presentation.*** Thermal injuries are a significant cause of morbidity and mortality in children, most commonly affecting children under age 6 years.[169] The hand is most commonly injured, followed by the face.[169,170]

***Imaging.*** Injury from thermal burns is usually to the soft tissues, leading to contractures and ankylosis. Heterotopic bone contributes to ankylosis, as does direct thermal injury of a joint.[171] Direct thermal injury to the physis may lead to premature fusion or growth disturbance (e-Fig. 142.82).[171,172] Electrical injury may lead similar sequelae because of tissue heating. Osteolysis may also occur.

***Treatment.*** Wound infection and sepsis are common, and surgical intervention may be necessary in some cases.[173,174]

## RADIATION

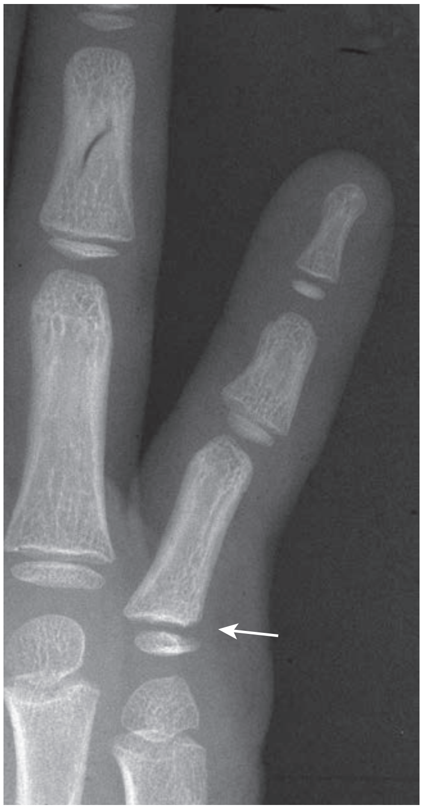
***Etiologies, Pathophysiology, and Clinical Presentation.*** Irradiation of tissues may cause immediate or delayed injury to tissues.[175] Radiation affects the immature skeleton by interfering with chondrogenesis and causing resorption of bone and cartilage at the physis, therefore affecting younger children with greater growth potential to the greatest degree.[175] Therapeutic radiation doses may be sufficient to cause permanent injury to bone. Microscopic changes are seen with as little as 300 centigrays (cGy) and growth retardation with as low as 400 cGy.[175] Histologic recovery occurs with doses up to 1200 cGy; however, beyond this level, almost uniformly permanent cell damage and premature physeal fusion occur.[175] Radiation-induced sarcomas are uncommon and occur years after therapy.[175]

***Imaging.*** Radiation injury includes growth retardation with hypoplasia (e-Fig. 142.83), premature physeal fusion, SCFE, osteonecrosis, osteochondroma formation, and radiation-induced sarcoma.[175–177]

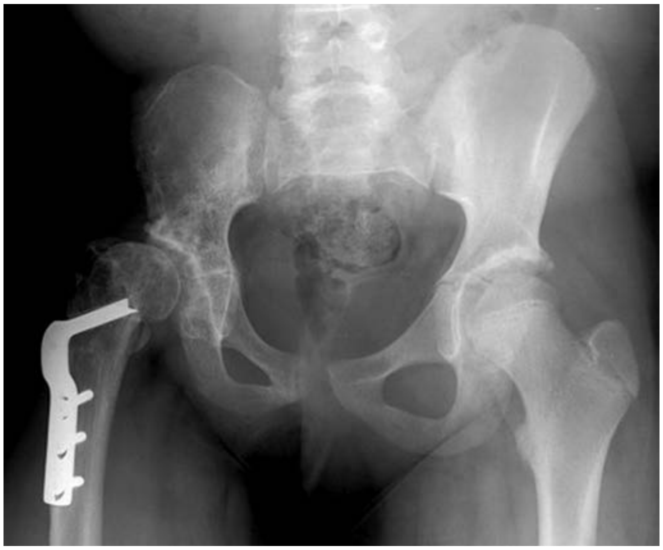
Metaphyseal sclerosis, fraying, and widening can be seen 1 to 2 months after long bone irradiation, resembling rickets.[175] The affected bone may return to normal after 6 months. A dense metaphyseal band may also be seen shortly after therapy.[175] SCFE can occur anywhere from 1 to 8 years after therapy, and long-term radiographic follow-up is warranted.[175] Horizontal sclerotic lines parallel to the vertebral body endplates may be seen (bone in bone appearance) 9 to 12 months after irradiation to the spine. With higher doses of radiation (2000–3000 cGy), vertebral body scalloping, loss of vertebral body height, and scoliosis from asymmetric vertebral body growth have been reported.[175]

### KEY POINTS

- The composition of a child's bones and the presence of the growth process predispose the child to different types of fractures and complications than are seen in adults.
- Higher grade Salter-Harris fractures have a higher incidence of premature physeal fusion.
- The medial epicondyle ossifies before the trochlea. In an injured elbow, visualization of an ossified trochlea without an ossified medial epicondyle in its normal location should raise suspicion for an avulsed medial epicondyle.
- When a child presents with bilateral symmetric SCFE or outside of the typical age range, an underlying metabolic disorder should be suspected.
- Classic toddler fracture of the tibia is one cause of pain and refusal to bear weight. Toddlers may also incur fractures of the fibula and tarsal bones (talus and cuboid) and present similarly.
- Because of the proximity of the nail bed, Salter-Harris fractures of the distal phalanx of the great toe are considered open fractures. Children should receive prophylactic antibiotics to prevent osteomyelitis.



**e-Figure 142.82. Sequelae of thermal injury.** The child was burned 7 years ago. Although the growth plate of the proximal phalanx appears patent *(arrow)*, growth disturbance has resulted in medial deviation of the phalanx.



**e-Figure 142.83. Sequelae of radiation therapy in an 11-year-old girl.** The patient underwent radiation therapy for Ewing sarcoma of the right ileum at age 3 years. Bones of the right hemipelvis are small. Premature fusion of the right proximal femoral growth plate and triradiate cartilage has occurred. A varus osteotomy of the proximal femur was performed to better center the right femoral head within the diminutive right acetabulum.

# 143 Child Abuse

Peter J. Strouse

## OVERVIEW

Radiology played a major role in defining child abuse as a medical entity, most notably with the landmark publications by Caffey (1946) and Silverman (1953).[1,2] Silverman also contributed to Kempe's 1962 paper, "The Battered Child," which demonstrated the prevalence of severe injury and death from child abuse and brought widespread public awareness to the diagnosis.[3] In the ensuing years, an enormous experience base and wealth of literature have defined and refined our knowledge of the radiologic appearance of child abuse and its differential diagnosis. In spite of this, child abuse remains a difficult and emotionally charged topic. Today, the diagnosis is increasingly challenged in the legal system, and radiologists are more frequently called upon to participate in legal proceedings. It behooves any radiologist interpreting pediatric imaging to be very familiar with the findings of child abuse and its differential diagnoses.

***Etiology, Pathophysiology, and Clinical Presentation.*** According to the most recent survey from the US Department of Health and Human Services, in the year 2014, 43.7 of every 1000 children (or approximately 3,248,006 children) in the United States were evaluated by child protective services for suspected abuse or neglect, and 9.3 of every 1000 children were confirmed as abused or neglected (24.4 of 1000 for those <1 year of age).[4] In 2014, 75.0% were victims of neglect, 17.0% of physical abuse, 8.3% of sexual abuse, 6.0% of psychological maltreatment, 2.2% of medical neglect, and 6.8% of other forms of maltreatment.[4] This totals 115.4%, as many children are victims of multiple forms of abuse or neglect.[4] Young children are at greatest risk for fatality; 70.7% of fatalities from child abuse are in children less than 3 years of age and 44.2% are in children less than 1 year of age.[4] An estimated 1580 children died from abuse or neglect in 2014.[4]

Clinical presentations of child abuse are myriad. Abuse may be suspected early in the clinical course; however, presentation is often cryptic until traumatic findings are made clinically or by imaging.[5,6] Children often present with bruising, burns, or evidence of neglect. Children may present with symptoms related to neuroaxis, thoracoabdominal, or extremity trauma. Manifestations of abuse may be found incidentally on imaging performed to evaluate a nontraumatic process.

***Imaging.*** Initial imaging of the abused child is directed by the clinical presentation.[6–10] Imaging is performed to evaluate for processes that need immediate management or may further threaten the child's well-being if not diagnosed and treated. Once the child's acute medical issues are addressed and their condition is stable, further imaging in the form of a radiographic skeletal survey is performed. The role of such imaging is to (1) catalog and document injuries; (2) identify occult injuries, especially those requiring treatment; (3) confirm or disprove abuse; and importantly, (4) make alternative diagnoses when present.[10]

Computed tomography (CT) and magnetic resonance imaging (MRI) are used to evaluate suspected head trauma.[10] There are no firm indications for CT of the chest in suspected physical abuse or infants with blunt traumatic injury. CT of the abdomen and pelvis is indicated only in children with physical examination and/or laboratory findings suggesting traumatic intraabdominal injury.[11–13]

In children less than 2 years of age who are possible victims of abuse, a skeletal survey is mandatory (Box 143.1).[8–10,14] A "babygram" consisting of single or few images of the entire infant is unsatisfactory. Ideally, a radiologist should review the images before the child leaves the radiography suite. Poorly positioned and otherwise suboptimal images should be repeated. Additional views may be obtained to further define positive or suspected abnormalities. Commonly acquired additional views include lateral views of the extremities, coned views centered at the joints (wrist, ankle, knee), and Townes view of the skull.

Follow-up skeletal survey performed 2 weeks later may provide additional information (e-Fig. 143.1).[15,16] As noted by Kleinman, the follow-up survey aids by (1) detecting additional fractures; (2) differentiating fractures from normal developmental variants; and (3) assisting in dating injuries.[15] Follow-up surveys may be limited or tailored to areas of interest.[17]

Beyond 2 years of age, the yield of radiographic skeletal survey is low as fractures are less common, fractures are less commonly occult, and the fracture patterns highly specific for abuse are no longer seen.[18] A skeletal survey may still be warranted if there is a high clinical suspicion for abusive trauma, particularly in children who are mentally incapacitated.

Radiographic skeletal surveys should be performed in all cases of fatal suspected abuse and unexplained infant death, following the same protocol as used in living infants.[19–22] Postmortem whole body CT may aid in delineation of some fractures.[23,24]

***Imaging Findings.*** No single radiographic finding is pathognomonic of child abuse. Individual findings vary from high to low specificity (Box 143.2).[9,25,26] High-specificity lesions are seen with abusive trauma but rarely with other forms of trauma. Low-specificity lesions are commonly seen with abusive trauma but are also common with other forms trauma.

Every patient is considered individually with respect to the presenting clinical history and the possibility of underlying abnormality or disease, which would predispose to fracture.[9] The plausibility of the injury having occurred from accidental nonabusive trauma must also be considered. Is the explanation offered for the injury plausible? Is the developmental level of the child consistent with that history? Answering these questions requires input of the radiologist to a multidisciplinary child protection team.

Nonambulatory infants do not normally incur fractures. The appropriateness of the provided history in relation to the mechanism of injury and age of the child is thus often an important clue to the diagnosis of abusive injuries. Inappropriate delay in seeking treatment is also concerning.

The constellation of radiographic findings within the context of the clinical presentation usually carries greater specificity than any single finding. Multiple fractures in different stages of healing are highly specific for child abuse, unless there is underlying bone dysplasia or metabolic disease.

## RIB FRACTURES

Rib fractures are found in approximately 50% of fatally abused infants.[27] In a surviving infant, the physician may palpate callus or, rarely, crepitus, but typically rib fractures are clinically occult. Most acute rib fractures are nondisplaced or minimally displaced buckle or greenstick fractures, which are subtle or not evident on radiography until callus formation (see e-Fig. 143.1).[28] Fractures may occur at any point along the arc of the rib including the rib head, costovertebral, posterior, lateral, anterior, or costochondral

## Abstract:

Radiology played a major role in defining child abuse as a medical entity in the 1940s and 1950s. Since then an enormous experience base and wealth of literature have defined and redefined our knowledge of the imaging appearance of child abuse and its differential diagnosis. Still child abuse remains a difficult and emotionally charged topic. Today, the diagnosis is increasing challenged in the legal system and radiologists are more frequently called upon to participate in legal proceedings. This chapter reviews the imaging evaluation of abuse in the skeleton of children.

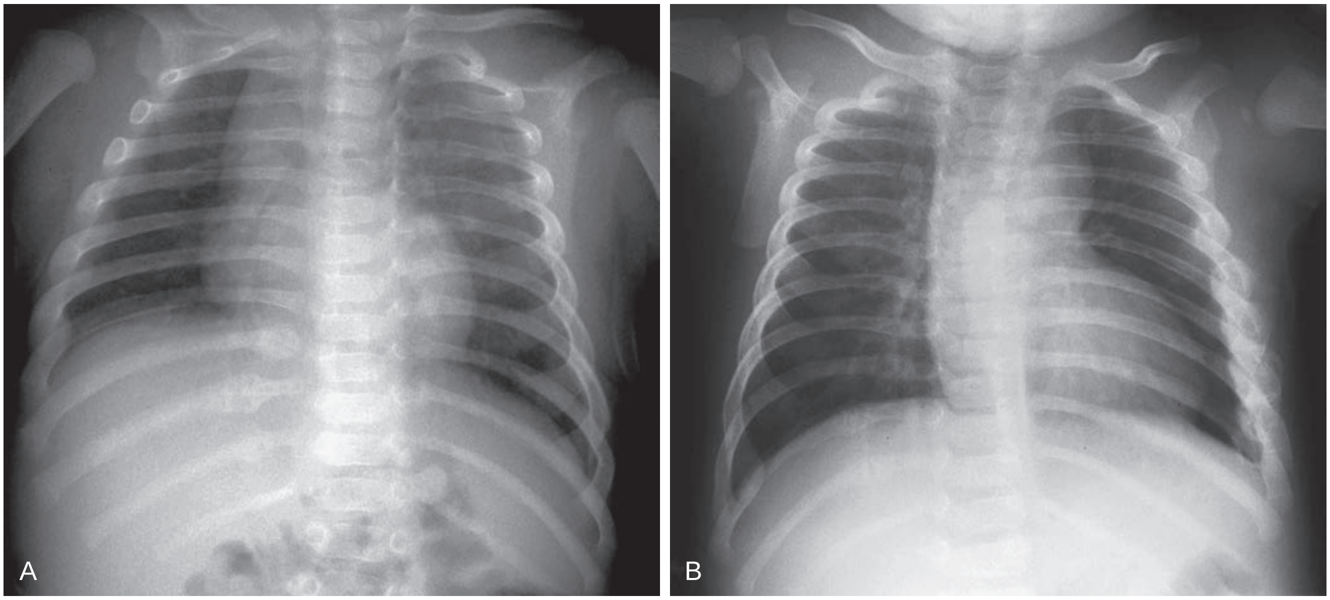
Radiography



**e-Figure 143.1. A 6-week-old male infant sent for an upper gastrointestinal series for evaluation of colicky pain.** (A) Initial chest radiograph identified healing fractures at the right 9th, 10th, and 11th ribs. (B) Follow-up chest radiograph 2 weeks later showed additional fractures, now healing, at the lateral aspect of the left 3rd through 9th ribs. The father admitted to shaking the infant.

**BOX 143.1** Skeletal Survey*

- Anteroposterior (AP) and lateral of skull (Townes view optional; add if any fracture seen)
- Lateral spine (C-spine may be included on skull radiographs; AP spine is included on AP chest and AP pelvis to include entire lumbar spine)
- AP, right posterior oblique, left posterior oblique of chest—rib technique
- AP pelvis
- AP of each femur
- AP of each leg
- AP of each humerus
- AP of each forearm
- Posteroanterior of each hand
- AP (dorsoventral) of each foot

*Images are reviewed by a radiologist before the child leaves. Poorly positioned or otherwise suboptimal images should be repeated. Lateral views are added for positive or equivocal findings in the extremities. Coned views of positive or equivocal findings (i.e., at the ends of the long bones, ribs) may be obtained.

**BOX 143.2** Skeletal Injuries From Child Abuse

**HIGH SPECIFICITY FINDINGS**

- Classic metaphyseal lesions
- Posterior rib fracture
- Scapular fracture
- Sternal fracture
- Spinous process fracture
- First rib fracture

**MODERATE SPECIFICITY FINDINGS**

- Multiple fractures
- Fractures of differing age
- Spine fracture
- Complex skull fracture
- Physeal fractures of the long bones
- Digital fractures

**LOW SPECIFICITY FINDINGS**

- Diaphyseal fractures of the long bones
- Simple skull fractures
- Clavicle fracture
- Subperiosteal new bone formation

*Modified from Kleinman PK.* Diagnostic Imaging of Child Abuse. *2nd ed. St Louis, MO: Mosby; 1998.*

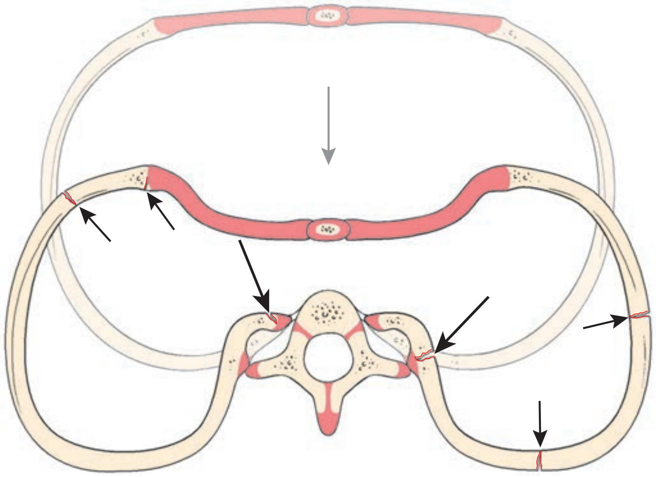


**Figure 143.2. Mechanism of rib injury.** With anteroposterior compression *(gray arrow)* of the chest, excessive leverage of the posterior ribs occurs over the fulcrum of the transverse processes. This places tension along the inner aspects of the rib head and neck regions, resulting in fractures at these sites *(long black arrows)*. This mechanism is consistent with morphologic patterns of injury occurring at other sites along the rib arcs and at the costochondral junctions *(short black arrows)*. *(From Kleinman PK.* Diagnostic Imaging of Child Abuse. *2nd ed. St Louis, MO: Mosby; 1998.)*

portions.[27,29] Posterior rib fractures at the costovertebral junction have a high specificity for abuse.[30–32] Boal et al reviewed 1463 rib fractures in 141 abused infants and noted that, when individual sites along the rib arc were compared, costovertebral junction fractures outnumbered all other individual sites but represented only 33% of the total number of rib fractures.[30] Fractures at the costochondral junction and rib heads appear radiographically similar to classic metaphyseal lesions of the long bones. Costochondral junction fractures have a high association with visceral trauma.[33] First rib fractures bear high specificity for child abuse.[34]

Squeezing injury results in leveraging of the posteromedial rib over the spinal transverse process. Excessive compression and distraction forces are also placed on the lateral and anterior rib arc and at the metaphyseal equivalent regions of the costovertebral junctions and rib heads (Fig. 143.2).[28,35] Multiple fractures may involve a single rib. Oblique views of the ribs increase the sensitivity for rib fractures and aid in their characterization (Fig. 143.3).[36,37] Follow-up radiographs (see e-Fig. 143.1 and Fig. 143.3) and CT also provide increased sensitivity.[38,39] CT is more sensitive for rib fractures than radiography, but the greater radiation dose of CT limits its use.[38] Nevertheless, focused CT may be helpful in problematic cases. If CT is performed for evaluation of visceral trauma, reconstruction of images with narrow slice thickness, bone detail algorithm, and multiplanar reformats facilitate identification and delineation of rib fractures (Fig. 143.4). Postmortem CT with increased tube current (mAs) exquisitely delineates rib fractures.

Rib fractures due to cardiopulmonary resuscitation (CPR) are rare in infants but may occur particularly with newer methods of infant CPR.[40–43] Infant rib fractures from CPR are predominantly anterolateral, middle ribs (4th–7th) and usually radiographically occult.[40,41,44] Rib fractures caused by birth trauma are extremely rare (except for in infants with osteogenesis imperfecta congenita).[45] Rib fractures are frequently found in infants with acquired metabolic bone disease and have been reported after thoracotomy, chest tube placement, chest physiotherapy, and blunt accidental trauma.[34,46–48] However, rib fractures in infants younger than age 12 months without a predisposing condition or instrumentation are strongly suspicious for abuse.[34,49,50]

## LONG BONE FRACTURES

### Metaphyseal Fractures

The classic metaphyseal lesion, commonly referred to as a *corner* or *bucket-handle* fracture, was reexamined by Kleinman in 1986 with correlation of histopathology and radiography.[51] Klienman showed that the lesions represent a shearing or planar fracture that extends through the primary spongiosa of the metaphysis and not an avulsion injury.[51,52] Depending on size and displacement of the metaphyseal fragment, positioning of the child and radiographic projection, the fracture may have the appearance of a “corner” or a “bucket-handle” (Figs. 143.5 and 143.6). These

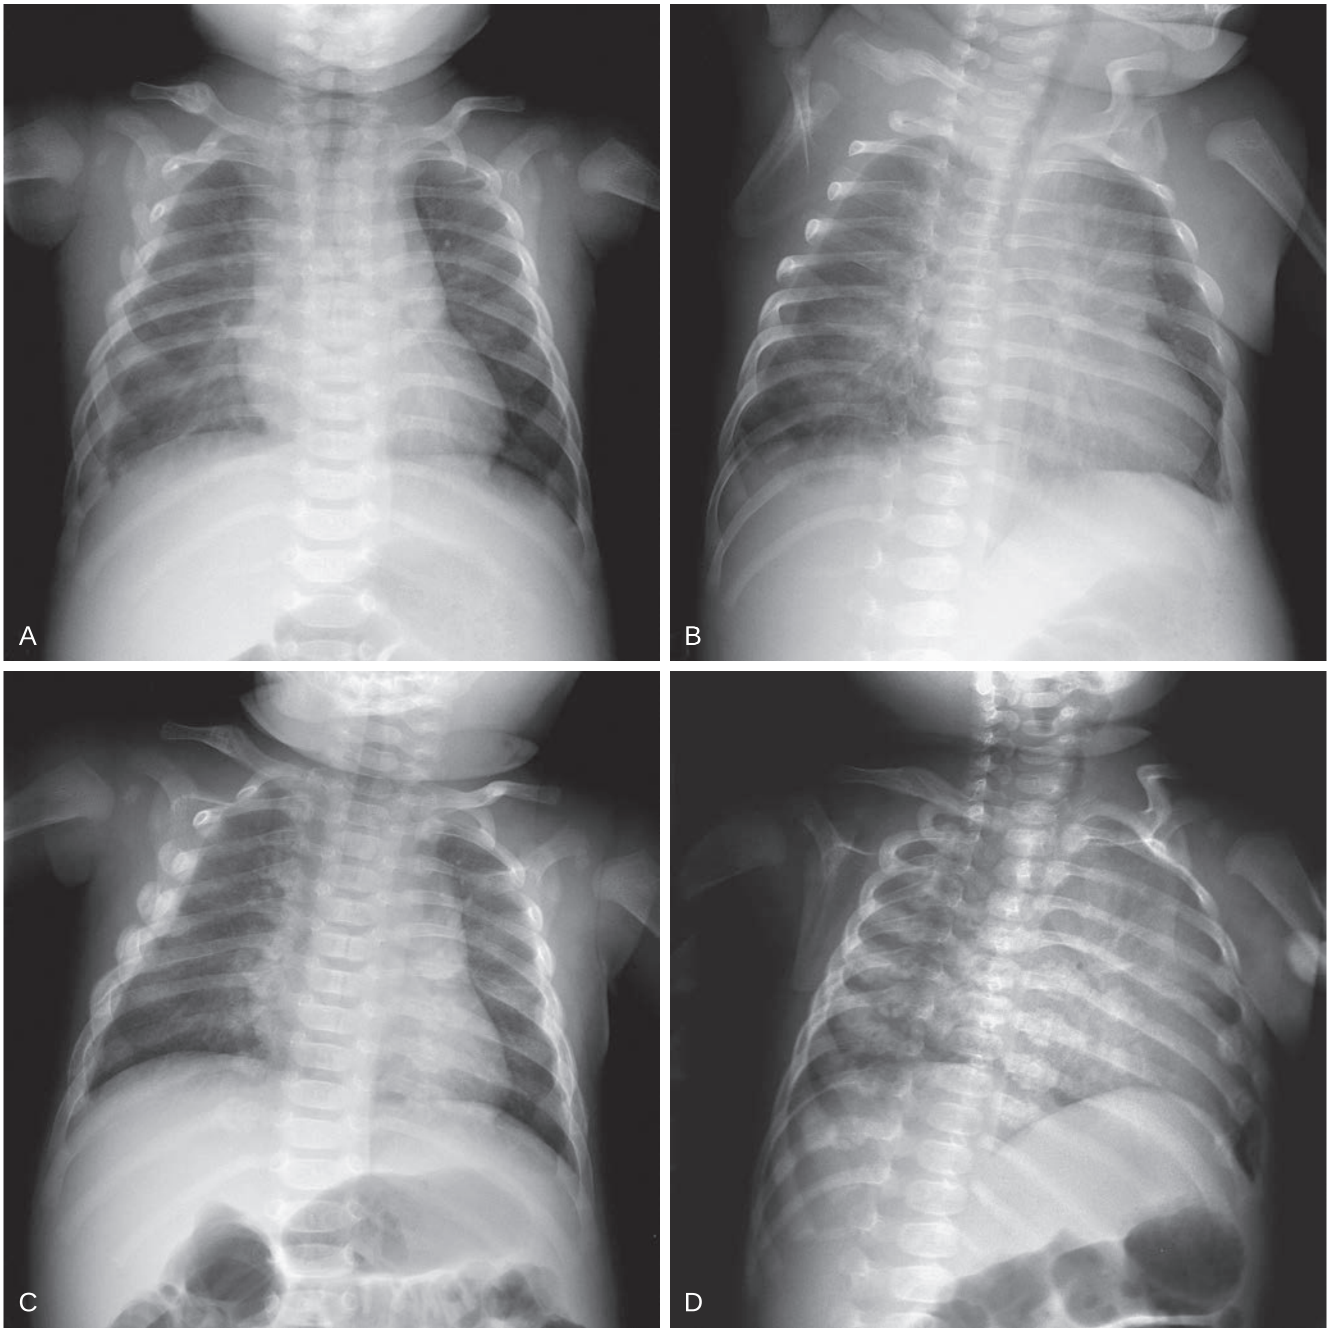

**Figure 143.3. A 2-month-old male infant with right pleural effusion.** (A) Anteroposterior radiograph shows healing right clavicular fracture and nine fractures of the right ribs and four fractures of the left ribs on initial survey. Adjacent pleural effusion is seen. (B) Some fractures are better depicted on the left posterior oblique view. (C and D) Two weeks later, anteroposterior and left posterior oblique radiographs of the chest clearly show 18 right rib fractures and 11 left rib fractures with multiple individual ribs fractured in multiple locations. This illustrates the value of a follow-up skeletal survey. The pleural effusion has also resolved on the follow-up radiographs.

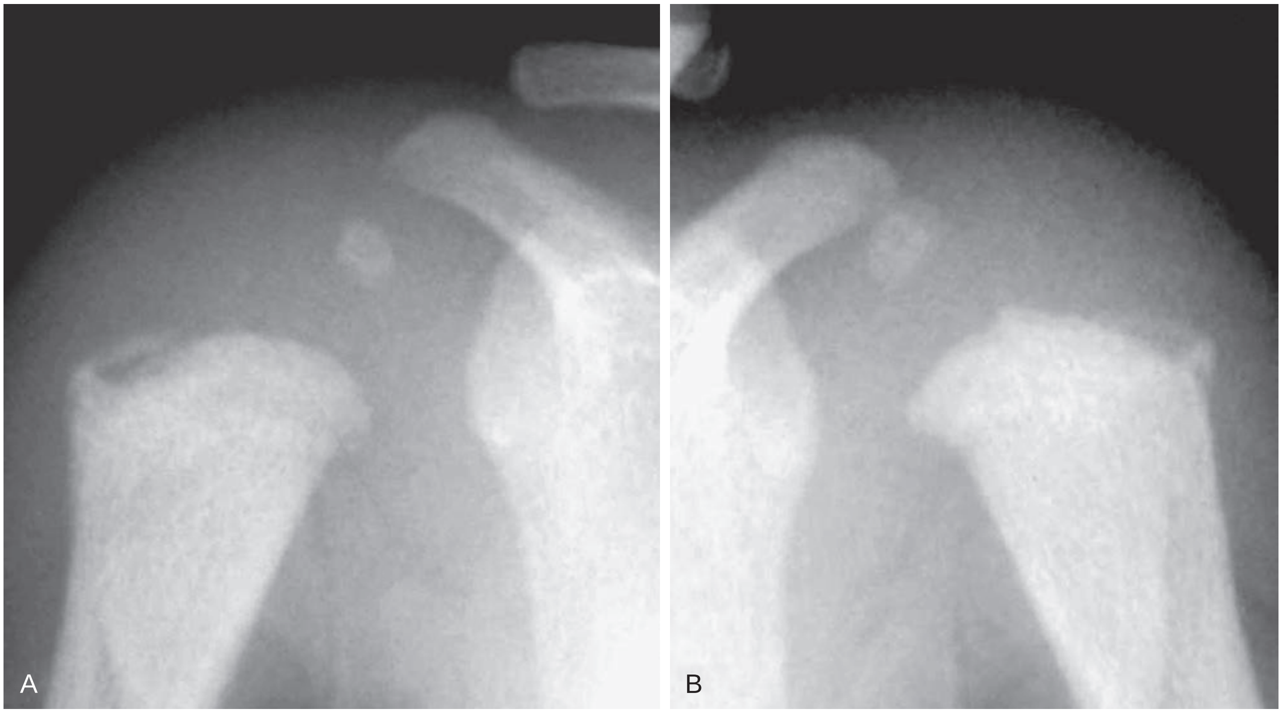
fractures are thought to occur from violent forces as the infant is held by the trunk (Fig. 143.7, e-Fig. 143.8, and Fig. 143.9). Torsional forces directly on a limb probably cause some fractures. Typically, no bruising is evident with a classic metaphyseal lesion. Classic metaphyseal lesions are most commonly seen distal femur, proximal and distal tibia, distal fibula, proximal humerus, and distal radius.[53–56]

Some classic metaphyseal lesions may become more conspicuous on short-term follow-up radiography.[52] With healing, classic metaphyseal lesions typically become indistinct and sclerotic (Fig. 143.10). Kleinman demonstrated subtle extension of physeal cartilage into the metaphysis as a sign of healing.[57] Subperiosteal new bone is not seen unless there is an associated periosteal injury.

Transverse, greenstick, and buckle fractures of the metaphysis may also be caused by child abuse but do not carry the same specificity as classic metaphyseal lesions. Such fractures are considered to be of low specificity. A small step off, beak, or spur



**e-Figure 143.8. Anteroposterior right (A) and left (B) shoulders of a 5-month-old female infant, deceased, cause of death unknown.** Eight fractures were identified at postmortem skeletal survey, including bilateral proximal humeral classic metaphyseal lesions.

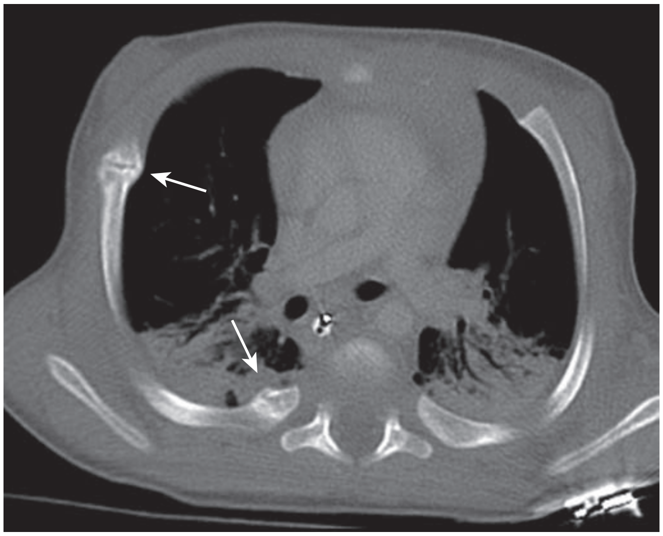


**Figure 143.4. A 3-month-old male with multiple rib fractures, multiple metaphyseal fractures (classic metaphyseal lesions), a small subdural hematoma, and disruption of the posterior wall of the hypopharynx.** This computed tomography scan was performed for concern of extension of infection into the chest. Images were also reconstructed with bone algorithm. *Arrows* indicate healing posterior and anterolateral rib fractures. The fracture lines are indistinct. Callus is present. Note the normal appearance of the costochondral junction of an anterior left rib.

related to the perichondrial ring at the margin of the metaphysis may mimic abusive injury.[58] Slight fragmentation of metaphyseal margins with physiologic bowing may also mimic abuse.[59] Iatrogenic classic metaphyseal-like lesions have been reported with birth trauma and as a complication of treatment of clubfeet.[60,61] Such reports are rare, and it is likely that the reported fractures occurred with a similar torsional mechanism as occurs in child abuse.

### Physeal Fractures

Physeal fractures are uncommon in child abuse. Fractures may be occult or subtle at presentation and some are not recognized until healing occurs.[62] Ultrasonography or MRI may be helpful to image the unossified epiphyses and assess the integrity of the physis.[63] Common sites of physeal fracture are the proximal and distal humerus and the proximal femur (Fig. 143.11).[62–64] As opposed to classic metaphyseal lesions, which heal without sequelae because the fracture does not traverse the growth plate, physeal fractures may be complicated by premature physeal fusion.

### Diaphyseal Fractures

Transverse, oblique, and spiral diaphyseal fractures of the long bones in the nonambulatory young infant should raise suspicion for abuse.[65–68] Once ambulatory, accidental fractures become common.[69] Factors that increase the likelihood of an abuse-related injury include association with another fracture (particularly if fractures are in different stages of healing) and other clinical features that produce a high level of suspicion for abuse, inappropriate clinical history, failure to seek medical attention, and discovery of the fracture in a healing state (see Figs. 143.7 and 143.12).[68,70,71]

## FRACTURES OF THE SCAPULA AND STERNUM

Although uncommon, fractures of the scapula are highly specific for abuse (e-Fig. 143.13).[72] Acromial fractures probably result from direct or indirect forces applied during shaking. It is usually accompanied by other bony thoracic trauma. Variants in ossification of the acromion may appear similar to a fracture.[73,74]

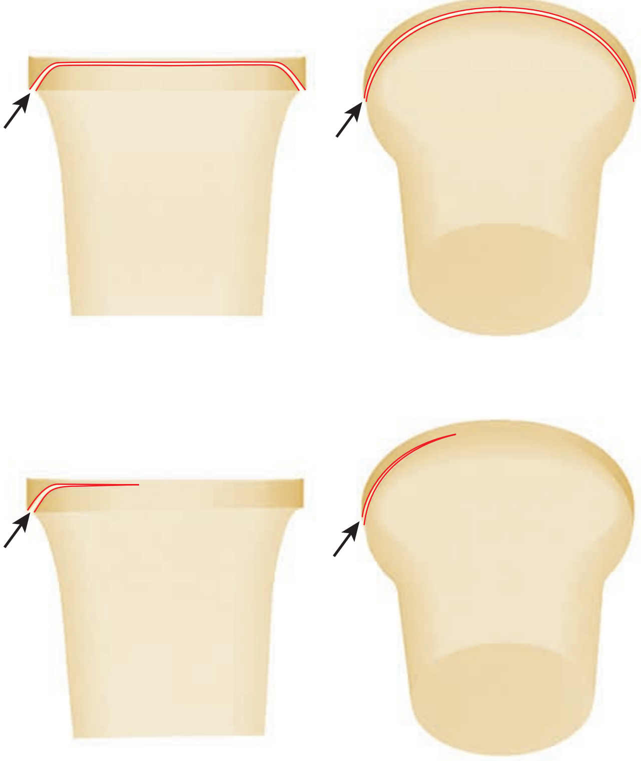

**Figure 143.5. Corner and bucket-handle fracture patterns of the classic metaphyseal lesion.** Fractures *(arrows)* extend adjacent to the chondro-osseous junction and then veer toward the diaphysis to undercut the larger peripheral segment that encompasses the subperiosteal bone collar. When the physis is viewed tangentially, the classic metaphyseal lesion appears as a corner fracture *(left images)*. When a view is obtained through beam angulation, a bucket-handle pattern results *(right images)*. *Top images,* Diffuse injury; *bottom images,* localized injury. *(From Kleinman PK.* Diagnostic Imaging of Child Abuse. *2nd ed. St Louis: Mosby; 1998. Originally modified from Kleinman PK, Marks SC, Jr. Relationship of the subperiosteal bone collar to metaphyseal lesions in abused infants.* J Bone Joint Surg Am. *1995;77:1471–1476.)*

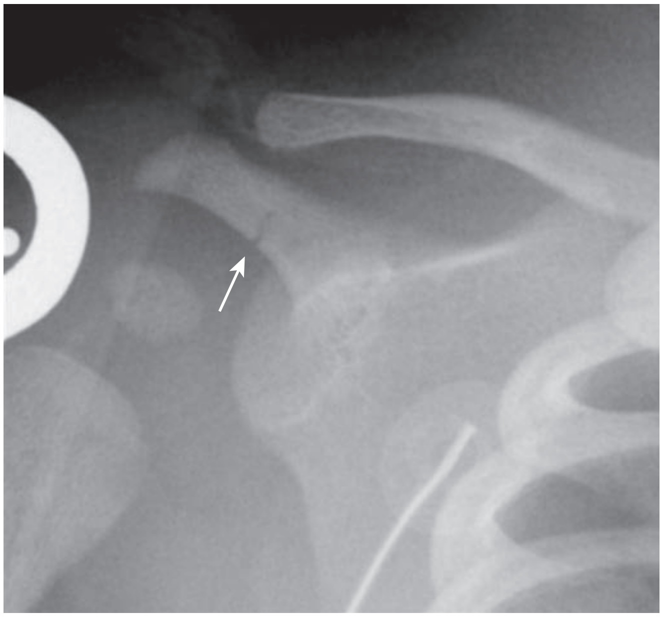
Fractures of the sternum are very uncommon in infants, including those who are abused.[72,75] Although Kleinman classifies sternal fractures as highly specific for child abuse, a recent series found these fractures less specific.[75]

## CLAVICLE FRACTURES

Fractures of the clavicle (Fig. 143.14) are common in child abuse but are also common from accidental and birth trauma and are therefore considered to be of low specificity for child abuse. Clavicle fractures occur in 0.5% of newborns.[76] Usually, a history of dystocia exists. It is not uncommon for clavicle fractures to escape detection on the newborn physical examination.[77] Clavicle fractures from birth exhibit callus by 10 to 14 days after birth.[77] A fracture that appears acute without visible callus in a child older than 10 to 14 days therefore becomes suspicious for having been incurred after birth.

## SPINAL FRACTURES

Although rare, spinal fractures in infants and young children are strongly associated with abuse.[9,72,78–80] The mechanism is usually



**e-Figure 143.13. A 10-week-old girl with fatal abusive head injury.** An acromial fracture *(arrow)* was the only fracture found by a postmortem skeletal survey.

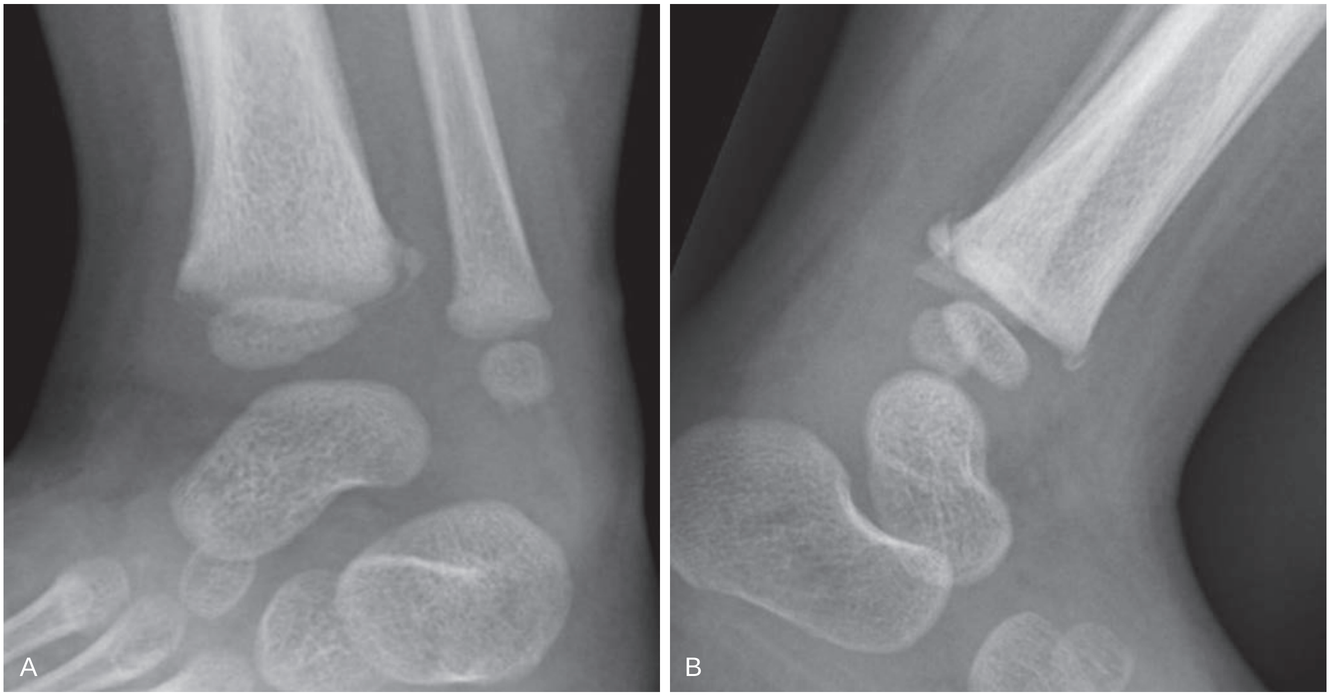


**Figure 143.6. Acute classic metaphyseal lesion fracture of the distal tibial metaphysis in a 9-month-old boy.** The fracture is seen as a “bucket handle fracture” on the anteroposterior view (A) and as a “corner fracture” on the lateral view (B).

due to hyperflexion and/or axial loading. On radiographs, injuries manifest as compression deformities of the vertebral bodies, often with associated end plate defects and avulsive injuries of the spinous processes.[79] Fractures may result in listhesis.[80,81] Injuries often involve multiple adjacent vertebral bodies and are most common near the thoracolumbar junction (Fig. 143.15).[78,80]

Cervical spine fractures are fortunately uncommon in child abuse but may be devastating.[80] Severe fracture-dislocations have been described, including classic hangman’s fracture of the C2 vertebra (e-Fig. 143.16).[82] Spinal cord injury is uncommon but can occur.[83,84]

Isolated spinous process fractures are considered highly specific for child abuse.[85] Avulsions may be caused by hyperflexion with axial loading or shaking.

## SKULL FRACTURES

Skull fractures are frequent in abuse and indicative of an impact injury. Skull fractures also commonly result from accidental injury. Multiple fractures, bilateral fractures, diastasis of fractures and sutures, fractures that cross suture lines, and occipital fractures are associated with abuse (e-Fig. 143.17).[86–88] However, no particular pattern of skull fracture is diagnostic of abuse.[89] Simple linear fractures are commonly seen in abuse and in accidental trauma are thus considered to be of low specificity for abuse.[25] Such fractures are common in short-distance falls onto a hard surface. Complex skull fractures are not expected from short-distance falls in the home environment and are thus considered to be of moderate specificity for abuse.[25] Soft tissue swelling is seen with acute fractures; lack of soft tissue swelling suggests that a fracture is not acute.[90] Diastatic fractures or widened skull sutures indicate a space-occupying process within the cranium such as diffuse swelling or large subdural hematoma (Fig. 143.18).

Anteroposterior and lateral skull radiographs are part of the radiographic skeletal survey in suspected abuse. A Townes view

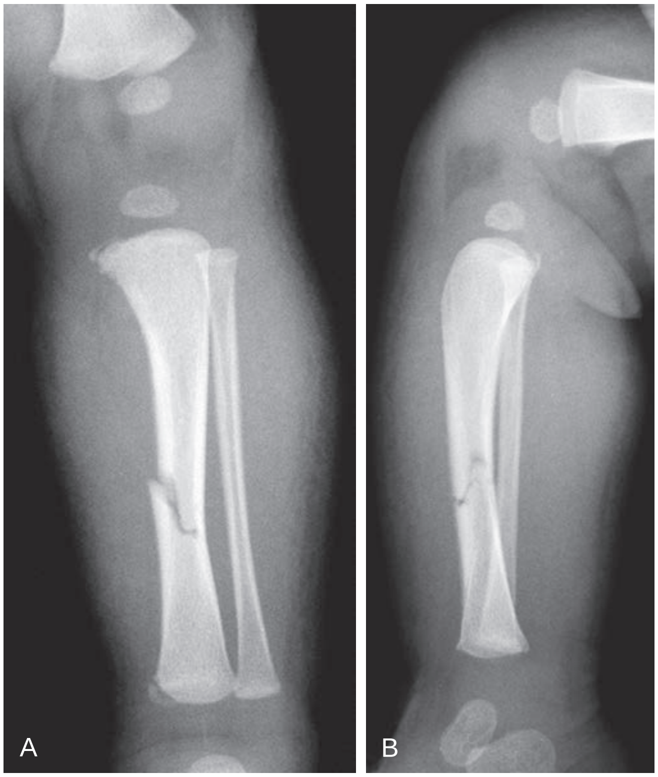

**Figure 143.7. A 1-month-old female infant was brought to the emergency department for swelling of the leg without history of trauma.** (A) Anteroposterior and (B) lateral radiographs of the left leg shows classic metaphyseal lesions at the proximal and distal tibia, as well as a short oblique mid-diaphyseal fracture. Multiple rib fractures and classic metaphyseal lesions of the right tibia were also discovered.

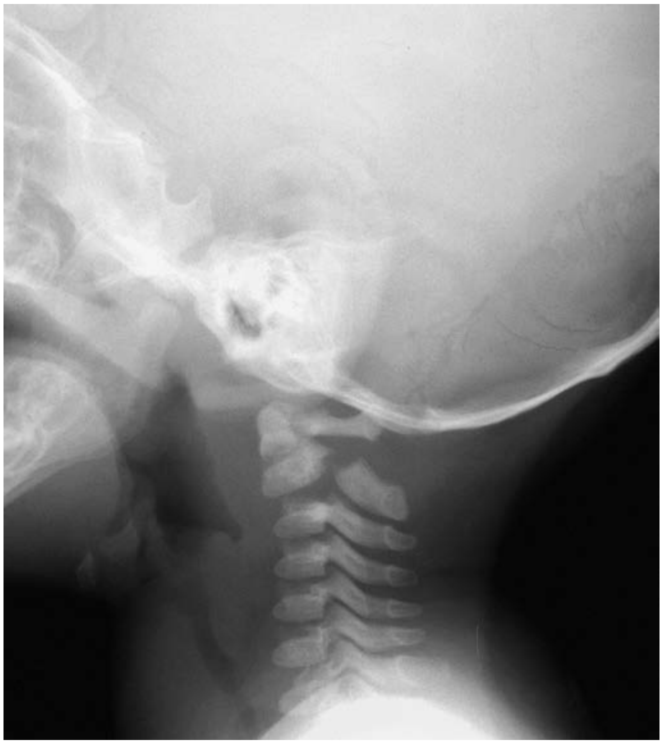
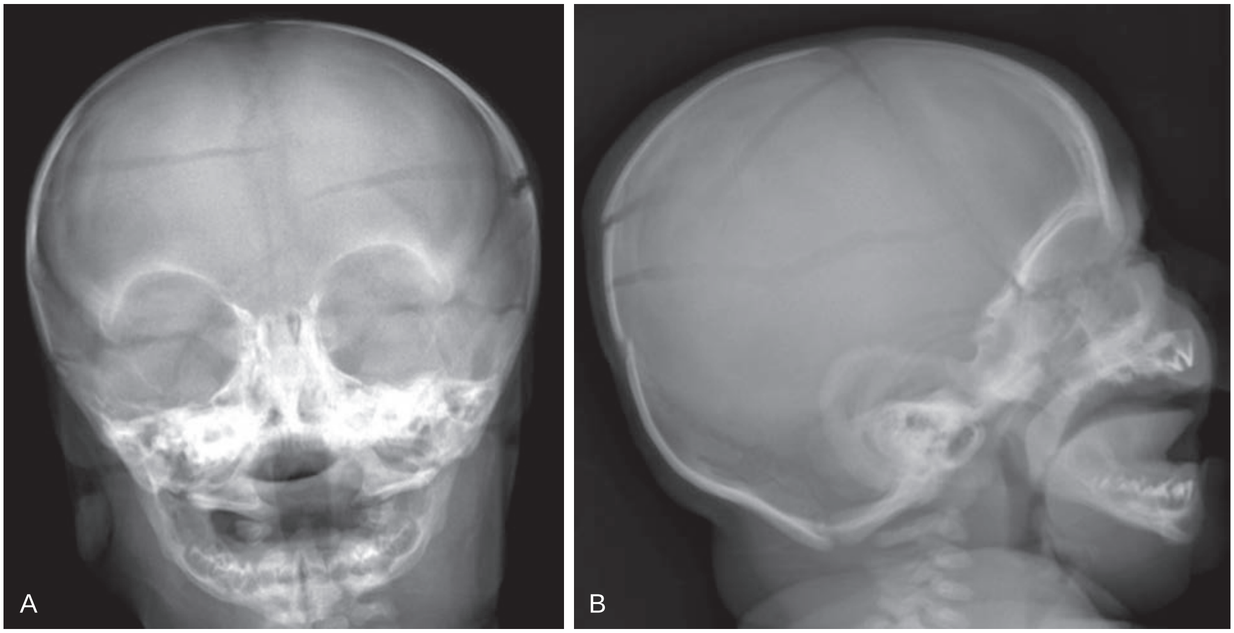


**e-Figure 143.16. Lateral cervical spine radiograph of a 6-month-old infant who presented with bruising over the left neck.** Although the infant was neurologically intact, 14 fractures, including hangman's fracture of C2, were identified.



**e-Figure 143.17.** A 2-month-old boy with bilateral parietal bone fractures. Anteroposterior (A) and lateral views (B) show bilateral parietal fractures. The two fractures lines are offset (not continuous) across the sagittal suture posteriorly. Mild extracranial soft tissue swelling is seen posteriorly and laterally over the fractures. The child presented to the emergency room with facial bruising and lip swelling. Small bilateral subdural hematomas were found on computed tomography. Multiple healing rib fractures and metaphyseal fractures (classic metaphyseal lesions) were found on skeletal survey.

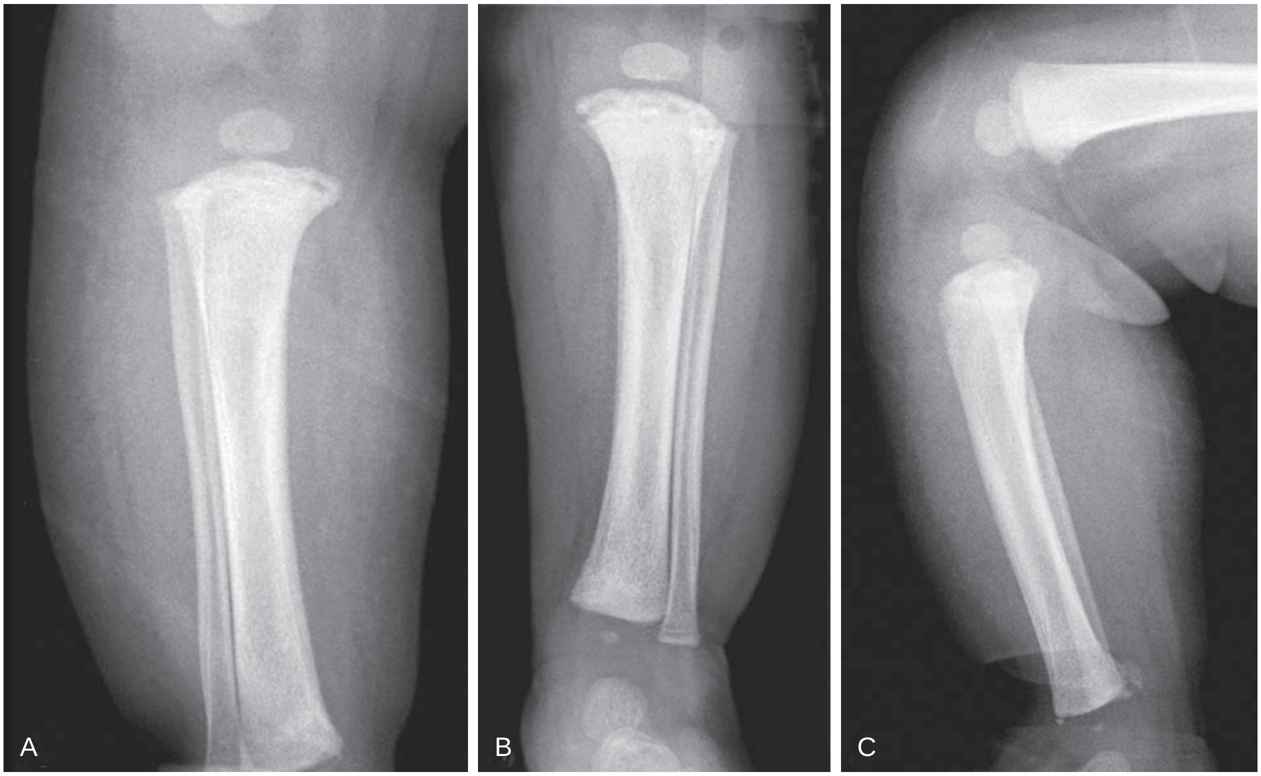


**Figure 143.9. Anteroposterior right (A) and left (B) leg, and lateral right (C) leg of 3-month-old male infant with an acute occipital skull fracture and 23 rib fractures.** Classic metaphyseal lesions are seen in both proximal tibias and the distal right tibia.

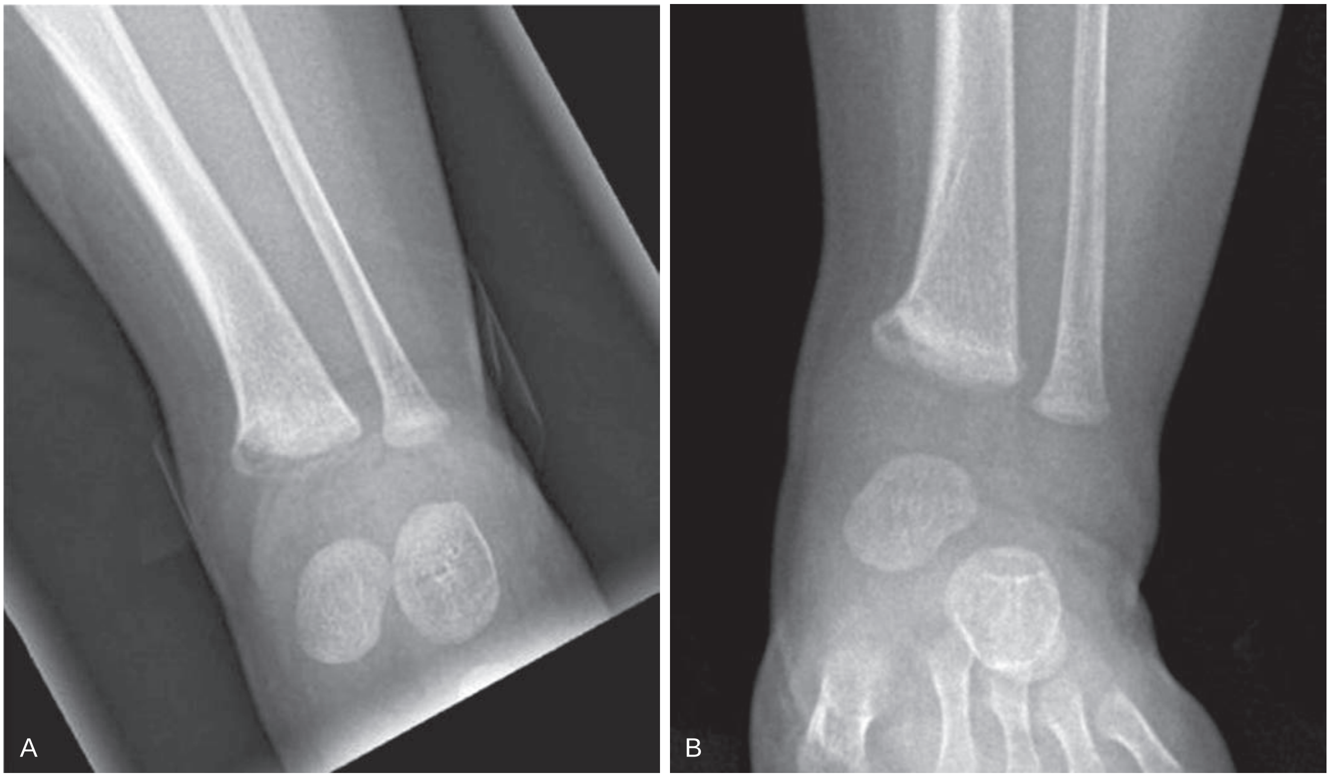

**Figure 143.10. Healing classic metaphyseal lesion of the distal tibia in a 4-month-old boy.** (A) The initial anteroposterior (AP) radiograph shows a well-defined metaphyseal corner fracture, consistent with an acute or subacute fracture. (B) On a follow-up AP radiograph 2 weeks later, the fracture is more ill-defined with sclerosis, consistent with interval healing.

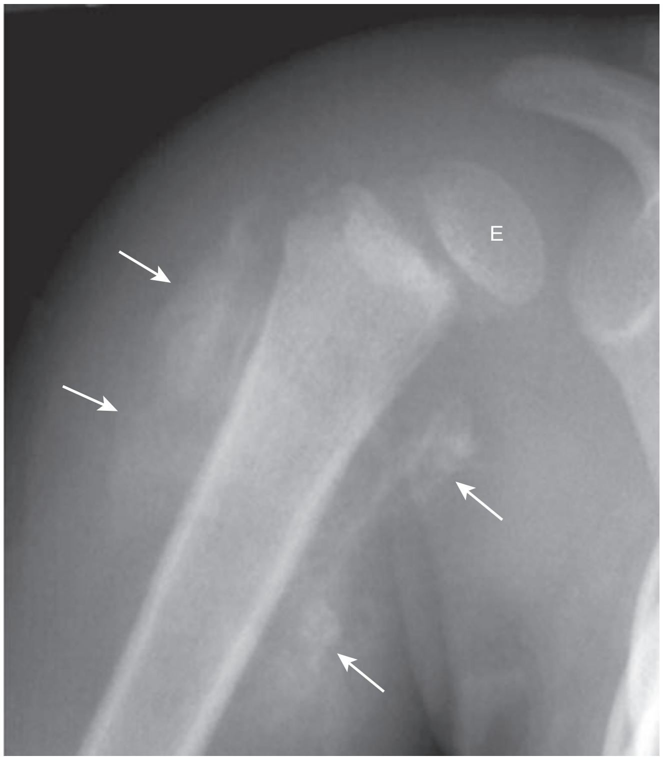

**Figure 143.11.** **A 2-year-old girl with delayed diagnosis of a Salter I fracture of the proximal right humerus.** The epiphysis *(E)* is displaced medial relative to the proximal humeral metaphysis. A cloak of early callus and subperiosteal new bone is seen around the proximal humerus *(arrows)*. The child presented with mental status changes caused by a head injury. This fracture and a subtler fracture of the left proximal humerus were noted on chest radiography after intubation. No other fractures were found on a skeletal survey. Follow-up radiographs demonstrated premature fusion of the right proximal humeral physis with marked shortening of humerus noted at age 6 years.

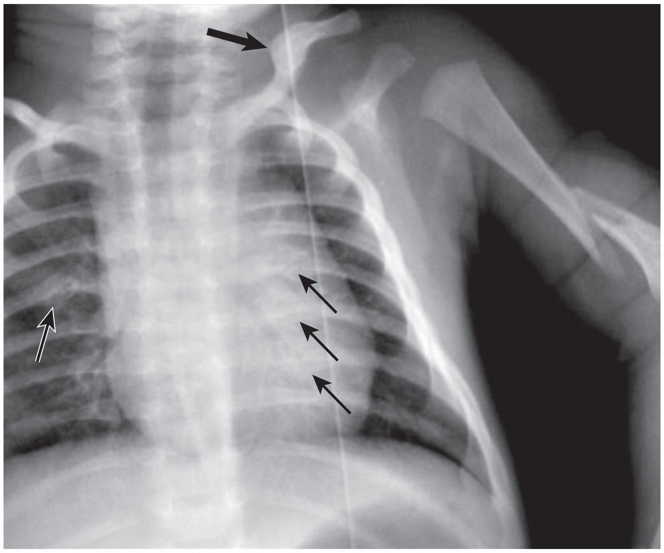

**Figure 143.12.** **A 7-week-old boy with an acute left humeral fracture.** The mechanism provided by history was suspect. Additional imaging demonstrated healing clavicular *(large arrow)* and posterior rib fractures *(small arrows)*. While it is possible that the healing clavicle fracture is due to unrecognized birth trauma, the healing posterior rib fractures are not compatible with birth injury.

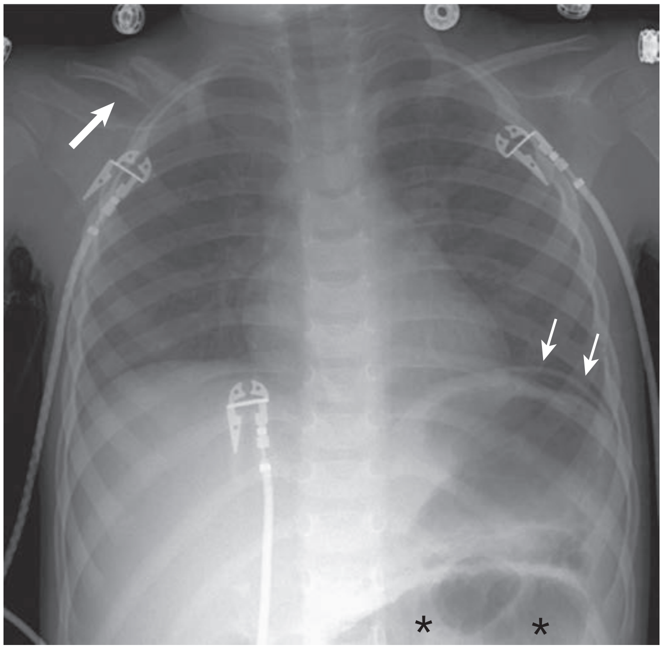

**Figure 143.14.** **A 2-year-old boy with clavicle fracture.** The child presented with fever and vomiting. Multiple bruises were noted. This chest radiograph demonstrated a healing, displaced right clavicle fracture with callus *(large arrow)*, free air underneath the left hemidiaphragm *(small arrows)*, and dilated small bowel in the left abdomen *(asterisks)*. At surgery, multiple small bowel perforations were found.

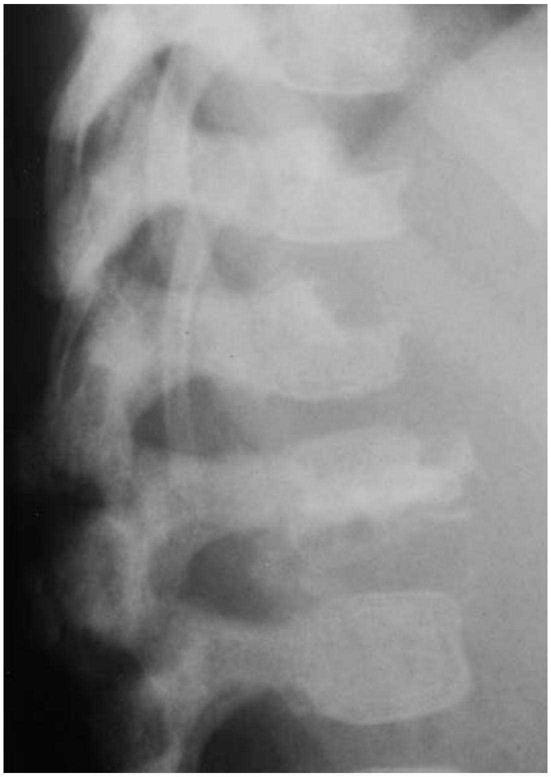

**Figure 143.15.** **A 10-month-old girl with compression fractures of the T12, L1, and L2 vertebral bodies.** She presented with paralysis of the lower extremities, and no history of trauma was initially provided. Unfortunately, the child did not recover lower extremity function.

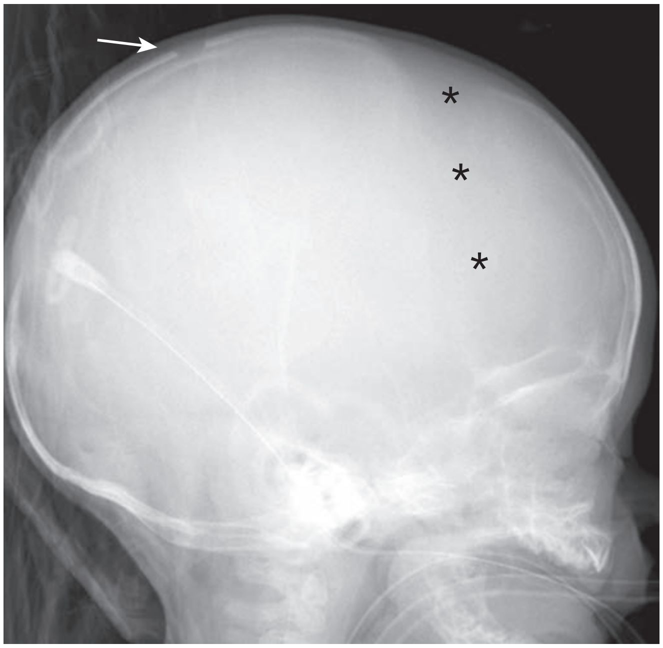

**Figure 143.18.** **A 3-month-old boy with a mildly diastatic parietal skull fracture *(arrow)* and splayed coronal sutures *(asterisks)*.** Computed tomography showed large bilateral subdural hematomas.

is helpful to evaluate the occipital bone and look for wormian bones in the sutures. Wormian bones are accessory intrasutural bones associated with metabolic bone disease, most notably osteogenesis imperfecta and Menkes syndrome.[91] Modern CT scan technique with orthogonal reformat images and three-deminsional volume rendered reconstructions may obviate the need for skull radiographs.[92,93]

Accessory sutures of the skull may mimic fractures on both radiography and CT.[94] Findings suggesting a fracture are a sharp linear lucency with nonsclerotic edges, widening of the lucency approaching a suture, crossing of a suture, unilaterality or asymmetry, and associated soft tissue swelling.[95] Findings suggesting an accessory suture are a zigzag pattern with sclerotic borders merging with an adjacent suture, bilaterality and symmetry, and lack of associated soft tissue swelling.[95] Accessory sutures tend to occur at characteristic locations.

## FRACTURES OF THE PELVIS

Fractures of the pelvic bones are uncommon in child abuse (e-Fig. 143.19).[96] Fractures of the pubic rami may occur from blunt trauma particularly in cases of sexual abuse.[97] Variants in pubic ossification may mimic fracture.[98]

## FRACTURES OF HANDS AND FEET

Nonaccidental fractures of the hands and feet occur in abused infants and toddlers (Fig. 143.20).[99,100] These fractures are often subtle torus fractures and may be better appreciated on oblique views or follow-up radiographs.[99] Fractures of the tubular bones of the hands and feet are probably caused by squeezing of the child's hands by the abuser.

## DATING OF FRACTURES

Dating of fractures is dependent on many variables, including the age of the child, the state of nutrition, immobilization or lack thereof, repetitive injury, and fracture location.[101,102] Fractures of the skull and spine cannot be satisfactorily dated, and the classic metaphyseal lesion is difficult to date with any degree of precision.

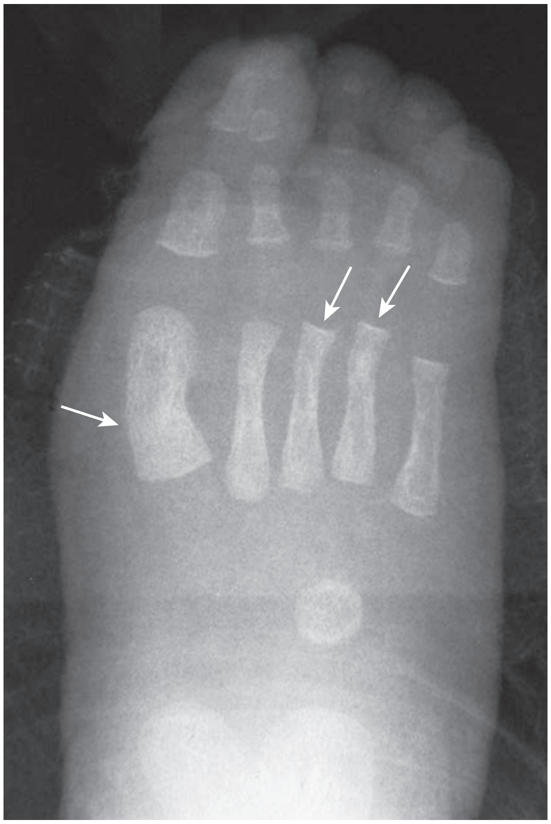

**Figure 143.20.** **A 3-month-old girl with healing fractures of the first, third, and fourth metatarsals *(arrows)*.** Her twin sister also had metatarsal fractures. Both twins had rib fractures, classic metaphyseal lesions, and skull fractures.

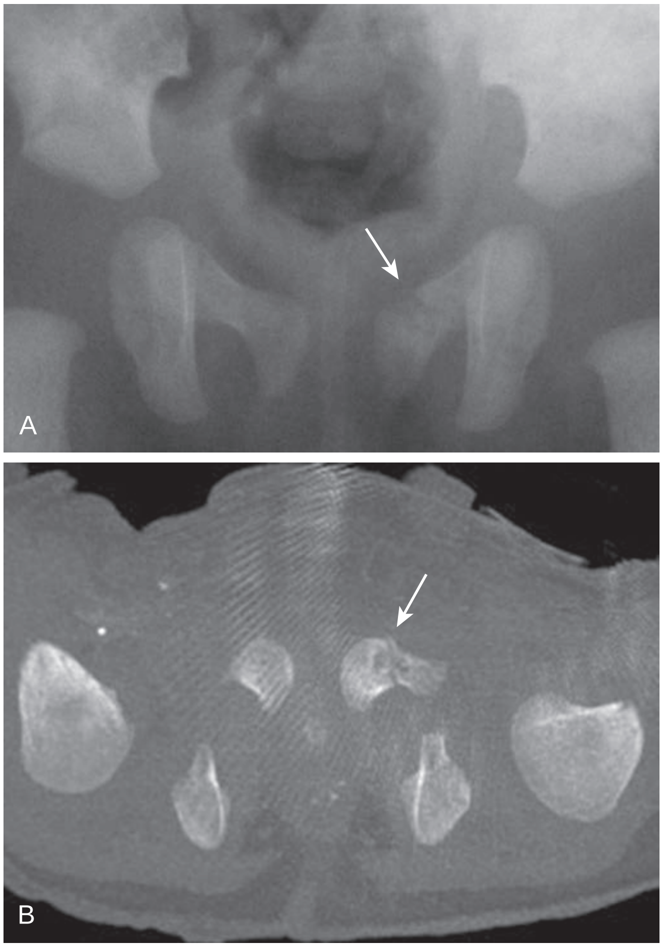
Infants develop subperiosteal new bone earlier and form callus more quickly but usually not until 10 to 14 days after injury.[102] Soft tissue swelling resolves during this same period with subsequent loss of fracture line definition. Although it is often possible to identify separate fractures as acute or subacute and others as healing, it is very difficult is ascribe different ages to fractures that are healing. Precise dating of fractures is not possible, and speculation of fracture age is merely an estimate.[103,104] Some general guidelines are provided in Table 143.1 (Fig. 143.21).[101,102,104]

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis for child abuse is broad and varies considerably, depending on both the clinical presentation and the radiologic findings (Box 143.3).[105,106] Accidental injury is not the only consideration. Unrecognized obstetric trauma may not be noted until days or weeks after birth. Normal processes including metaphyseal variants, physiologic new bone formation, accessory ossification centers, and accessory skull sutures may mimic fracture.[107–109]

Metabolic bone disease of prematurity may result in multiple rib fractures, diaphyseal fractures, and metaphyseal fractures.[48,110–112] Such fractures are typically buckle or transverse fractures, not classic metaphyseal lesions. Other disease processes including inherited bone dysplasias, copper deficiency, Menkes syndrome, congenital syphilis, Caffey disease, neurologic disorders, and osteogenesis imperfecta may have radiographic features that overlap with those of abuse (see Box 143.3).[105,106,113–120] Metaphyseal abnormalities



**e-Figure 143.19. A 1-month-old boy presented with failure to thrive and fever.** A fracture of the left superior pubic symphysis *(arrows)* is seen on radiography (A) and axial bone algorithm computed tomography (CT) image (B), reformatted from a CT scan of the abdomen and pelvis to evaluate for suspected visceral injury. He was also found to have subdural hematomas and healing rib fractures.

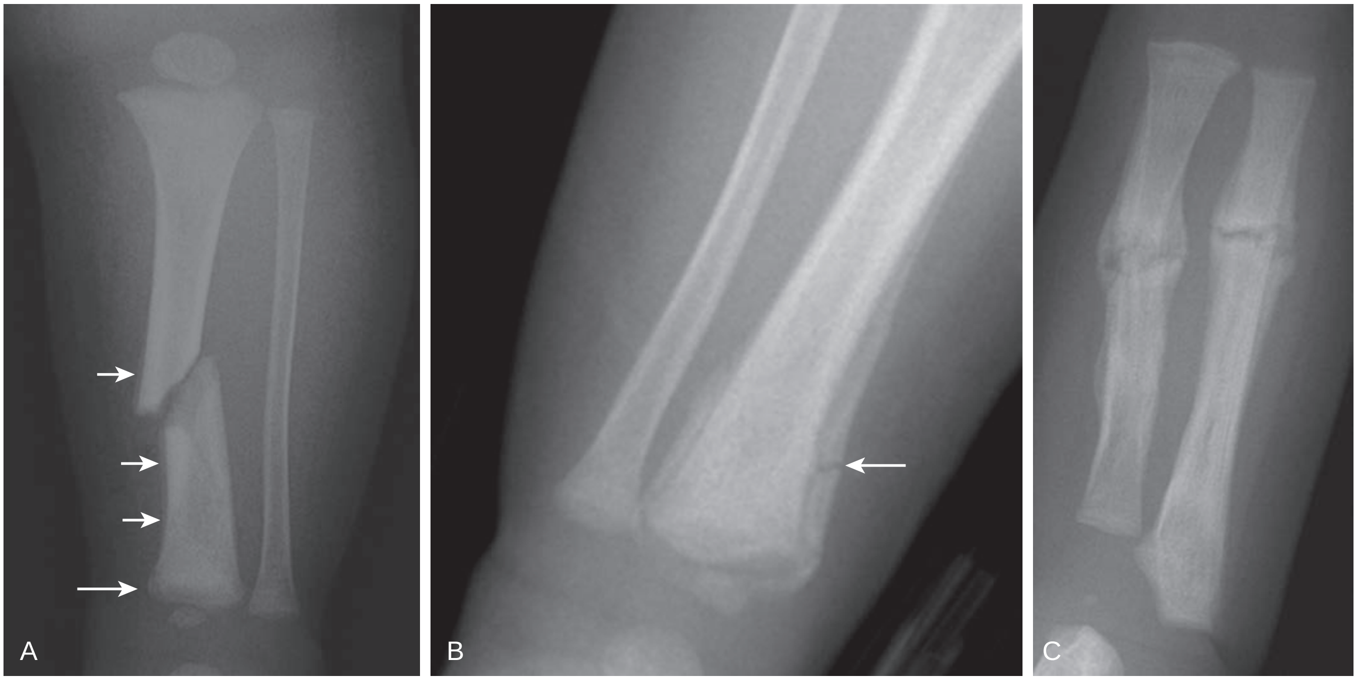


**Figure 143.21. A 3-month-old boy with multiple fractures of differing age.** The child presented with left leg swelling. (A) Radiograph of the left leg shows an acute or subacute oblique fracture of the left tibia. No ossified callus is seen; however, subperiosteal new bone *(short arrows)* is present along the medial margin of the distal tibia, possibly unrelated to the oblique fracture. Irregularity of the distal metaphysis *(long arrow)* is suggestive of a preceding classic metaphyseal lesion, but not definitive. Soft tissue swelling is noted. (B) Radiograph of the distal right leg shows a healing bucket handle fracture with associated distal tibial subperiosteal new bone indicative of an injury at least 10 to 14 days old. A fracture through the subperiosteal new bone *(arrow)* indicates injuries of different age. (C) Transverse fractures of the left radius and ulna show a more advanced state of healing with abundant callus and indistinct, partially obliterated fracture lines. These fractures are clearly older than the oblique left tibial fracture. Images of the ribs showed multiple healing lateral and posterior rib fractures with mature callus.

**TABLE 143.1** Approximate Timetable of Radiographic Healing of Children's Fractures*

| Finding | Early | Peak | Late |
|---|---|---|---|
| Resolution of soft tissue swelling | 2-5 days | 4-10 days | 10-21 days |
| Subperiosteal new bone formation | 4-10 days | 10-14 days | 14-21 days |
| Loss of fracture line definition | 10-14 days | 14-21 days | |
| Soft callus | 10-14 days | 14-21 days | |
| Hard callus | 14-21 days | 21-42 days | 42-90 days |
| Remodeling | 3 months | 1 year | 2 years to physeal closure |

*Assessment of fracture dates is an estimate. Healing is affected by repetitive injury, immobilization or lack thereof, and the general health and metabolic state of the patient.

*From Kleinman PK.* Diagnostic Imaging of Child Abuse. *2nd ed. St Louis: Mosby; 1998.*

similar to child abuse are seen with some rare skeletal dysplasias, notably spondylometaphyseal dysplasia (Sutcliffe "corner fracture" type) and metaphyseal dysplasia (Schmid type).[121,122] Clues as to the presence of a dysplasia include family history, short stature, and lack of change of the findings on follow-up radiographs.

Kleinman's seminal text *Diagnostic Imaging of Child Abuse* presents an excellent overview of the differential diagnosis and a review of diseases that may simulate abuse.[25] It should be remembered that the presence of an underlying bone disease or dysplasia does not exclude the possibility of physical abuse or neglect.

With regard to the differential diagnosis of the radiographic findings of child abuse, two topics of generated controversy warrant brief mention—temporary brittle bone disease (TBBD) and vitamin D deficiency/rickets.

TBBD was proposed as a variant of osteogenesis imperfecta by Paterson et al, who identified a group of young infants who were thought to have diminished bone strength, possibly because of temporary deficiency of a metalloenzyme related to copper deficiency.[123] Evidence provided to support the existence of TBBD included denial by caregivers of wrongdoing, absence of episodes of trauma that may explain fractures, lack of bruising, absence of systemic injury, radiographs revealing normal bones, and normal laboratory studies.[123] The purported evidence and the particular diagnosis of TBBD has been refuted by others, including the authors of a critical review of TBBD prepared by the Committee on Child Abuse of the Society for Pediatric Radiology.[117,124,125] To date, no scientific proof definitively supports the existence of TBBD.

More recently, fractures consistent with abuse have been ascribed to vitamin D deficiency and rickets by some authors.[126,127] While literature supports a high prevalence of infants with low vitamin D levels, no evidence exists in the literature to support low levels of vitamin D predisposing children to the high-specificity lesions characteristic of child abuse.[6,128–131] In fact, fractures in children with overt rickets are uncommon, not seen until ambulatory or mobile, and have low specificity patterns, and are only seen with florid radiographic changes of rickets.[132]

**BOX 143.3** Radiographic Differential Diagnostic Considerations for Child Abuse

**TRAUMA**
- Accidental trauma
- Birth trauma
- Iatrogenic trauma

**VARIANTS OF OSSIFICATION AND MATURATION**
- Accessory acromial ossification center(s)
- Normal metaphyseal variants of development
- Accessory skull sutures
- Physiologic subperiosteal new bone
- Sternal ossification center (mimicking posterior rib fracture)

**METABOLIC BONE DISEASE**
- Metabolic bone disease of prematurity
- Copper deficiency (Menkes syndrome)
- Rickets
- Scurvy
- Vitamin A toxicity

**DYSPLASIA**
- Osteogenesis imperfecta
- Metaphyseal and spondylometaphyseal dysplasia

**DRUG INDUCED**
- Prostaglandin $E_1$ therapy

**NEUROGENIC**
- Spina bifida
- Congenital insensitivity to pain

**MISCELLANEOUS**
- Caffey disease
- Congenital syphilis
- Neoplastic-metastatic round cell tumors
- Leukemia
- Osteomyelitis

## TREATMENT

Treatment of the individual patient with abuse-related injuries is dictated by the injuries that are present. Injuries to the brain, spinal cord, and viscera may be life-threatening. Brain and spinal cord injuries may cause substantial lifelong morbidity. Fortunately, most skeletal injuries heal without permanent sequelae, with fractures of the growth plate being an occasional exception.

Intracranial trauma is the leading cause of death and permanent morbidity in abused infants. Debate is ongoing about whether or not shaking alone is sufficient to result in brain injury or whether an impact injury must accompany the shaking event.[133] Apnea and cerebral hypoxia also play a prominent role.

Infants with shaken baby syndrome commonly have subdural hematomas, retinal hemorrhages, and characteristic skeletal injuries (posterior rib fractures and classic metaphyseal lesions). The presence of characteristic osseous lesions is therefore indication for brain imaging and ophthalmologic evaluation.

Reporting of suspected child abuse is mandated by law. Failure to report suspected child abuse may result in fines, censure, and even prosecution. Radiologists should be aware of the legal requirements and mechanisms for reporting in their state. Responsible treating clinicians or child protection team personnel will take ownership of this task. Nevertheless, the radiologist bears responsibility for reporting if he or she suspects child abuse and no one else reports it.

Imaging findings are just one piece of the clinical, social, and legal investigation of possible child abuse. The radiologist must function as part of the child protection team by providing timely and accurate interpretations that are properly communicated, by providing expertise on the significance of the radiologic findings, and by providing guidance as the utility of additional imaging studies. Radiology reports should be complete, precise, and must appropriately consider the specificity of the findings and the possibility of differential diagnoses. Verbal communications of the report should be properly documented. Proper wording and careful editing of reports avoids embarrassment or confusion in court.

Radiologists are frequently called upon to testify in civil and criminal court proceedings related to cases of suspected child abuse. If called to testify, it is the duty of the radiologist to do so in a professional manner, providing only honest opinions based on personal experience and scientific evidence.

### KEY POINTS

- The radiologist is occasionally the first to suggest the diagnosis of child abuse.
- No single radiographic finding is pathognomonic for child abuse.
- Individual radiographic findings may be of low, moderate, or high specificity for child abuse.
- The constellation of radiographic findings may bear greater specificity than any one finding.
- Accidental trauma, normal processes, and diseases may mimic child abuse radiographically.

# 144 Sports Medicine

J. Herman Kan and Erica K. Schallert

In the United States, more than than 30 million (approximately one-third) of school-aged children participate in organized sports.[1] Sports-related injuries occur more frequently in the lower extremities compared with the upper extremities. This section will review acute and chronic sports injury patterns with an emphasis on entities that are unique in children as well as cover multimodality imaging with an emphasis on important magnetic resonance imaging (MRI) features. Skeletal trauma, including acute fractures and dislocations, is covered in Chapter 142.

## AVULSION INJURIES AND MUSCLE INJURIES

***Etiology.*** Avulsion injuries or fractures may occur at musculotendinous or ligamentous attachments to an apophysis. Avulsion injuries may occur at either the physeal equivalent or chondro-osseous junction of an apophysis.

The musculoskeletal unit of the child is composed of the apophysis, tendon, myotendinous junction, and muscle belly. In the skeletally mature patient, the weakest component of the musculoskeletal unit is the myotendinous junction, whereas in the skeletally immature patient, particularly during periods of rapid growth, the cartilaginous physeal equivalent region of the apophysis is the weakest link in the musculoskeletal unit.[2] As a consequence, apophyseal avulsion injuries (Fig. 144.1), rather than myotendinous tears, may occur when the musculoskeletal unit is stressed.

Apophyseal and ligamentous avulsion injuries are more frequent in the lower extremity than in the upper extremity. In particular in the lower extremity, the pelvis and knee are the most common sites for apophyseal avulsion injuries.[3]

After the apophysis, the next weakest component of the musculoskeletal unit is the myotendinous junction, which is therefore the most common site of muscular injury. Myotendinous tears are an acute event during a physical activity in which a child can pinpoint the time (within seconds) in which the injury occurred. This should be differentiated clinically from delayed onset muscle soreness (DOMS), which is not related to a single event but rather an activity with repetitive eccentric and concentric muscle contractions with no acute pain at the time of the activity. Instead, symptoms and pain usually are felt in the days after the activity.[4]

***Imaging.*** In the acute setting, the displaced avulsion fracture fragment is present without proliferative callus formation (see Fig. 144.1). During healing, proliferative callus will form, suggesting its subacute or chronic nature.

When radiographs are negative and no displaced fragment exists, an MRI scan may be obtained. MRI may demonstrate subtle edema of the apophysis and metaphyseal equivalent bone, physeal equivalent edema and widening, and adjacent soft tissue edema (e-Fig. 144.2). The term *fracture* should be used only when a linear displaced or nondisplaced fracture is present. When edema alone is present within the apophysis and adjacent soft tissues, the term *avulsion injury* can be used.

MRI may also demonstrate avulsion injuries and fractures at the level of the chondro-osseous junction (Fig. 144.3).

MRI is preferred for delineating the remainder of the musculoskeletal unit. When muscle edema is present related to trauma, three possible etiologies exist: (1) DOMS (Fig. 144.4), (2) direct muscle contusion (e-Fig. 144.5), and (3) myotendinous muscle tear (Fig. 144.6). With DOMS, MRI shows diffuse edema on fluid sensitive sequences without discrete fiber disruption. Direct muscle contusions show similar changes to DOMS but are more focal in nature when the injury is mild, with discrete fiber disruption and hematoma formation when the injury is more severe. In the setting of muscle hematomas, these may mimic an intramuscular abscess. Gadolinium-enhanced, T1-weighted, fat-saturated magnetic resonance (MR) imaging may demonstrate rim enhancement for both hematomas and intramuscular abscess. T1-weighted imaging without gadolinium may demonstrate T1-weighted hyperintense foci related to blood products and may suggest muscle hematoma and, less likely, intramuscular abscess with proteinaceous content. Evidence of myotendinous muscle injury can range from edema to complete disruption with muscle fiber and aponeurosis retraction.

***Treatment and Follow-up.*** Treatment varies, depending on the location of the apophyseal avulsion injury. In the pelvis, the majority of apophyseal avulsion injuries are treated conservatively with rest. Surgical reduction and fixation may be necessary when the avulsed fracture fragment is greater than 2 cm.[3] During the healing phase, radiographs may be helpful to monitor callus formation and alignment. Apophyseal avulsion fractures elsewhere are usually treated conservatively, and surgical reduction is based on degree of apophyseal displacement. For instance, medial epicondylar avulsion fractures are typically treated surgically when the displaced fragment is greater than 5 mm.[5]

Myotendinous tears are treated conservatively with 2 to 3 weeks of rest before returning to sport activities.[4] DOMS is also treated conservatively, and symptoms usually resolve within a week.

## ANTERIOR COMPARTMENT INJURIES OF THE KNEE

***Etiology.*** The anterior compartment of the knee is composed of the quadriceps tendon, patellar bone, patellar tendon, and tibial tuberosity. The patella is a sesamoid equivalent for the quadriceps mechanism. Acute forceful concentric or eccentric contraction of the quadriceps muscle may lead to acute avulsion injuries of the inferior patellar pole (chondro-osseous avulsion injury, patellar sleeve fractures) and tibial tuberosity (apophyseal avulsion injury); whereas repetitive motion is the culprit for tendinopathy and chronic avulsive injuries affecting the inferior patellar pole in *Sinding-Larsen-Johansson disease* and the tibial tuberosity in *Osgood-Schlatter disease*.[1] When pathology is isolated to only the proximal patellar tendon, it is called *jumper's knee* and tends to occur in patients who are skeletally mature. Sinding-Larsen-Johansson and Osgood-Schlatter diseases usually occur during adolescence and often affect both knees. Both bone and tendon injuries often coexist in the same knee.

***Imaging.*** Although imaging is helpful for the diagnosis of Sinding-Larsen-Johansson and Osgood-Schlatter diseases, the diagnosis for these chronic conditions is made clinically with radiographic confirmation of findings, not by imaging alone. Advanced imaging confirms the diagnosis and excludes alternative etiologies. MRI should not be performed routinely on these patients if radiography and clinical diagnosis confirm the disease.

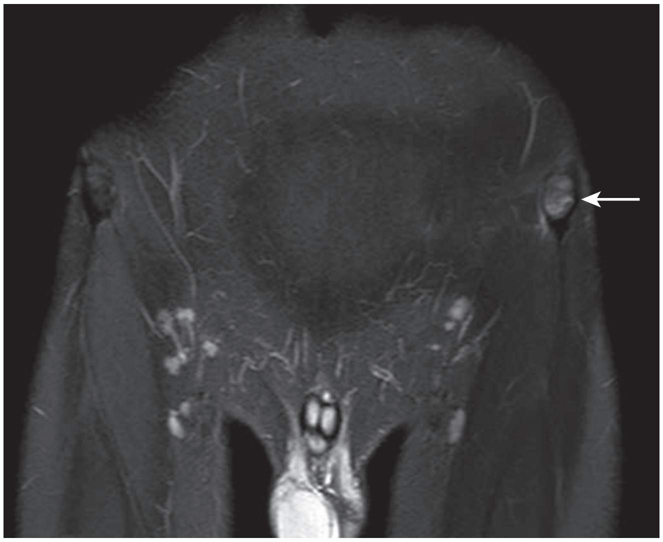
Patellar sleeve fractures represent an acute avulsion fracture of the inferior pole of the patella. This occurs at the chondro-osseous junction of the patella tendon origin. On radiography and MRI, a small linear or curvilinear fragment of bone may be identified (Fig. 144.7). On MRI, edema within the patella, the superior aspect of Hoffa's fat pad and in the peripatellar soft tissues are present in the acute setting. This should be differentiated

## Abstract:

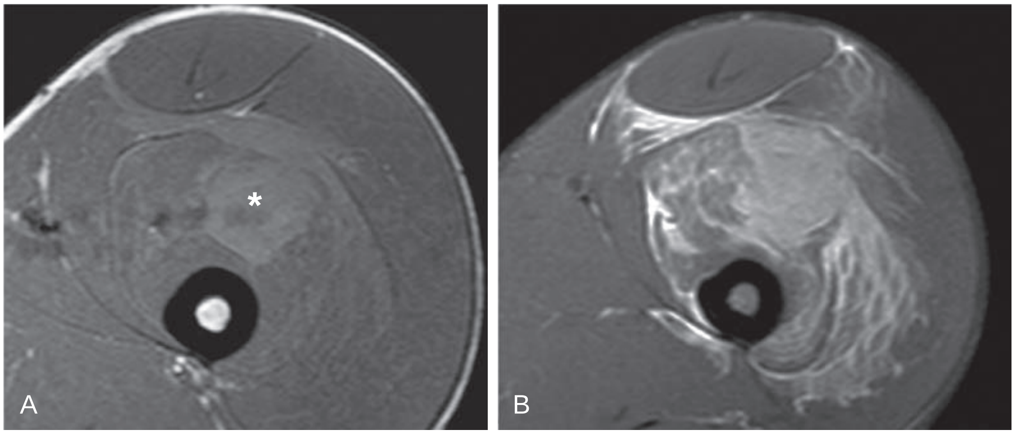
With increasing participation in organized sports and emphasis on high level performance, sports-related injuries are a high volume component of pediatric musculoskeletal imaging. Due to the nature of their developing musculoskeletal system, they are prone to a wide spectrum of both acute and chronic injury patterns. This section will review these injury patterns, emphasizing those unique to children as well as cover multimodality imaging with an emphasis on important magnetic resonance imaging(MRI) features. Topics covered include acute and chronic avulsion injuries, anterior compartment injuries, osteochondral injuries and internal derangement of the hip.

## Keywords:

pediatric sports related injuries
acute sports injuries
chronic sports injuries
transient patellar dislocation
osteochondral injuries
throwing injuries



**e-Figure 144.2. Nondisplaced left anterosuperior iliac spine avulsion fracture in a 16-year-old boy.** Coronal short-tau inversion recovery coronal MR image shows abnormal increased signal at the avulsion *(arrow)* related to the sartorius muscle origin.



**e-Figure 144.5. Vastus intermedius direct muscle contusion in a 17-year-old boy.** (A) T1-weighted axial MR image demonstrates hyperintense material, consistent with blood products, located in the vastus intermedius muscle belly *(asterisk)*. (B) T2-weighted fat-suppressed axial MR image demonstrates muscle fiber disruption of the vastus intermedius and associated muscular and fascial edema-like signal.

from chronic repetitive avulsive injuries to the inferior patellar pole occurring in Sinding-Larsen-Johansson disease in which the inferior patellar bone has had time to remodel. Therefore on radiography and MRI, well-corticated variable size ossicles are typically seen (Fig. 144.8) with adjacent soft tissue swelling and edema. As previously noted, this is typically a clinical diagnosis and, if well-corticated ossific fragments are present without adjacent edema, this finding may be related to an accessory ossicle(s).

Acute tibial tuberosity avulsion fractures result from forceful contraction of the patella tendon leading to a tibial tuberosity–sided linear or curvilinear avulsion fracture fragment at the level of the chondro-osseous junction (Fig. 144.9) or to uplifting of the entirety of the tibial tuberosity, with resultant Salter-Harris-type injury with physeal equivalent widening (Fig. 144.10). On MRI, edema is seen within the tibial tuberosity, and this may extend posteriorly to involve the remainder of the tibial epiphysis. Inferior Hoffa's fat pad and pretibial edema are often present. These changes should be differentiated from chronic repetitive avulsive injury affecting the tibial tuberosity and leading to Osgood-Schlatter disease. With Osgood-Schlatter disease, rather than linear avulsion fracture fragments, the tibial tuberosity and tibial tuberosity avulsion fragments have had time to remodel. Therefore on radiography and MRI, well-formed, variable-size, well-corticated ossicles may be seen (e-Fig. 144.11). On MRI, edema within the avulsed separate ossicles and tibial tuberosity are present and are related to the acute on chronic nature of the injury. In addition, edema within Hoffa's fat pad and pretibial edema are often present as well.

Patella tendinopathy and patellar tears (e-Figs. 144.12 and 144.13) may be evaluated by ultrasonography or MRI. Thickening of the tendon with longitudinally or transversely oriented tears may be seen as well as edema within the prepatellar soft tissues and Hoffa's fat pad. Marked tendinous hyperemia on color sonography denotes neovascularity and has been associated with a higher degree of pain.[6] MRI diagnosis of jumper's knee should ideally be made on longer echo time sequences to avoid "magic angle artifact."

***Treatment and Follow-up.*** Sinding-Larsen-Johansson disease, Osgood-Schlatter disease, and jumper's knee are all treated conservatively with rest. When displaced, acute avulsion fractures of the inferior patellar pole or tibial tuberosity may be treated by open reduction with patellar tendon reconstruction, particularly if patella alta is also present.[7] For avulsion fractures, care should be made to determine if the fracture is complete, incomplete, displaced, or nondisplaced. If the avulsion fracture is incomplete (see Fig. 144.9), affected children may benefit from conservative nonsurgical treatment.

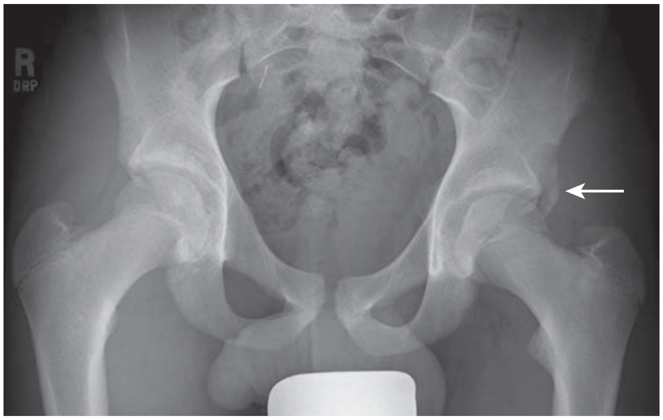


**Figure 144.1.** A 15-year-old boy with left anteroinferior iliac spine avulsion fracture *(arrow)* related to the rectus femoris origin.

## PATELLAR DISLOCATION AND PATELLOFEMORAL DYSPLASIA

***Etiology.*** The patella is a sesamoid bone in the extensor mechanism that lies within the concave-shaped femoral trochlear fossa. It has two primary facets: medial and lateral. The lateral facet is usually the dominant and larger facet, and articulates with the lateral aspect of the trochlear fossa. With knee flexion, the patella will concentrically locate within the trochlear fossa. With knee extension, the patella preferentially subluxes laterally in patients with or without underlying patellofemoral dysplasia because the lateral patellofemoral articulation is shallow compared with the medial articulation, and the vastus lateralis activates when the knee is extended.

Multiple variables may predispose a patient to patellar dislocation. This includes a large Q-angle, muscle imbalance with dominant vastus lateralis musculature, patella alta, rotational abnormalities of the tibia and femur, and overall ligamentous laxity.[8] Larger Q-angles direct the quadriceps muscle vector force on the

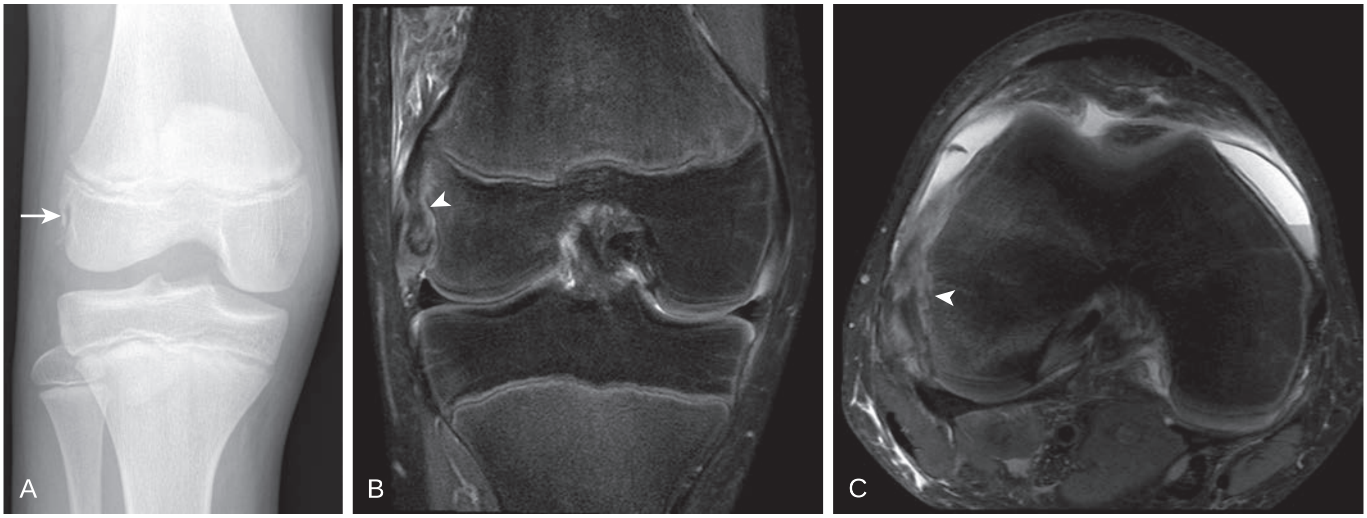

**Figure 144.3. Popliteus origin chondro-osseous avulsion fracture in a 13-year-old boy.** (A) An anteroposterior knee radiograph Popliteus origin chondro-osseous avulsion fracture at *(arrow)*. **e-Figure 144.12. Partial patellar tendon tear.** (A) T2-weighted fat-suppressed sagittal and (B) proton density fat-suppressed axial MR images demonstrate a partial tear of the patellar tendon at its patellar bone origin *(arrow)*.

**e-Figure 144.13. Proximal patellar tendinopathy (jumper's knee) in a 17-year-old male.** Longitudinal color Doppler sonogram demonstrates a thickened and hypoechoic proximal patellar tendon *(arrowheads)* with superimposed more well-defined hypoechoic areas and a few anechoic clefts representing superimposed interstitial tearing. There is associated hyperemia and mild edema in the anterior superior aspect of Hoffa's fat pad. Note normal width and hyperechoic fibrillar architecture of the normal mid to distal tendon.

patella laterally. Because the patellar bone captures within the trochlear groove with knee flexion, in the setting of patella alta, it takes relatively more knee flexion for the patellar bone to capture. Both excessive external tibial torsion and increased femoral anteversion can predispose a child to patellar dislocation.[8,9] The normal degree of external tibial torsion is approximately 28 degrees at age 4 years and increases to approximately 38 degrees at skeletal maturity.[10] The normal degree of femoral anteversion is approximately 40 degrees at birth and approximately 15 degrees at skeletal maturity.

The earlier age at the first time patellar dislocation occurs, the higher the incidence of recurrent patellar dislocation and the higher the propensity to develop more severe secondary patellofemoral dysplasia. This may be related to laxity of the injured medial retinaculum and remodeling at the level of the patellofemoral joint after initial injury. Secondary patellofemoral dysplasia results from poor articulation at the level of the patellofemoral joint and can be exacerbated by muscle imbalance and traumatic patellar dislocation. Therefore patients with secondary patellofemoral dysplasia may have had a normally appearing patellofemoral joint at birth, but over time, the joint becomes dysplastic. Patellofemoral dysplasia can also occur as a primary congenital anomaly.

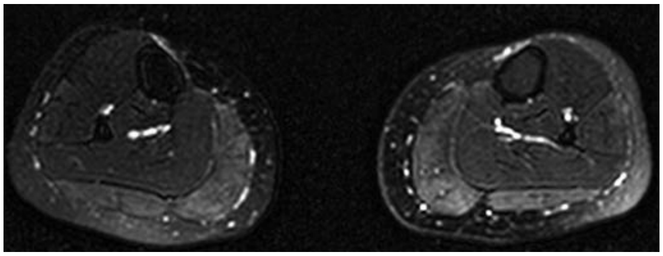

**Figure 144.4. Delayed onset muscle soreness in an adolescent.** A short-tau inversion recovery axial MR image of both legs shows edema-like signal within the gastrocnemius muscles.

***Imaging.*** Radiographs can identify risk factors for patellar dislocations, such as patella alta and patellofemoral dysplasia, as well as injuries related to a dislocation/relocation event, such as joint effusions, osteochondral fractures, and osseous avulsions. An axial view of the patella (i.e., merchant or sunrise view) is helpful to evaluate for avulsion fractures, which occur along the medial pole and are a result of avulsion injury at the insertion of the medial patellofemoral ligament in both the acute setting (Fig. 144.14) and for old injuries (e-Fig. 144.15). Acute patellar avulsion fractures are sliver-like, whereas old injuries are round and corticated.

The axial view should also be assessed for osteoarthritic changes of the patellofemoral joint, lateral patellar tilt, and patellar subluxation/dislocation. With regard to patellar location, the axial view may be misleading if not obtained with the knee in 30 degrees flexion. Knee flexion facilitates patella reduction, whereas knee extension may exaggerate patellar tilt and lateral patellar subluxation. When the knee axial view is obtained with less knee flexion, the trochlear fossa may appear shallow and should not be mistaken for patellofemoral dysplasia. Because of positioning variability, a true lateral view of the knee is a great resource that displays the entire trochlear floor and can support a diagnosis of trochlear dysplasia.[11] A positive crossing sign indicates that the lateral side of the trochlea is flat or in plane with the lateral condyle.[12] This can be correlated with a properly flexed axial view to confirm a flat or even convex-appearing trochlear fossa. On the axial view, a lateral dominant patellar facet can be a feature suggestive of patellofemoral dysplasia. With progressive patellofemoral dysplasia, the trochlear fossa becomes more convex in appearance, and the patellar bone loses its normal angular appearance.

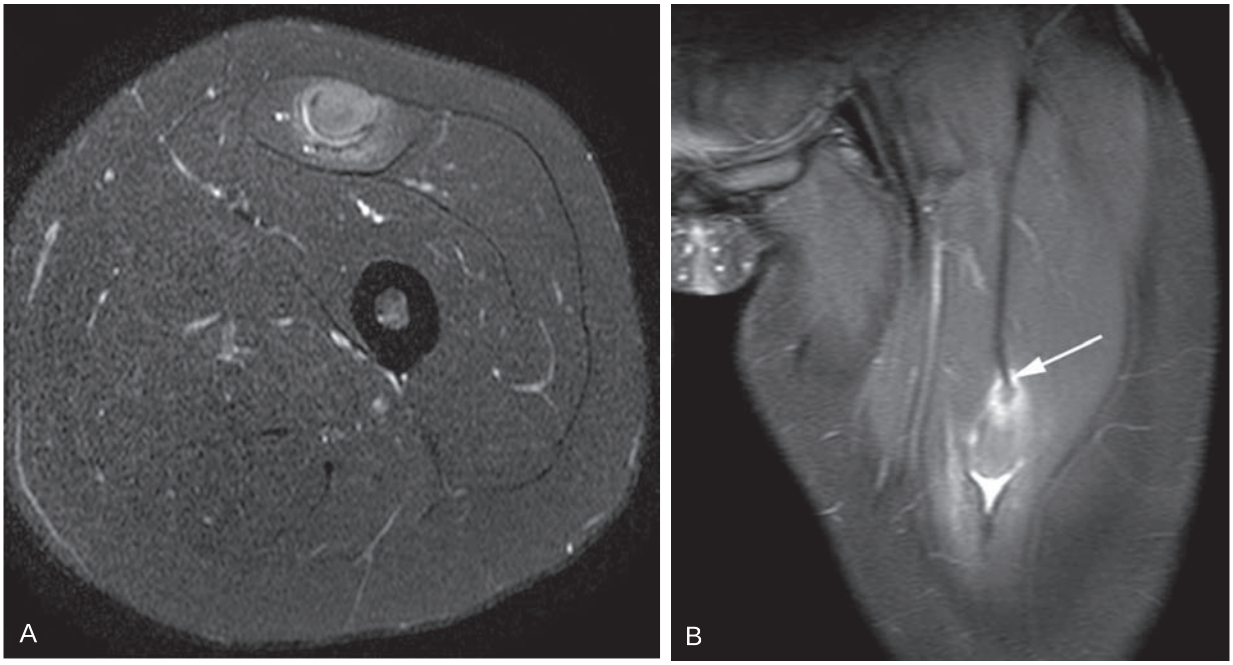

**Figure 144.6. Intramuscular degloving type injury of the rectus femoris musculotendinous junction in a 17-year-old female.** (A) T2-weighted fat suppression axial MR image demonstrates edema-like signal within the central portion of the rectus femoris with fluid signal replacing the normal low signal intensity of the central tendon *(indirect head)* of the rectus femoris. (B) Short-tau inversion recovery coronal MR image demonstrates proximal retraction of the torn central tendon *(indirect head)* of the rectus femoris *(arrow)* with a small amount of fluid separating it from the outer muscle at the myotendinous junction.

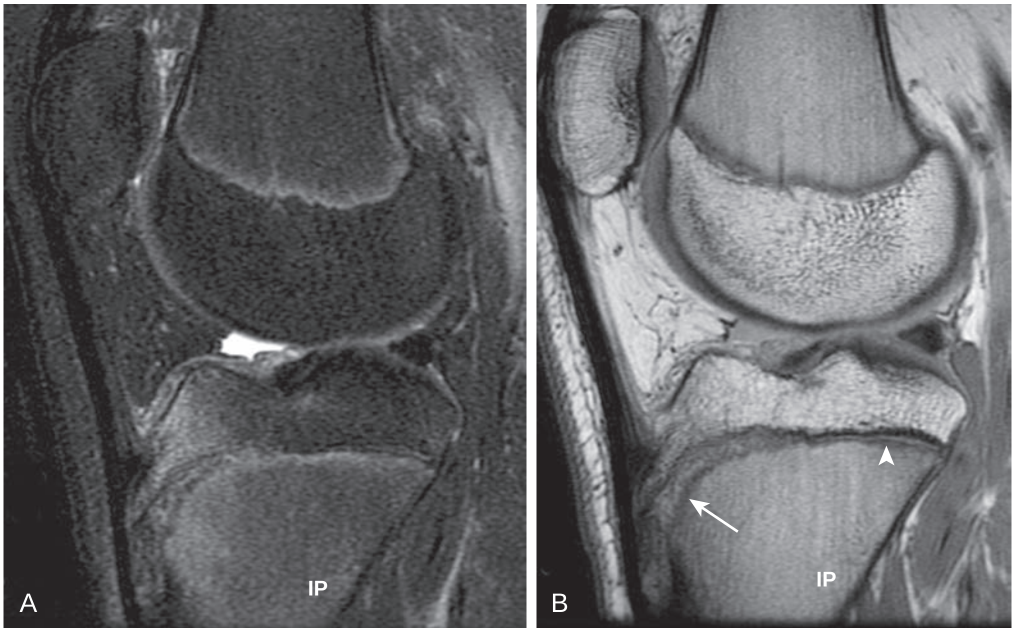

**Figure 144.10. Tibial tuberosity avulsive injury in a 14-year-old girl.** (A) T2-weighted fat-suppressed sagittal MR image demonstrates diffuse edema of the tibial tuberosity, physis, and deep metaphyseal equivalent region of the tibia. (B) Proton density sagittal image delineates physeal equivalent widening of the tibial tuberosity *(arrow)*. Compare this with the normal posteriorly located tibial physis *(arrowhead)*.

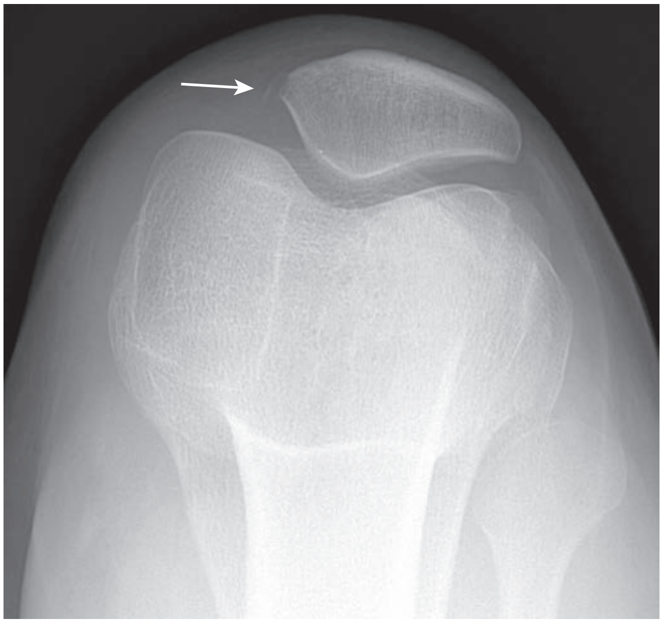

**Figure 144.14. Acute patellar dislocation/relocation in an 18-year-old.** There is an acute avulsion fracture *(arrow)* from the medial patella.

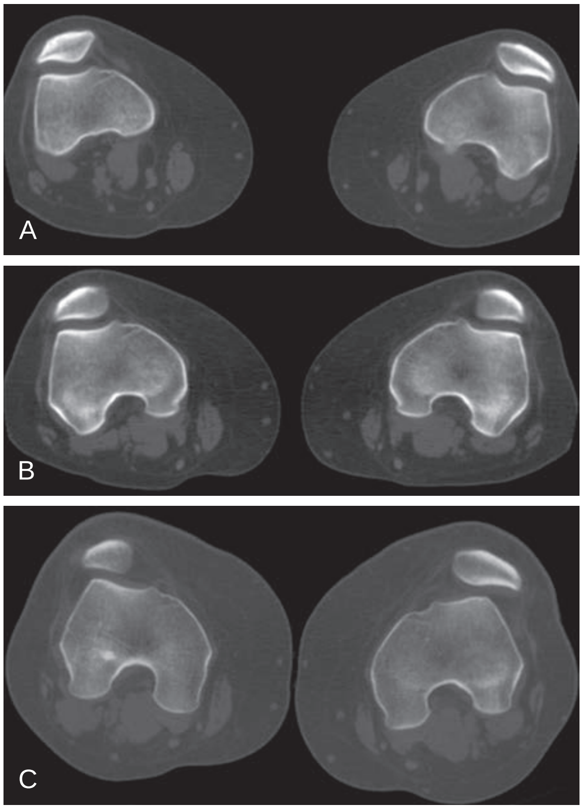
Computed tomography (CT) may be obtained in the workup of patellofemoral dysplasia to evaluate for rotational abnormalities (namely excessive external tibial torsion and femoral anteversion) and for a dynamic evaluation (e-Fig. 144.16). Three separate CT acquisitions are obtained at different degrees of knee flexion (e.g., 45, 30, and 15 degrees). If the patella dislocates at 15 degrees but is located at 45 and 30 degrees, it is considered a mild degree of patellar dislocation. However, if the patella dislocates at 30 or 45 degrees of knee flexion, it is a more severe degree of patellar dislocation. CT for patellar dislocation can also be used to evaluate the degree of patellofemoral dysplasia and secondary patellofemoral osteoarthritis, with changes similar to what may be seen on axial-view radiographs. The degree of lateralization of the tibial tuberosity should also be determined. This represents the distance between the midpoint of the tibial tuberosity and the deepest component of the trochlear groove on axial slices, the tibial tuberosity-trochlear groove (TT-TG) distance. If the tibial tuberosity is greater than 2 cm lateral with respect to the trochlear groove, a higher incidence of patellar instability exists (e-Fig. 144.17).[13]

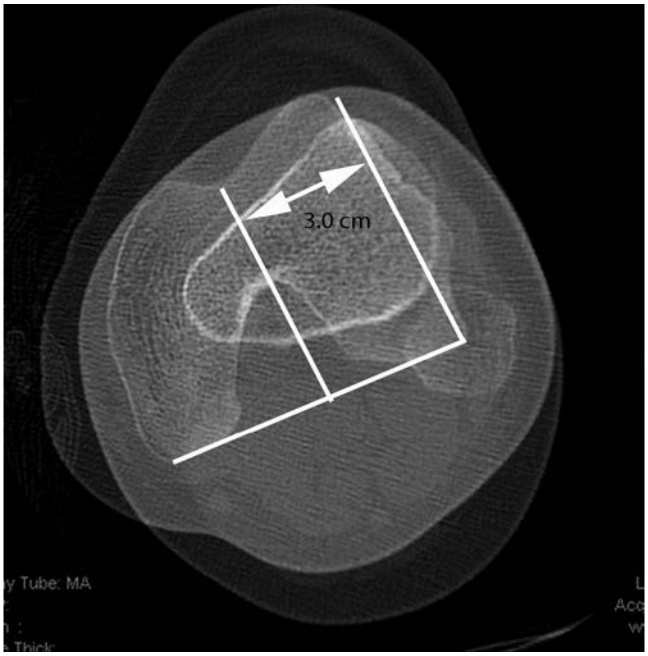
MRI complements radiography and CT findings and can also evaluate rotational abnormalities.[14] Sometimes, children are referred for knee pain, and the diagnosis of patellar dislocation and patellofemoral dysplasia may be first suspected on MRI. On MRI for acute patellar dislocation, characteristic bone contusions may be seen along the medial patellar pole and anterolateral femoral condyle (Fig. 144.18). The bone contusions occur from compressive forces during relocation of the patella after the dislocation. Other findings that may be seen include patellar avulsion fractures, medial retinacular and patellofemoral ligament tears, cartilage injuries, and intraarticular bodies. Patellofemoral dysplasia (Fig. 144.19) and secondary degenerative changes should also be assessed by MRI.

***Treatment and Follow-up.*** Treatment for patellar dislocation should be approached from two perspectives: (1) treat biomechanical instability, which can be addressed by physical therapy and operative repair, and (2) treat mechanical symptoms related to sequelae from acute dislocation usually from intraarticular bodies or chondral injuries.

Patients with first-time patellar dislocation and those with recurrent patellar dislocation may be treated conservatively with physical therapy and bracing. The goal of treatment is to improve gluteal and vastus medialis muscle activity, which facilitates medial location of the patella.[13] Should physical therapy not improve symptoms, surgical repair is considered, although no single effective surgical technique has been advocated in the literature. Surgical approaches include lateral retinacular release, patellofemoral ligament repair and reconstruction, trochleoplasty (to deepen the



**e-Figure 144.16. Patellofemoral dysplasia.** A dynamic CT scan of bilateral patellofemoral joints at 45 degrees (A), 30 degrees (B), and 15 degrees (C) of knee flexion shows that, with progressive knee extension, the patella subluxes and tilts laterally, left greater than right.



**e-Figure 144.17. Tibial tubercle-trochlear groove (TT-TG) distance.** A 15-year-old with chronic lateral patellar dislocation with a TT-TG distance of 3 cm. CT axial images with the trochlear groove and tibial tuberosity are overlayed. The distance is calculated between the deepest portion of the trochlear groove and midpoint of the tibial tuberosity at the patella insertion. The measurement should be made parallel to the posterior margins of the femoral condyles.

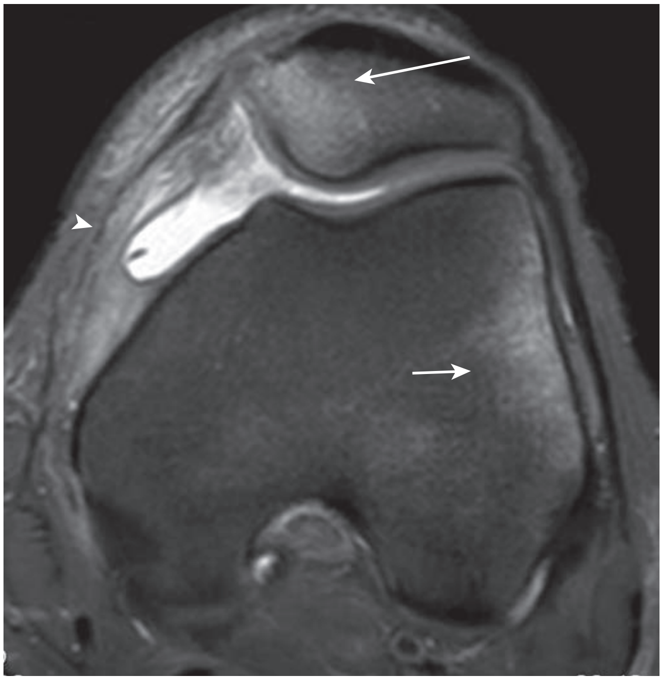


**Figure 144.18. Lateral patellar dislocation with characteristic kissing contusions in a 19-year-old.** Axial proton density fat-suppressed MR image shows increased signal *(arrows)*. Note partial tearing of the medial patellofemoral ligament *(arrowhead)* as well.

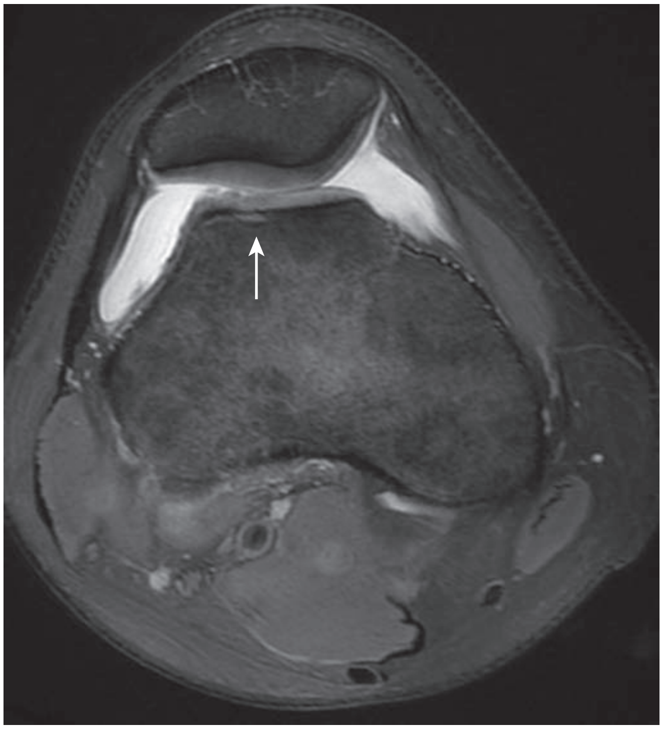

**Figure 144.19. Patellofemoral dysplasia in a 16-year-old boy.** Axial proton density fat-suppressed MR image shows a flat *(arrow)* dysplastic trochlear fossa. The normal trochlear fossa has a concave shape.

sulcus), and tibial tubercle transfers (medialization of the tibial tubercle), as well as rotational osteotomies to treat excessive tibial torsion and femoral version. The surgical goal is to facilitate patellar bone capture by the trochlear fossa and medialization of patellar biomechanical vector forces.

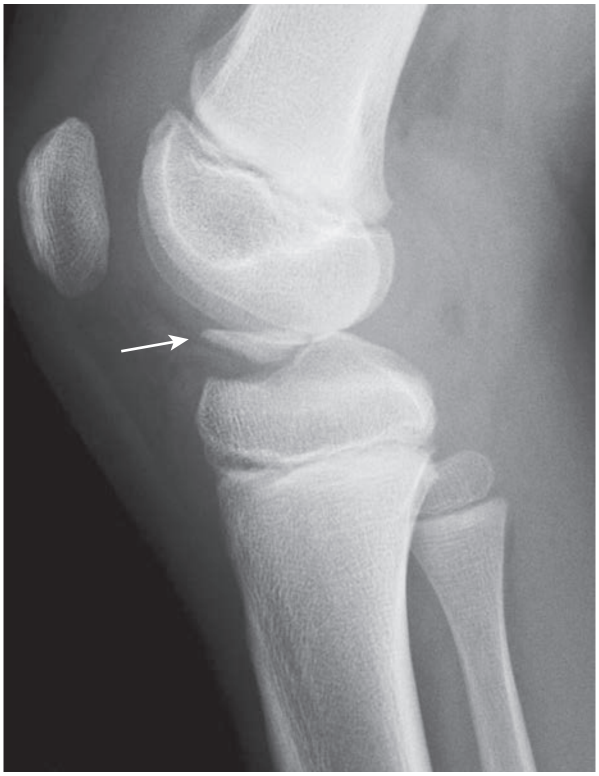

**Figure 144.21. Posteriorly hinged tibial eminence avulsion fracture in a 9-year-old boy *(arrow)*.**

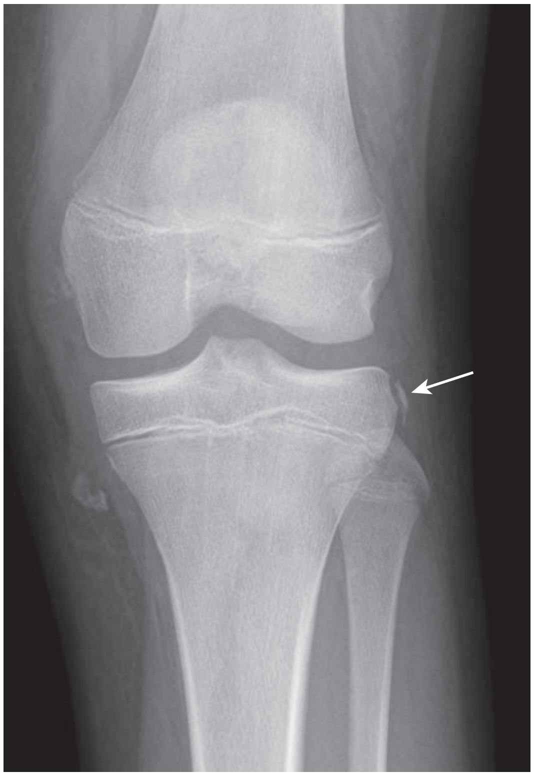
When intraarticular bodies or cartilage injury is identified and the child has mechanical symptoms such as locking, arthroscopy may be performed to remove the bodies and perform cartilage debridement or more advanced cartilage restoration techniques.[13]

## ANTERIOR CRUCIATE LIGAMENT COMPLEX INJURIES

***Etiology.*** The anterior cruciate ligament (ACL) complex is composed of the ACL, its femoral origin, and its tibial insertion. The femoral and tibial chondro-osseous attachments of the ACL complex are relatively weak in the skeletally immature and are predisposed to chondro-osseous avulsion fractures.[15] Chondro-osseous avulsion fractures occur far more commonly at the tibial eminence insertion compared with the femoral origin. The ACL is composed of two fiber bundles: the anteromedial and posterolateral bundles, which extend from the medial aspect of the lateral femoral condyle to the level of the tibial eminence.[16] Coexisting full-thickness ACL tear and complete tibial eminence fractures are unusual as the force of injury usually is dissipated by either the ACL tear or the avulsion fracture. However, arthroscopic evidence of partial ACL tears is often present in the setting of a complete tibial eminence avulsion fracture. ACL tears are often seen in children with a narrow intercondylar notch, and ACL tibial eminence avulsion fractures tend to occur in children with a wider intercondylar notch.[17,18]

Multiple mechanisms of injury have been attributed as causes for ACL complex injuries in children, including varus or valgus stress, and twisting injuries of the knee. Risk factors include female gender, noncontact indirect injuries, and contact direct injuries (e.g., forceful blow to the lateral knee).[18]

***Imaging.*** Radiographic findings that may indicate an ACL complex injury include Segond (e-Fig. 144.20) and tibial eminence avulsion fractures (Fig. 144.21). A Segond fracture represents an



**e-Figure 144.20. Segond fracture.** Frontal radiograph in an 11-year-old girl shows a Segond fracture *(arrow)*, as well as osteochondral fragments in the medial aspect of the joint.

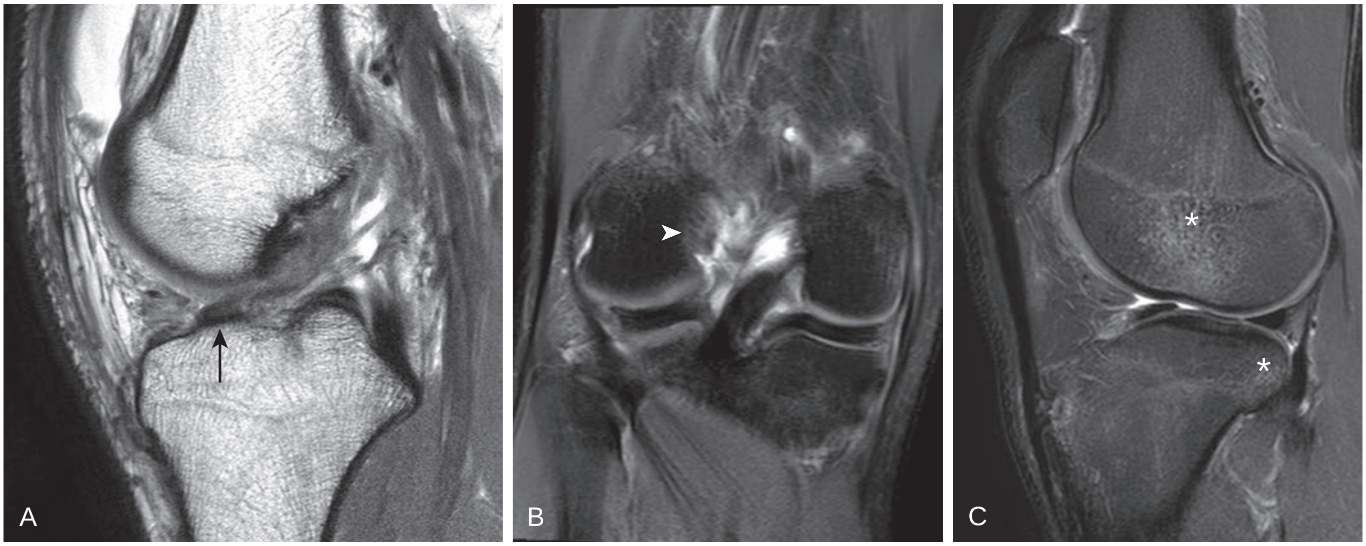


**Figure 144.22. Full-thickness anterior cruciate ligament (ACL) tear in a 16-year-old boy.** (A) Proton density sagittal MR image demonstrates full-thickness intrasubstance tear of the ACL near its femoral origin. Distal to the tear, ACL fibers are intact at the tibial insertion *(arrow)*. (B) Proton density fat-suppressed coronal MR image demonstrates full-thickness tear with residual femoral origin ACL fibers *(arrowhead)*. (C) T2-weighted fat-suppressed sagittal MR image demonstrates characteristic kissing contusion pattern related to ACL mechanism injury *(asterisks)*.

anteromedial capsular avulsion fracture at the chondro-osseous junction of the lateral tibial plateau. Tibial eminence avulsion fractures should be categorized as nondisplaced, minimally displaced with intact posterior hinge, or completely displaced with comment on comminution as this determines nonoperative versus operative management.[19] Because of ligamentous instability related to an ACL deficient knee, anterior translation of the tibia may be present on the lateral view.

On MRI, identification of complete disruption of the ACL should be confirmed on all three orthogonal planes (Fig. 144.22). ACL tears should be subcategorized as partial versus full-thickness tears. Some of the additional features to suggest ACL complex injuries are bone contusions related to anterior translation and twisting of the tibia, including anteromedial or anterolateral femoral condylar bone contusions, with kissing posteromedial or posterolateral tibial plateau contusions (see Fig. 144.22). When bone contusions are evident, a T1-weighted or proton-density sequence is useful for determining the presence of an underlying subchondral fracture. When subchondral bone contusions are present, the presence or absence of overlying articular cartilage injury should be identified. MRI also demonstrates tibial eminence avulsion fractures.

Additional findings on MRI include medial collateral ligament tears (e-Fig. 144.23) and meniscal tears. Medial collateral ligament injuries are subclassified as involving superficial or deep (meniscofemoral or meniscotibial) fibers. Tear location (femoral or tibial-sided) must be identified and whether the tear is partial or full thickness. Meniscal tears can be seen in up to 69% of ACL injuries in children.[20] The most common location for meniscal tears is the posterior horn of the lateral meniscus (e-Fig. 144.24).

Classification of meniscal tears includes vertical (see e-Figs. 144.24 and 144.25), horizontal, displaced (Fig. 144.26), and location (red or white zone) types. Vertical tears extend from the superior to inferior articular surface. They are subclassified into radial, longitudinal, or parrot-beak tears. Horizontal tears usually extend to only one articular surface and are usually degenerative in nature. Displaced tears include bucket handle tears (see Fig. 144.26) and displaced free fragment tears. Bucket handle tears result from large vertical longitudinal tears.

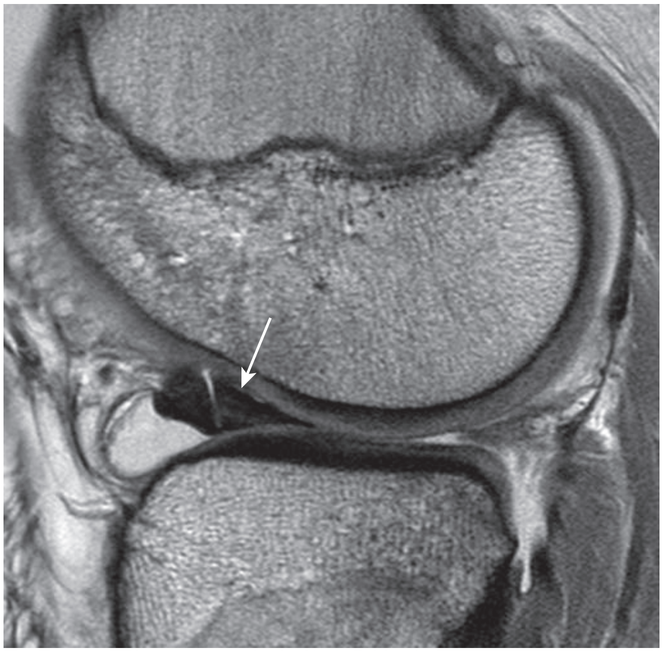

**Figure 144.26. Lateral meniscus bucket handle tear in a 14-year-old girl.** Proton density sagittal MR image shows that the posterior horn of the lateral meniscus has flipped anteriorly *(arrow)*, leading to a double anterior horn sign.

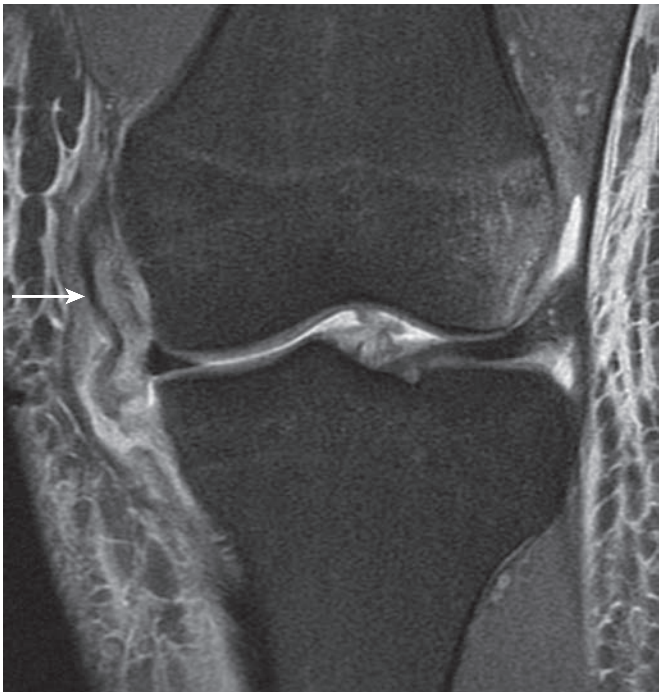
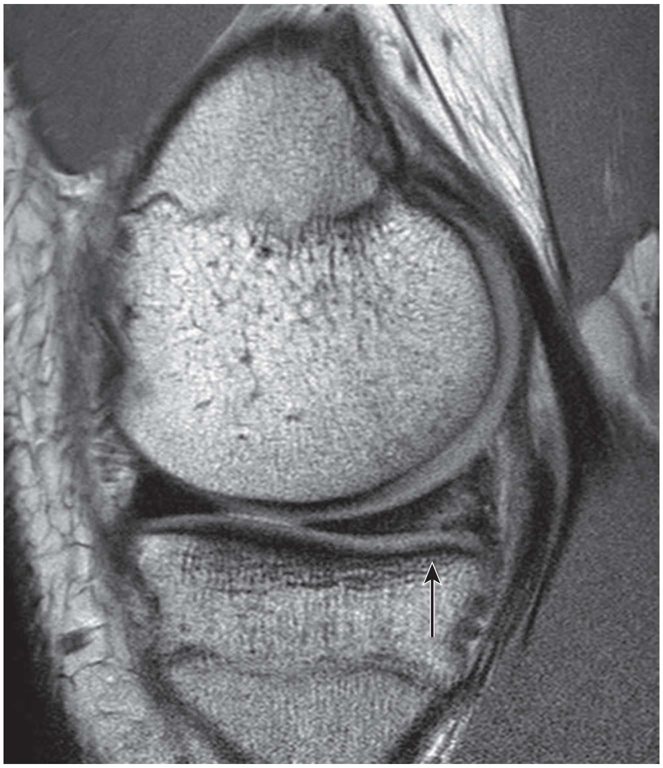
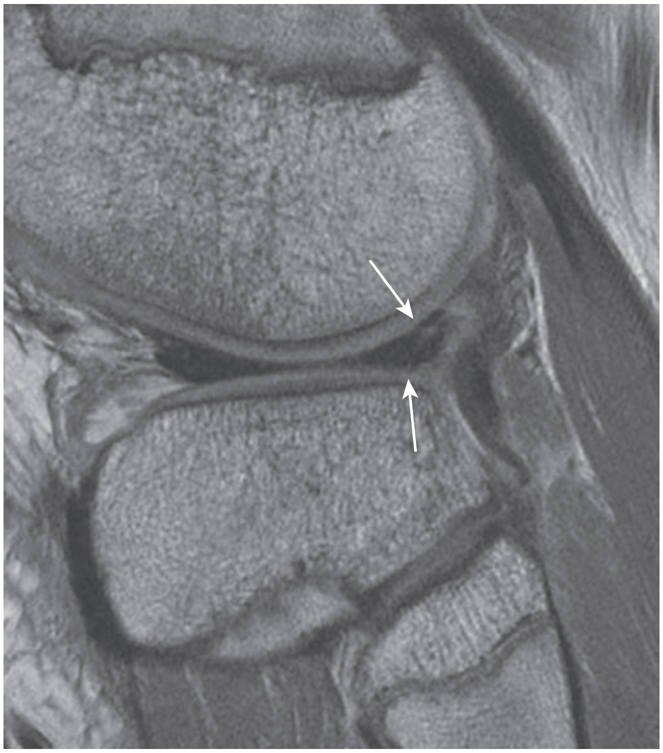
***Treatment and Follow-up.*** Treatment for full-thickness ACL tears is surgical. The natural evolution of ACL-deficient knees includes early osteoarthritis with cartilage injury and meniscal tears.[21] Diagnosing high-grade partial ACL tears should be approached with extreme caution, as partial ACL tears may heal nonsurgically with appropriate physical therapy and rest. High-grade partial ACL tears are surgically significant if clinical examination suggests an ACL deficient knee or progressive instability of the knee



**e-Figure 144.23. Medial collateral ligament tear in a 16-year-old boy.** Coronal inversion recovery MR image shows a full thickness medial collateral ligament tear *(arrow)* with retraction from the tibial insertion. Note disruption of meniscotibial and meniscofemoral ligaments as well.



**e-Figure 144.25. Vertical tear of the posterior horn of the medial meniscus in a 16-year-old boy *(arrow)*.**



**e-Figure 144.24. Peripheral vertical tear of the posterior horn of the lateral meniscus in a 14-year-old boy *(arrows)*.** This should be distinguished from the meniscofemoral ligament that can simulate a tear because of its superior sulcus. Meniscofemoral sulci should only involve the peripheral aspect of the superior articular surface of the posterior horn of the lateral meniscus.

occurs after initial injury. Surgical treatment for complete ACL tears includes tibial eminence repairs and various types of ACL reconstruction surgeries including physeal sparing, transepiphyseal, and transphyseal approaches. Boys over age 16 years, girls age 14 years or older, or those at Tanner stage 5 with closed or near closed physes may be treated with conventional adult methods for ACL reconstruction.[21] MRI is important presurgically to identify not only the ACL injury but also additional meniscal and cartilage injuries so that these areas can be repaired or débrided during ACL reconstruction.

## DISCOID LATERAL MENISCUS

***Etiology.*** Discoid menisci most frequently affect the lateral meniscus. This represents a congenital enlargement of the lateral meniscus with respect to the lateral tibiofemoral joint compartment. The relative disproportionate size of the lateral meniscus alters the biomechanics of the lateral tibiofemoral compartment, and the meniscus is predisposed to tears and degeneration. The utilization of approximate coverage of the lateral joint space is preferred compared with reference measurement of meniscal size in children. Using the adult reference of 12 mm width for normal meniscal size may be inaccurate in children, particularly in preschoolers who present with suspected discoid lateral menisci.[22]

The Watanabe arthroscopic classification of discoid lateral menisci includes (1) complete, (2) incomplete, and (3) Wrisberg variant.[23] The Wrisberg variant is a discoid meniscus with absence of normal posterior meniscocapsular fascicles and coronary ligaments, with the meniscofemoral ligament being the only attachment.[24] Type 1 and 2 discoid lateral menisci are usually stable, and type 3 is unstable because of its lack of posterolateral meniscocapsular attachment.

***Imaging.*** Radiographs may show relative widening of the lateral tibiofemoral joint space in the setting of a discoid lateral meniscus. However, radiographs are not adequate to suggest or exclude the diagnosis, as the lateral joint space may be artifactually widened by patient positioning or weight-bearing status.

MRI is the optimal method for diagnosing a discoid lateral meniscus. All three orthogonal planes should be used to determine size of the lateral meniscus and degree of coverage of the lateral tibiofemoral joint compartment. When a discoid lateral meniscus is present, it can be partial (e-Fig. 144.27), complete (Fig. 144.28), or a Wrisberg variant. Counting sagittal slices to determine meniscal size is not useful, as no meniscal size references are available for children. The Wrisberg variant may be suggested when normal posterior meniscocapsular fascicles and coronary ligaments are absent, independent of the size and shape of the lateral meniscus.

It is important to describe the discoid lateral meniscus morphology, including presence or absence of tears or degeneration, and the nature of the discoid morphology. Discoid lateral meniscus may be uniformly enlarged or may be asymmetrically enlarged with a dominant posterior, midbody, or anterior horn.[24]

***Treatment and Follow-up.*** Asymptomatic discoid lateral meniscus may be observed; however, the Wrisberg type may be treated preemptively due to its inherent instability. Treatment of symptomatic discoid lateral meniscus is surgical. Discoid lateral menisci are usually trimmed and saucerized to conform to the expected normal size and shape of the lateral meniscus and any tears are repaired. Tears are débrided and trimmed until a stable margin is created. Wrisberg-type discoid menisci may be treated with reduction and posterior fixation.

## OSTEOCHONDRAL INJURIES

***Etiology.*** Osteochondral lesions represent a broad spectrum of acute or chronic injuries with variable involvement of the articular and epiphyseal cartilage, spherical growth plate, and epiphyseal ossification center. Osteochondral lesions are separated into two basic lesions: (1) acute osteochondral fractures and (2) osteochondritis dissecans (OCD). OCD results from chronic repetitive injury.

OCD has juvenile and adult types.[25] Juvenile OCD tends to involve epiphyseal and spherical growth plates with either growth disturbance or injury to the epiphyseal ossification center. These have a greater tendency for spontaneously healing than adult types. Adult OCD affects articular cartilage and the epiphyseal bone. These lesions occur when the epiphyseal ossification is mature and usually only articular cartilage remains; they less commonly heal spontaneously and are more likely to be unstable compared with the juvenile variant.

Osteochondritis dissecans most commonly affects the knee but also can occur in the ankle and elbow (Table 144.1). These locations often have different prognostic significance, symptoms, and underlying etiology. For instance, OCDs of the talus tends to be asymptomatic and incidentally noted when the medial talar dome is involved, whereas lateral talar dome lesions tend to be symptomatic. At the elbow, capitellar OCDs are often seen in

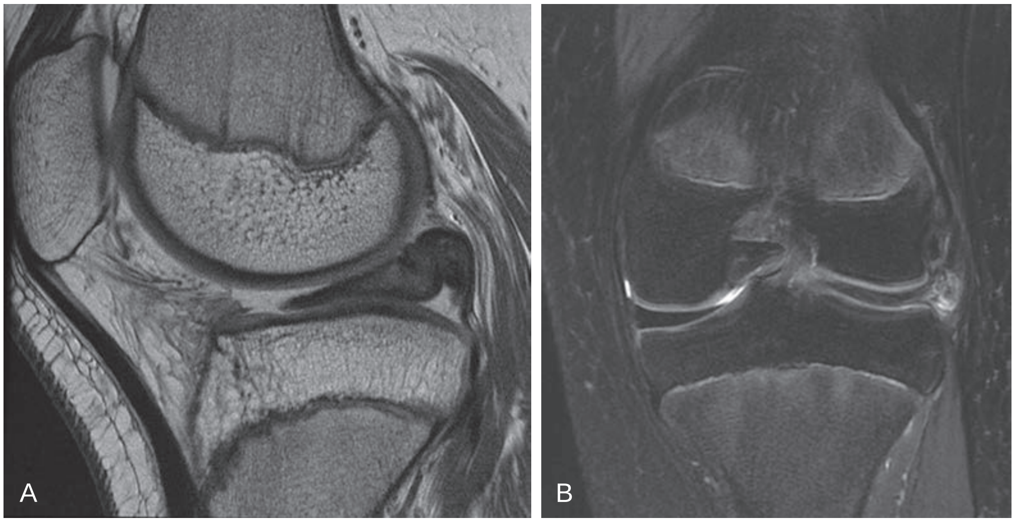


**Figure 144.28. Complete discoid lateral meniscus in a 14-year-old boy.** (A) Proton density sagittal and (B) proton density fat-saturated coronal MR images show a discoid lateral meniscus with a capsular tear and posterior subluxation.

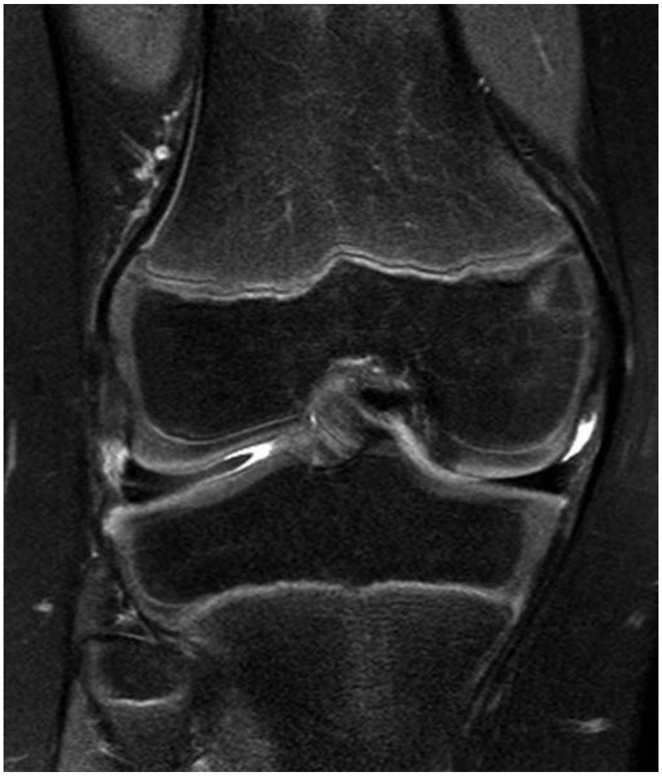

**e-Figure 144.27. Partial discoid lateral meniscus in a 6-year-old boy.** Notice how the free edge of the meniscus tapers toward the intercondylar notch, making this a partial discoid meniscus.

throwing athletes. Because of repetitive valgus loading of the elbow, capitellar OCDs occur related to repetitive compressive forces of the radial head abutting the capitellum in the lateral elbow compartment.

Osteochondral lesions may also occur as a secondary process when the underlying epiphyseal bone is abnormal, as can be seen in the setting of Perthes disease (e-Fig. 144.29).

***Imaging.*** Radiography is typically the first line of imaging for osteochondral lesions. However, MRI is more sensitive and provides a more detailed evaluation. In OCD, subchondral fragmentation may be seen (Fig. 144.30). Tunnel views are important in the evaluation of OCDs of the knee, but these can be misleading, as they delineate the posterior femoral condylar area in which normal femoral condylar irregularities are often seen (Fig. 144.31).

MRI is the optimal method for imaging osteochondral injuries. Noncontrast images are usually sufficient, and intraarticularly administered contrast agent is not necessary in most cases when MRI studies are performed using dedicated coils and on a high field magnet.

Acute chondral or osteochondral fractures are classified as partial (Fig. 144.32), full-thickness (Fig. 144.33), or delamination injuries (Fig. 144.34). When only cartilage is involved, these should technically be referred to as *acute chondral fractures* (see Fig. 144.32). The presence or absence of a chondral or osteochondral intraarticular bodies should be documented when reporting an osteochondral injury.

**TABLE 144.1** Common Locations for Osteochondritis Dissecans

| Location | Most Common | Less Common |
|---|---|---|
| Elbow | Capitellum | Radial head |
| Knee | Lateral aspect of the medial femoral condyle | Lateral femoral condyle, trochlear fossa, patella |
| Ankle | Medial talar dome | Lateral talar dome, midtalar dome |

Osteochondritis dissecans are classified as unstable (Fig. 144.35) or stable (Fig. 144.36). Criteria for instability are different when assessing juvenile (those seen in skeletally immature children with open physes) and adult types of OCDs. MRI findings with high specificity for instability of juvenile OCDs include: fluid signal

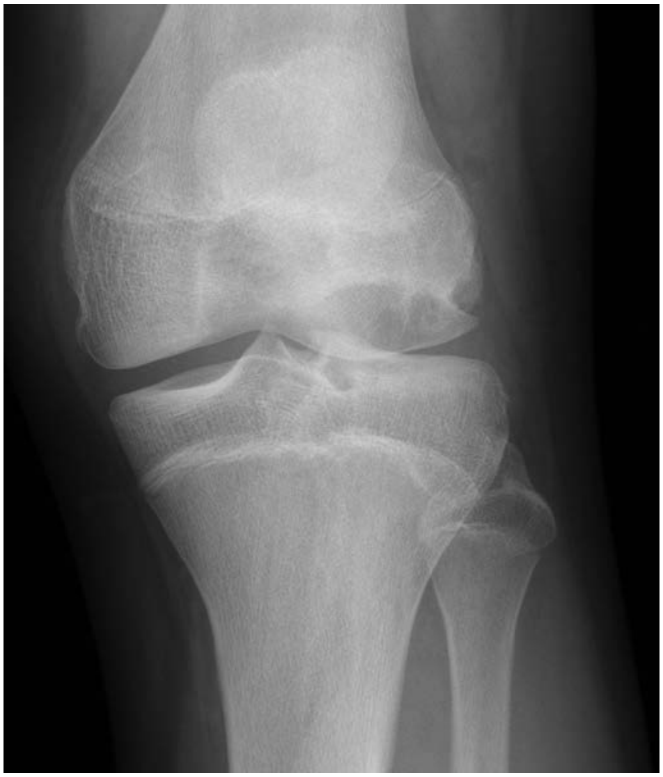

**Figure 144.30. Osteochondritis dissecans (OCD) of the lateral femoral condyle.** Anteroposterior radiograph of the knee in a 16-year-old shows a large OCD lesion.

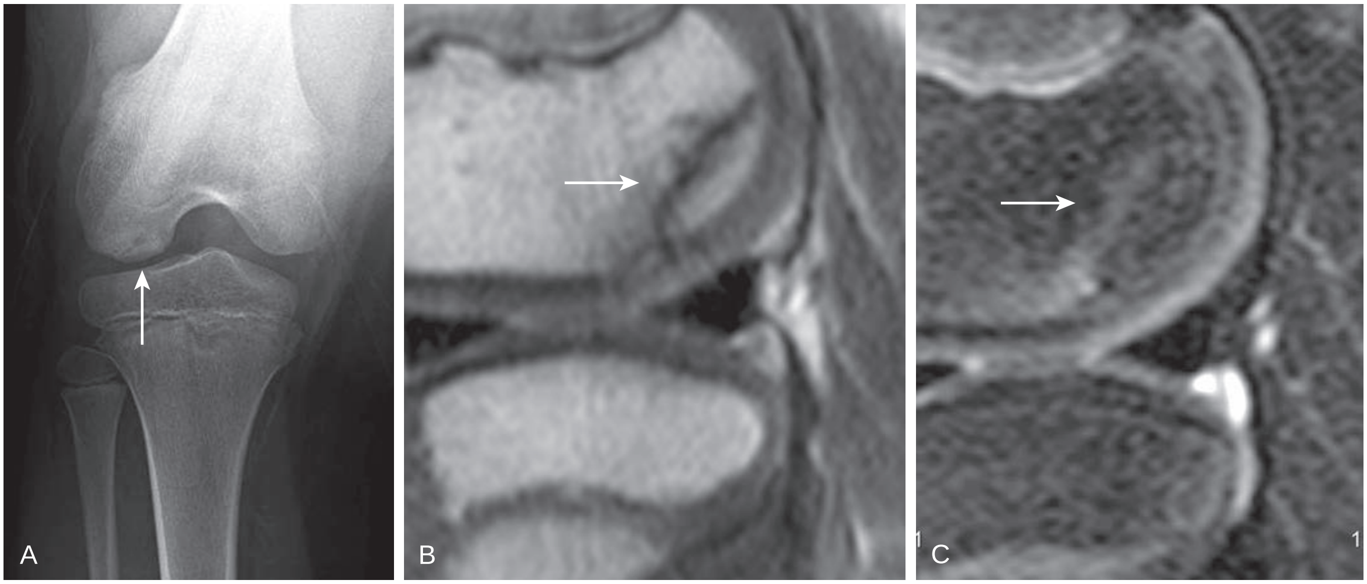

**Figure 144.31. Normal femoral condylar irregularity in a 10-year-old boy.** (A) Tunnel view radiograph demonstrates lateral femoral condylar irregularities *(arrow)*. (B) Proton density sagittal MR image and (C) T2-weighted fat-suppressed sagittal MR image demonstrates subchondral semilunar sharp demarcation between the condylar irregularity and epiphyseal parent bone *(arrow)*. Because substantial edema of the subchondral irregularity is not present and because the overlying articular cartilage and spherical growth plate are intact, this is considered a normal finding, not osteochondritis dissecans.

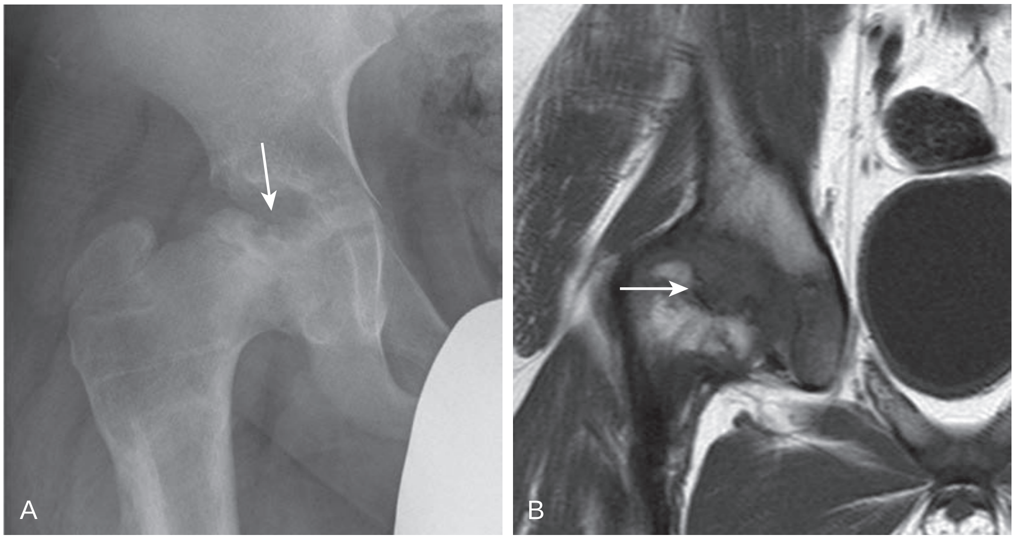

**e-Figure 144.29. Perthes disease in a 9-year-old girl.** (A) Anteroposterior hip radiograph and (B) T1-weighted coronal MR image demonstrates a large central osteochondral lesion *(arrows)* along the weight-bearing portion of the capital femoral epiphysis related to Perthes disease.

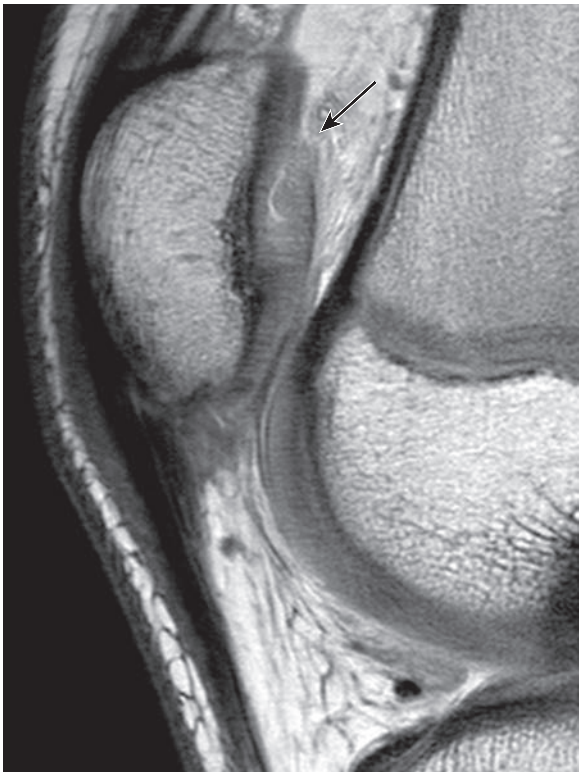

**Figure 144.32.** Acute partial thickness cartilage injury *(arrow)* of the patella on a proton density sagittal MR image.

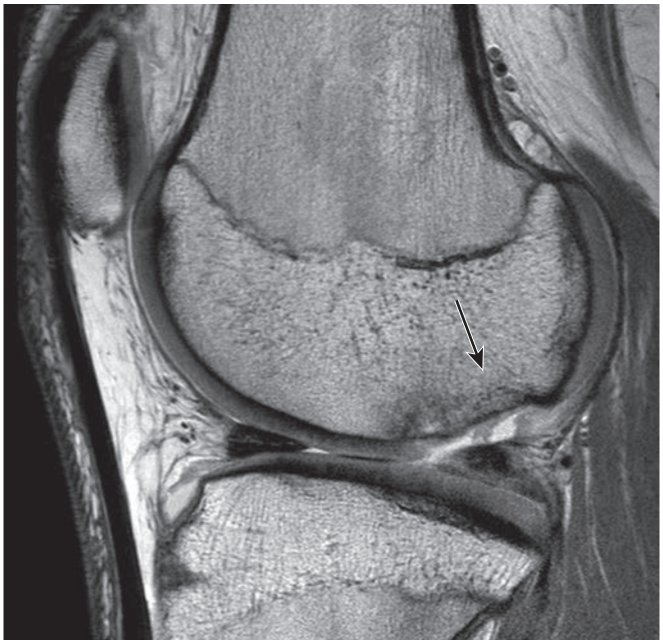

**Figure 144.33.** Full thickness cartilage injury *(arrow)* of the lateral femoral condyle with subchondral bone involvement on a proton density sagittal MR image.

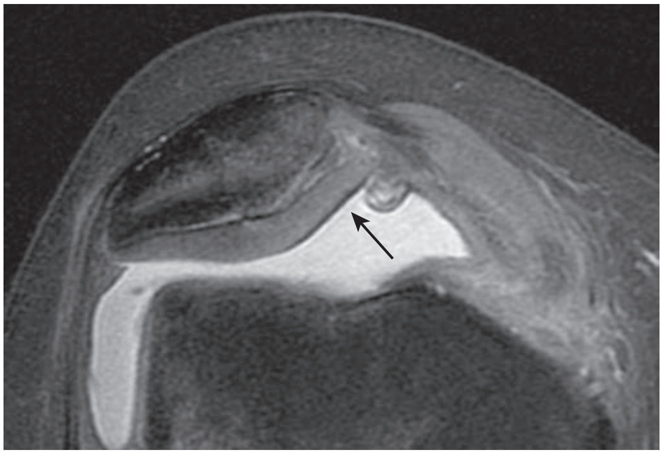

**Figure 144.34.** Delamination injury of the medial patella facet *(arrow)* secondary to a prior lateral patellar dislocation on a proton density fat-suppressed axial MR image.

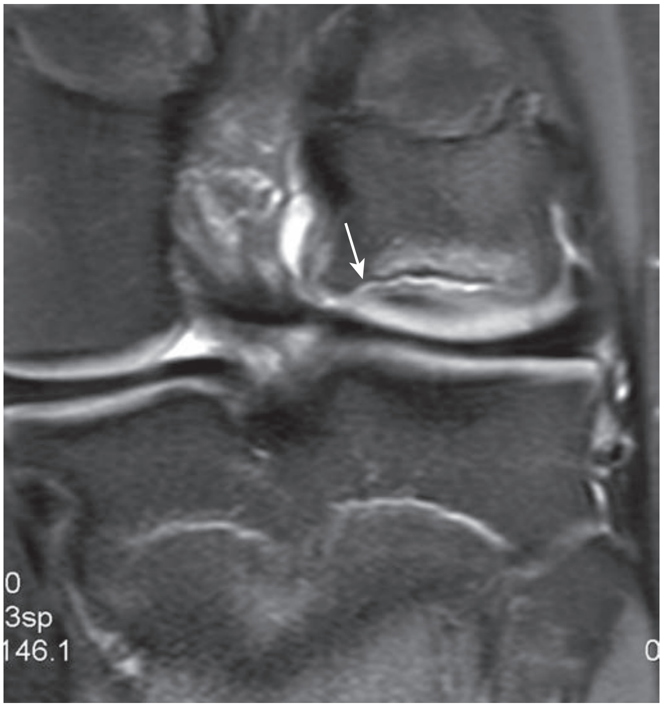

**Figure 144.35. Unstable lateral femoral condylar osteochondritis dissecans in a 14-year-old boy.** Proton density fat-suppressed coronal MR image demonstrates fluid signal insinuating between the parent bone and osteochondral fragment *(arrow)*.

deep to the lesion (Fig. 144.35), a junctional cyst >5 mm or multiple cysts, multiple breaks in the subchondral bone plate on T2-weighted images, articular cartilage fracture lines on T2-weighted images, a rim of low T2 signal intensity deep to a hyperintense rim, a fluid-filled osteochondral cavity, and intraarticular bodies.[26] Unlike adult type OCDs, single cysts smaller than 5 mm and increased signal on T2-weighted images that is not isointense to fluid alone are not specific for instability in juvenile OCDs. This difference is likely due to the greater ability of juvenile OCD lesions to heal with conservative measures, which in turn is likely because the spherical growth plate remains open in these skeletally immature children. Fat-suppressed T1-weighted gradient echo sequences can be helpful in differentiating marrow edema (hypointense signal intensity) from fibrovascular tissue (hyperintense signal intensity), which may have prognostic and treatment implications.[27]

Osteochondritis dissecans should be differentiated from normal condylar fragmentation, which is usually identified along the far

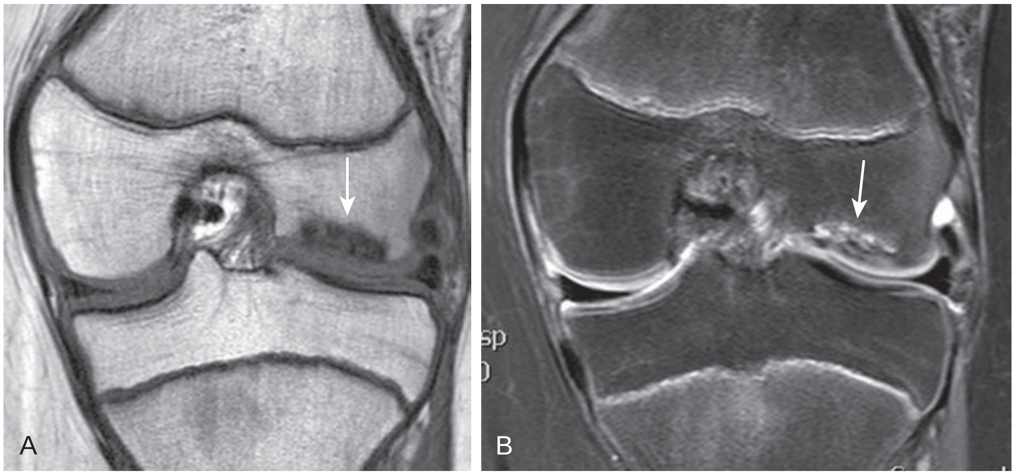

**Figure 144.36. Stable lateral femoral condylar osteochondritis dissecans in a 13-year-old boy.** (A) T1-weighted coronal and (B) proton density fat-suppressed coronal MR image demonstrates a well-demarcated osteochondritis dissecans with edema-like signal deep to the lesion *(arrow)*, but no fluid intensity signal was present deep to the lesion and no other MRI findings of instability were present.

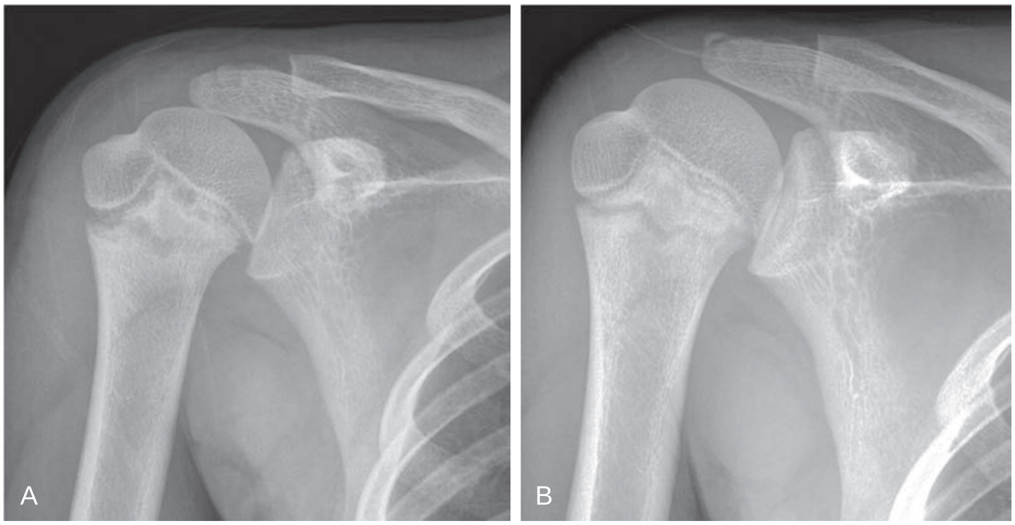

**Figure 144.37. "Little League" shoulder in a 12-year-old.** (A) Anteroposterior radiograph at presentation demonstrates proximal humeral physeal widening and metaphyseal fraying. (B) Anteroposterior radiograph 3 months later shows resolution with rest.

posterior, nonweight-bearing portion of the femoral condyles (see Fig. 144.31).

***Treatment.*** Nonsurgical therapy is recommended when imaging features suggest stability. OCDs in patients with an open physis are more likely to heal spontaneously, compared with osteochondritis dissecans in older children with closing or closed physis.[25] Surgical management of unstable OCDs includes arthroscopic drilling or microfracture methods to improve blood supply and healing, removal of any potential loose bodies, autologous osteochondral plugs, and autologous chondrocyte implantation.[25]

## THROWING INJURIES

***Etiology.*** "Little league shoulder" is an overuse injury that may occur with throwing activities, leading to a chronic Salter-Harris I injury of the proximal humerus.[28] This physeal injury occurs related to rotational torque created during throwing.

Little league elbow represents a constellation of medial and lateral compartment soft tissue, cartilage, and bone injuries related to throwing. With overhead throwing, repetitive elbow valgus stress occurs and causes tensile forces along the medial joint line and compressive forces along the lateral joint line. Along the medial joint line, this results in medial epicondylar apophysitis and medial epicondylar avulsion fractures in younger children, and anterior band ulnar collateral ligament injuries in adolescents who are skeletally mature.[29] Along the lateral joint line, repetitive compressive forces lead to osteochondral lesions of the capitellum, and less frequently osteochondral lesions of the radial head. In younger children, Panner disease of the capitellum may result, rather than discrete osteochondral lesions.

***Imaging.*** Radiographs of little league shoulder manifests with proximal physeal widening, juxtaphyseal metaphyseal fraying (Fig. 144.37), or proximal humeral metaphyseal periostitis. Imaging the contralateral asymptomatic shoulder may be necessary when the only finding present is physeal widening. This should be differentiated from physiologic proximal humeral physeal widening related to growth spurts. Physiologic proximal humeral physeal widening should be bilateral and symmetric.

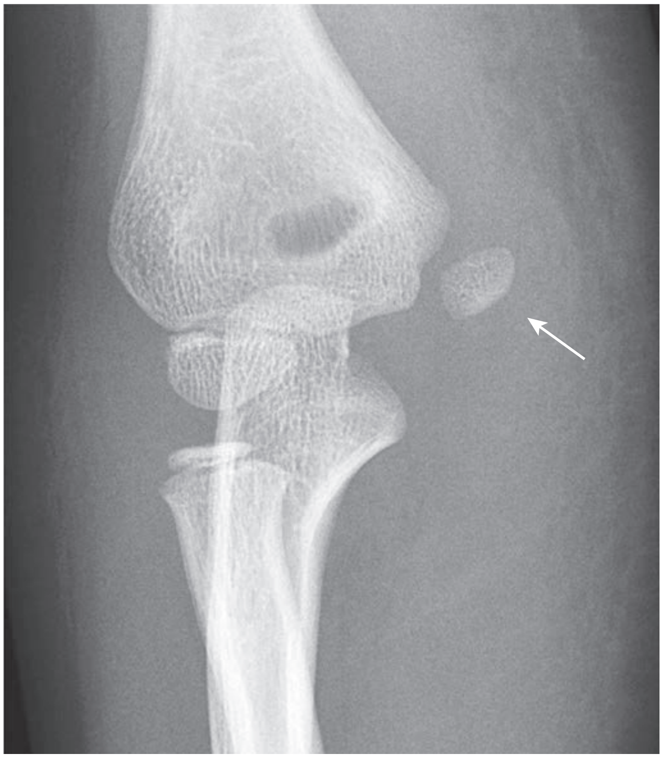

Figure 144.38. Medial epicondylar avulsion fracture in a 5-year-old girl *(arrow)*.

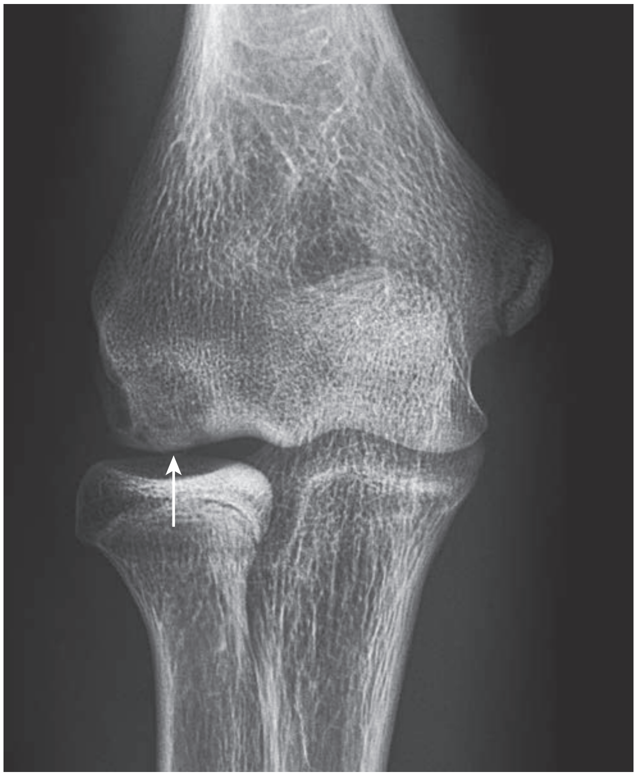

**Figure 144.40. Capitellar osteochondritis dissecans in a 14-year-old boy.** Frontal radiograph shows subchondral lucency and irregularity *(arrow)*.

Radiographic findings related to throwing injuries of the elbow include medial epicondylar avulsion fractures (Fig. 144.38). The avulsion injury may alternatively occur at the level of the chondro-osseous junction of the medial epicondyle with an intact medial epicondylar physeal equivalent region (e-Fig. 144.39). Radiographic features of capitellar osteochondritis dissecans include subchondral lucency (Fig. 144.40), fragmentation, and intraarticular loose bodies.

When radiographs are negative for medial epicondylar avulsion fractures, MRI may be helpful for evaluation of medial epicondylar pain. On MRI, marrow edema may be seen in the medial epicondyle and adjacent soft tissue. In adolescents who are skeletally mature, common flexor tendon tears and ulnar collateral ligament tears are more commonly seen. The most common ligament that is torn is the anterior band of the ulnar collateral ligament (e-Fig. 144.41), which is best evaluated by magnetic resonance arthrography. The most common location of anterior band ulnar collateral ligament tears is at its insertion on the sublime tubercle of the ulna.

Panner disease is seen in younger children compared with patients with osteochondritis dissecans and presents with diffuse sclerosis and fragmentation of the capitellum, with diffuse marrow edema seen on MRI.

***Treatment.*** Little league shoulder is treated nonsurgically with rest and activity modification.[28] Elbow medial epicondylitis and Panner disease are also treated conservatively. Medial epicondylar avulsion fractures are surgically reduced if greater than 5 mm displacement exists. Anterior band ulnar collateral ligament tears are treated conservatively in most instances. In high-level athletes, reconstruction with tendon autograft may be performed.[29] Osteochondritis dissecans of the capitellum are surgically treated if MRI features of instability are present.

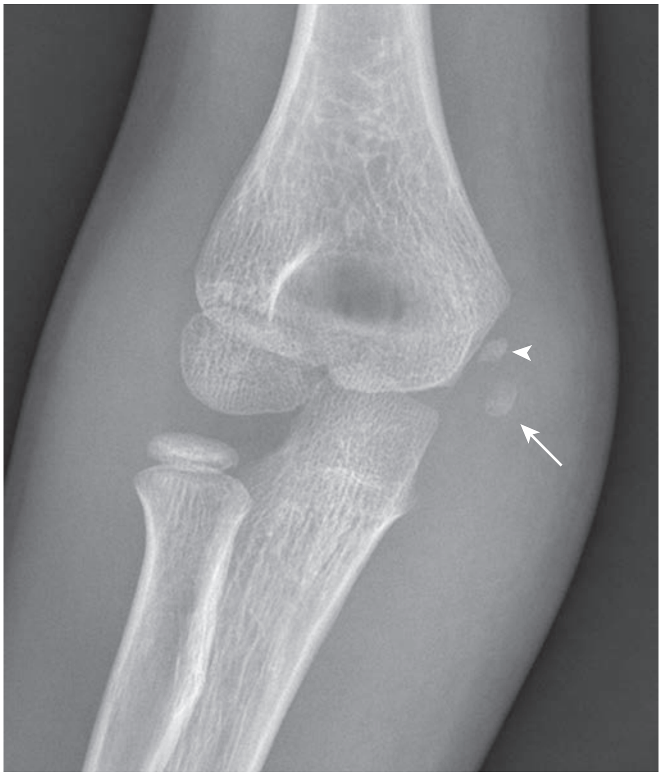
## INTERNAL DERANGEMENT OF THE HIP

***Etiology.*** *Femoroacetabular impingement* describes a constellation of femoral head or acetabular anatomic deformities causing hip joint incongruity that may lead to early osteoarthritis and labral tears. Femoral-sided deformities are classified as *cam-type impingement*, and acetabular-sided deformities are classified as *pincer-type impingement*. Both cam- and pincer-type impingements coexist in patients 86% of the time.[30]

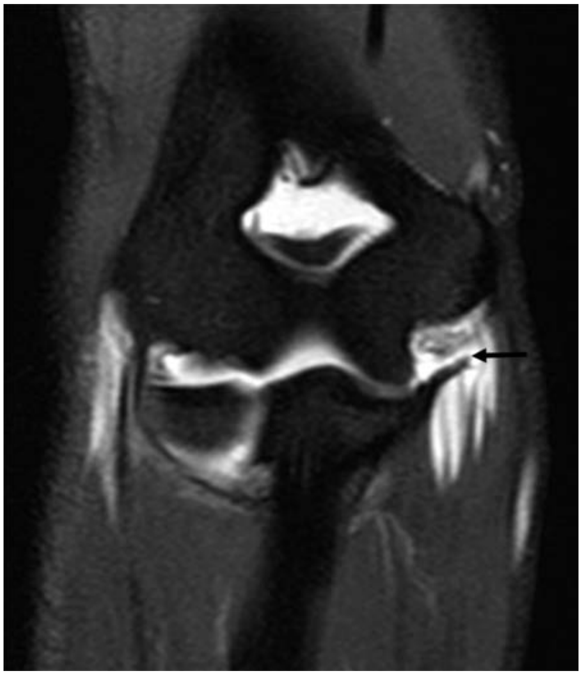
The diagnosis of femoroacetabular impingement is controversial, as many patients may have the anatomic deformity present and yet be asymptomatic.[31,32] The diagnosis may be suggested when positive clinical symptoms such as pain with hip flexion and hip internal rotation, as well as imaging findings of femoroacetabular impingement are present.

Common etiologies for cam-type femoroacetabular impingement in children include Perthes disease and slipped capital femoral epiphysis (SCFE).[33] Perthes disease may lead to a primary cam-type femoroacetabular impingement because the femoral head becomes aspherical. A secondary pincer-type femoroacetabular impingement may occur because the acetabulum is relatively too large compared with the aspherical small femoral head. SCFE may also lead to an abnormal femoral head–neck offset with a cam-type femoroacetabular bump, which may impinge on the labral acetabular rim, leading to labral tears and acetabular chondral injuries. In more severe cases, a “pistol grip” deformity (loss of the normal concavity of the lateral femoral neck) may occur.

Etiologies that may cause a pincer-type impingement include acetabular retroversion, sequelae of inflammatory arthritis, and acetabular protrusio deformity. *Acetabular version* describes the orientation of the acetabular cup, which is normally mildly anteverted. *Acetabular retroversion* describes a posteriorly oriented acetabular cup and can cause a pincer-type impingement due to anterosuperior overcoverage of the femoral head. Acetabular retroversion may be congenital or secondary as a developmental alteration caused by femoral head deformities (a congruent normal femoral head is necessary to develop a normal acetabulum, and



**e-Figure 144.39. Medial epicondylar chondro-osseous avulsion fracture in an 8-year-old boy.** Frontal radiograph shows that when the medial epicondylar ossification center is disrupted, both an *in situ* portion of the epicondyle *(arrowhead)* and an avulsed fragment *(arrow)* are seen.



**e-Figure 144.41. Complete tear of the anterior band of the ulnar collateral ligament in a 16-year-old wrestler.** MR arthrogram demonstrates full thickness disruption of the midportion of the anterior band fibers *(arrow)*.

vice versa). Inflammatory arthritis may cause concentric narrowing of the joint, which leads to a pincer-type deformity from relative overcoverage of the femoral head. In the setting of inflammatory arthritis with uniform decreased joint space, less space is available for the femoral head to clear during hip motion. Acetabular protrusio deformity, which may also result from inflammatory arthritis, similarly leads to overcoverage of the femoral head, which causes a pincer-type deformity.

Developmental dysplasia of the hip (DDH) may cause a pincer-type impingement, cam-type impingement, or a combination of both. Cam-type femoroacetabular impingement results from a size mismatch between a small dysplastic acetabular cup and relatively large femoral head (Fig. 144.42). Subtrochanter varus osteotomy to relocate the hip may further exacerbate a cam-type impingement. Alternatively, periacetabular osteotomies such as a Salter osteotomy may increase the acetabular coverage, resulting in a pincer-type deformity.

***Imaging.*** Radiographic findings suggesting cam-type femoroacetabular impingement include insufficient offset at the femoral head–neck junction (Fig. 144.43), coxa vara, and femoral retroversion. On MRI, anterosuperior labral tears are most frequently related to cam-type femoroacetabular deformities (Fig. 144.44). More obvious deformities leading to cam-type femoroacetabular impingement include Perthes disease (e-Fig. 144.45) and DDH (see Fig. 144.42). Labral tears are best assessed with magnetic resonance arthrography.

On MRI or CT, an alpha-angle may be used to calculate the degree of femoral head deformity related to a cam-type deformity. The normal alpha-angle is less than 55 degrees. The alpha-angle is calculated by doing the following:

1. Drawing a best-fit circle around the femoral head outlining the cortical margin.
2. Drawing a line from the center of the circle parallel to the femoral neck.

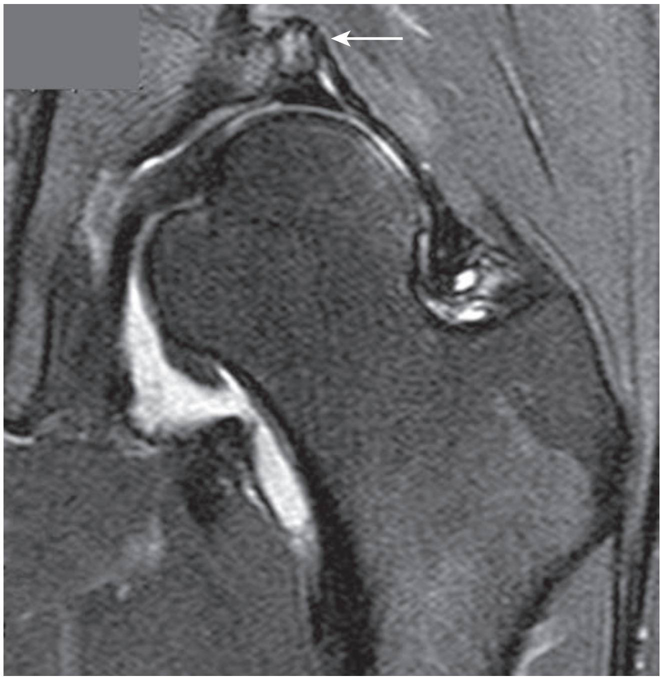


**Figure 144.42. Untreated developmental dysplasia of the left hip in a 19-year-old girl.** T2-weighted fat-suppressed coronal MR image demonstrates size mismatch of relatively large femoral head and small acetabular fossa leading to cam-type impingement with resultant early labral degeneration and a chronic acetabular rim fragment *(arrow)*.

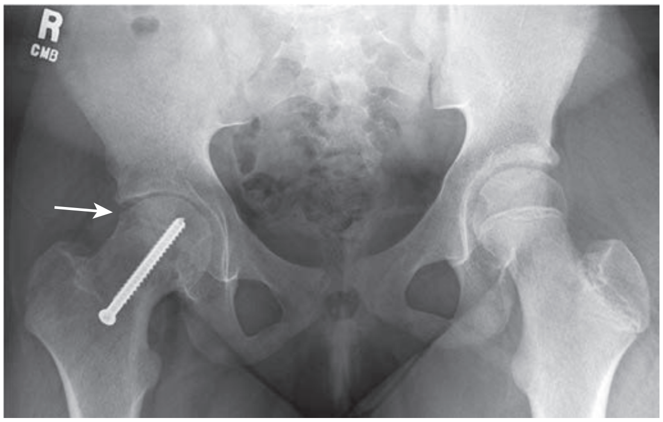

**Figure 144.43. Femoroacetabular impingement after slipped capital femoral epiphysis in a 10-year-old girl.** Frontal radiograph shows a right-sided healed slipped capital femoral epiphysis with idiopathic chondrolysis and development of a junctional osteophyte *(arrow)*, with resultant mixed cam-type and pincer-type femoroacetabular impingement.

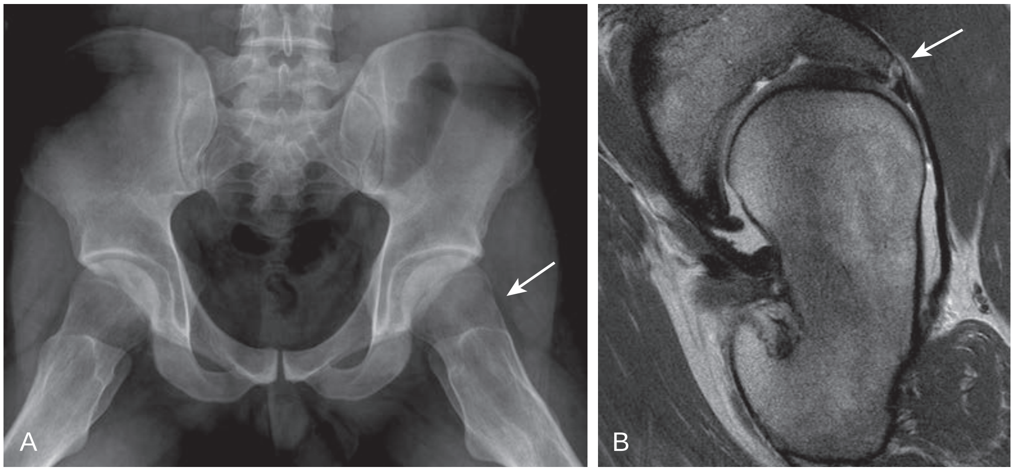

**Figure 144.44. Femoroacetabular impingement.** (A) Frog-leg lateral radiograph shows cam-type femoroacetabular impingement with pistol-grip deformity and loss of normal femoral head–neck offset *(arrow)*. (B) Proton density radial MR image again shows loss of femoral head-neck offset and a anterosuperior labral tear *(arrow)*.

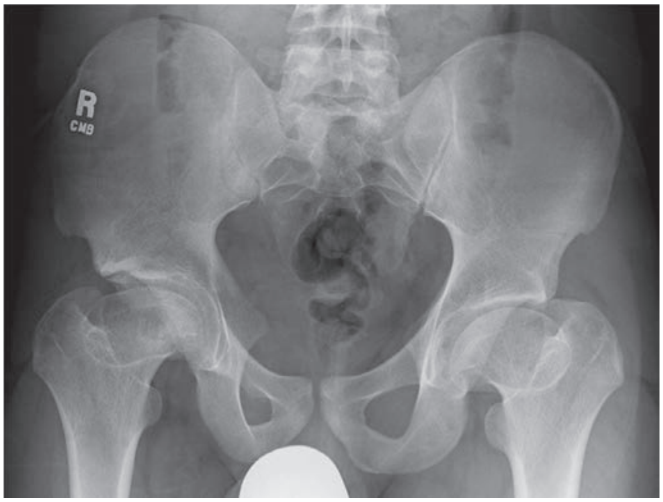

**e-Figure 144.45. Sequela of bilateral Perthes disease in an 18-year-old male.** Frontal pelvis radiograph shows bilateral cam-type femoroacetabular impingement caused by flattened, aspherical femoral heads, loss of the normal femoral head–neck offset, and lateral femoral neck concavity bilaterally.

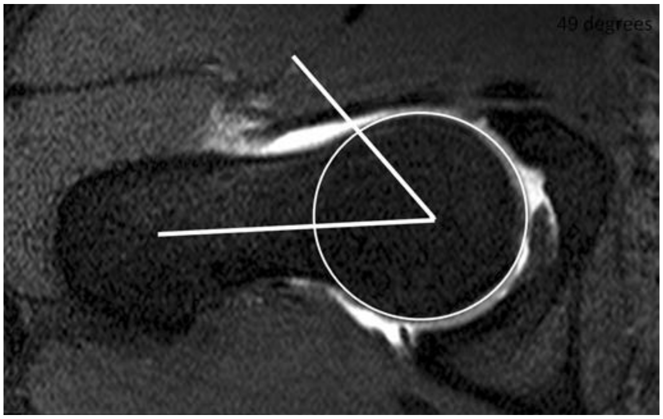

**Figure 144.46. Alpha-angle calculation.** Oblique axial T1-weighted fat-suppressed MR arthrogram image demonstrating lines for calculating the alpha-angle.

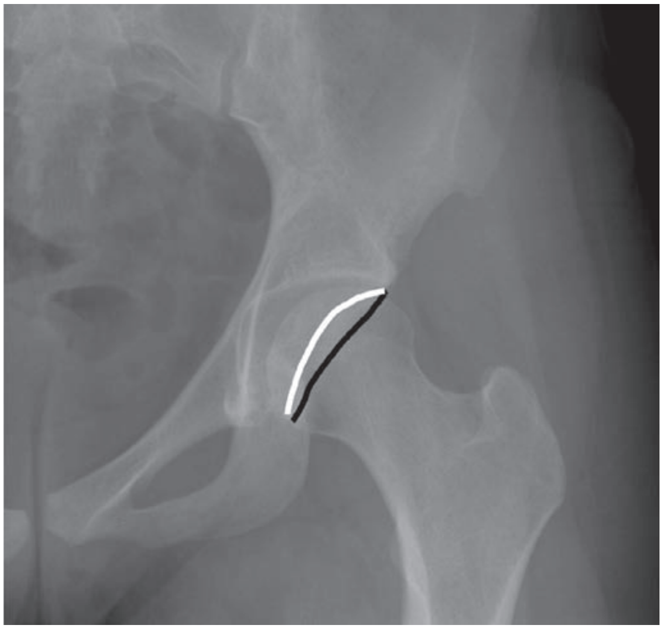

**Figure 144.47. Normal hip showing the no cross-over sign.** Anteroposterior radiograph of the hip: the *white line* represents the anterior acetabular wall, the *black line* represents the posterior acetabular wall.

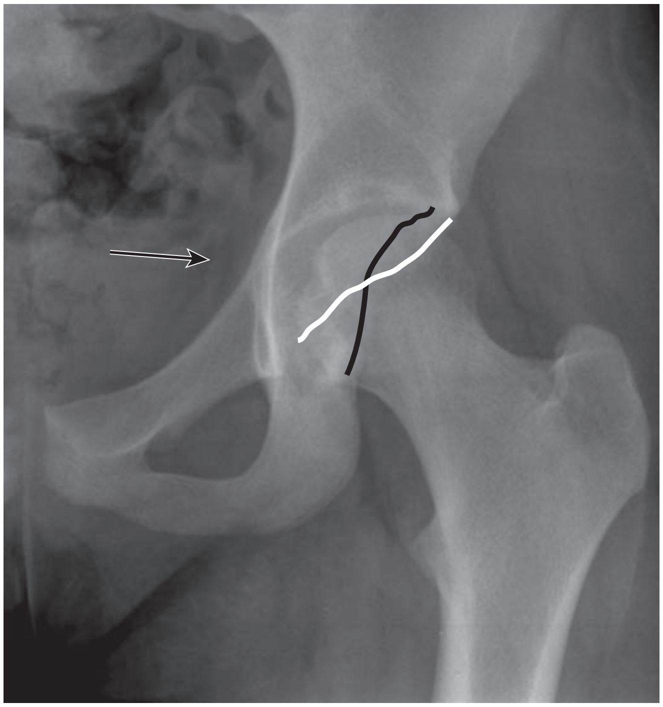

**Figure 144.48. Acetabular retroversion and cross-over sign.** Anteroposterior radiograph of the hip: the white line represents the anterior acetabular wall, the black line represents the posterior acetabular wall. Note the ischial spine sign is present as well *(arrow)*, an additional indicator of a pincer deformity.

3. Drawing a line from the center of the circle to where the femoral head or neck protrudes from the circle.
4. Calculating an angle between lines created from items 2 and 3 (Fig. 144.46).

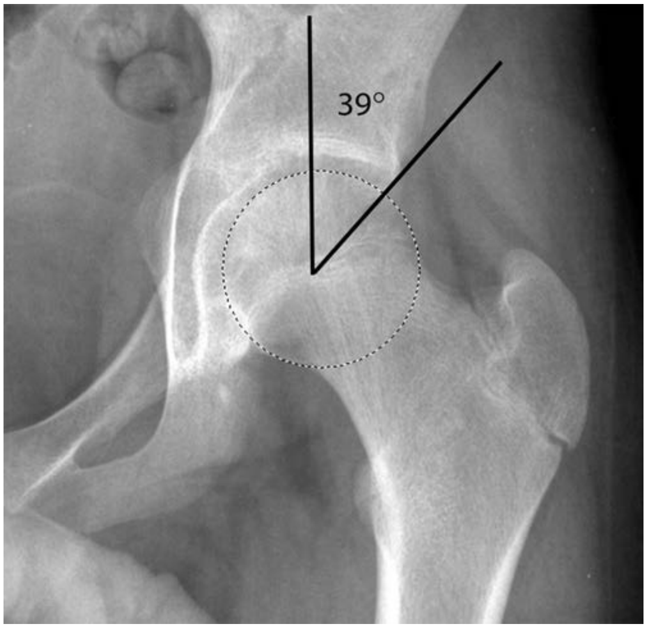
Radiographic findings associated with pincer-type femoroacetabular impingement include the cross-over sign (Figs. 144.47 and 144.48), a lateral center edge angle greater than 29 degrees (e-Fig. 144.49), prominent posterior wall, coxa profunda, protrusio acetabuli, and ischial spine sign.[30,34] On frontal radiographs of the pelvis, the anterior acetabular wall is normally more medial with respect to the posterior acetabular wall (see Fig. 144.47) and they should meet at the superolateral margin of the sourcil. The cross-over sign occurs when the anterior and posterior acetabular wall lines intersect, indicative of acetabular retroversion (see Fig. 144.48). This should be evaluated for an appropriately positioned frontal view of the pelvis, as obliquity and pelvic tilt may cause an artifactual cross-over sign. The normal acetabulum is usually in 19 degrees of anteversion in adult patients.[35] With acetabular retroversion, anterior overcoverage of the femoral head occurs. There is little consensus on where in the acetabulum to measure version, therefore it is best to confer with local referring orthopedic surgeons.

***Treatment.*** Treatment is predicated on symptoms, not on the degree of imaging deformity. When surgery is indicated, treatment focuses on removal of the anatomic cause of the impingement to improve acetabular and femoral head congruity so that the acetabulum and the femoral head–neck junction do not abnormally abut during normal range of motion.[36] This includes removing cam-type deformities at the femoral head–neck junction as well as reshaping the femoral head to conform to a spherical shape and addressing any associated labral tears and chondral injuries. For pincer-type femoroacetabular deformity related to acetabular retroversion, a periacetabular rotational osteotomy or acetabuloplasty may be performed to decrease the amount of anterior overcoverage.

## STRESS INJURIES OF BONE

***Etiology.*** A fatigue fracture occurs when supraphysiologic repetitive stress is applied to normal bone. Insufficiency fractures occur when normal stress is applied to abnormal bone.[37] Stress injuries to bone can occur on either the compressive side or the tensile side of bone, leading to trabecular injury. Before fracture, stress changes to bone can include periosteal edema, marrow edema, cortical edema, and microfractures (occult fractures not visible on imaging). With proper training, bone and muscle physiologic adaptation to repetitive stress is protective and may prevent stress reaction and stress fractures to bone.

Risk factors for stress injuries to bone include inadequate or improper athletic training, postpubertal females (female athlete triad: [1] menstrual irregularity, [2] disordered eating, and [3] osteoporosis), and abnormal biophysical geometry of the child such as leg length discrepancies, varus alignment, abnormal femoral version, and pes cavus.[38]



**e-Figure 144.49. Acetabula protrusio in a 12-year-old boy.** Frontal radiograph shows mild protrusio deformity with a lateral center-edge angle measuring approximately 39 degrees. Center-edge angle is the angle between a vertical line drawn through the center of the femoral head and line from the center of the femoral head to the lateral edge of the sourcil.

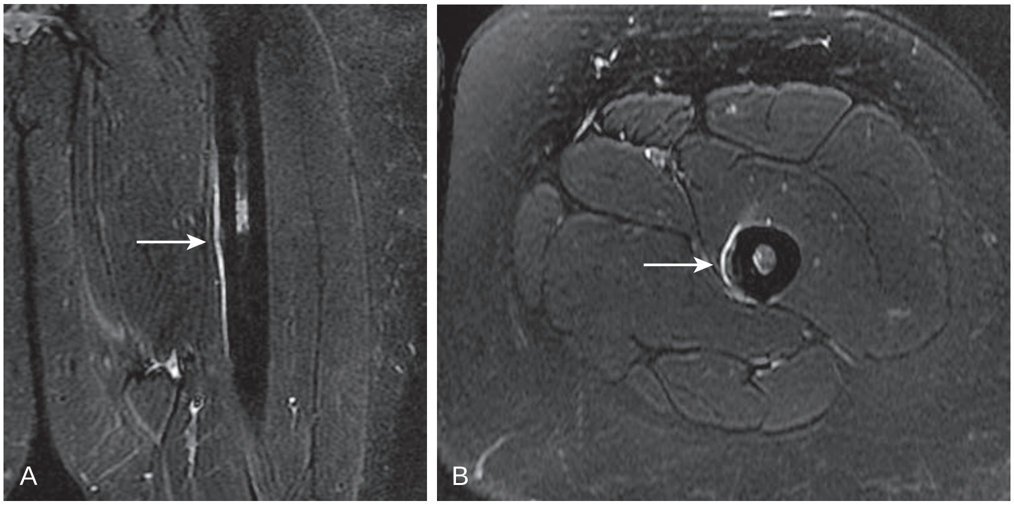


**Figure 144.50. Stress reaction of the femur without discrete fracture in a 16-year-old boy.** Short-tau inversion recovery axial (A) and coronal (B) MR images show periosteal reaction *(arrows)* and endosteal edema.

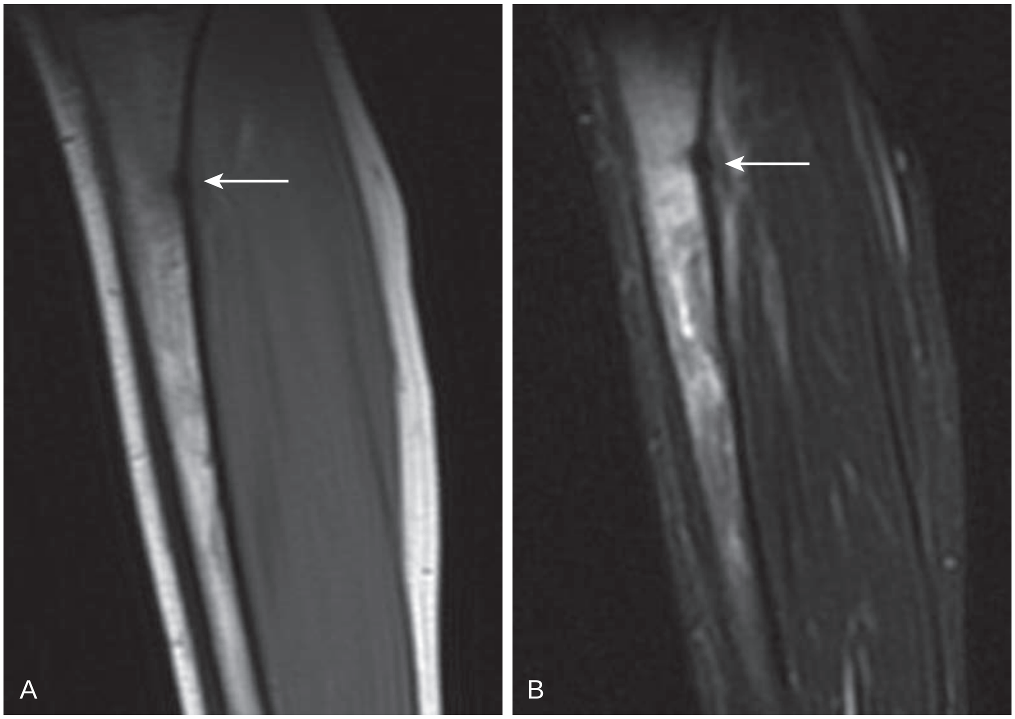

**Figure 144.51. Nondisplaced proximal tibial stress fracture in an 8-year-old boy.** T1-weighted sagittal (A) and short-tau inversion recovery sagittal (B) MR images show abnormal signal *(arrows)*.

Symptoms related to stress fractures are not present at rest but occur with physical activity.[38] *Shin splints*, or *medial tibial stress syndrome*, is a vague term to describe pain that most often occurs over the posteromedial aspect of the distal third of the tibia.[39] Proposed etiologies include muscle attachment inflammation, fascial edema, posterior compartment syndrome, and tibial stress fractures. Because of its nonspecific broad definition, shin splints should be reserved as a clinical diagnosis, not a radiologic diagnosis.

***Imaging.*** With radiography, the spectrum of stress reaction to bone includes normal (most common), periostitis, and discrete fracture. Radiographs are the first line of imaging when suspected fracture is present. MRI is a complementary tool when radiographs are normal.

MRI is indicated when symptoms do not resolve with conservative management or failed physical rehabilitation in the setting of normal radiographs. When radiographs are abnormal, demonstrating a discrete nondisplaced stress fracture, MRI does not add additional value with regard to treatment in most cases. MRI will add value if the fracture has an intraarticular component, may involve the physis, or the fracture is pathologic because of an underlying primary neoplasm of bone.

MRI grading for bone stress injuries includes the spectrum from isolated periosteal edema (Fig. 144.50) to a true fracture (Fig. 144.51) (Table 144.2).[38] MRI may also suggest alternative soft tissue etiologies for symptoms such as muscle tears or DOMS.

**TABLE 144.2** Magnetic Resonance Grading of Stress Injuries to Bone

| Grade | T2 | T1 |
|---|---|---|
| 0 | Normal | Normal |
| 1 | Periosteal edema, no marrow edema | Normal |
| 2 | Periosteal edema, marrow edema | Normal |
| 3 | Periosteal edema, marrow edema | Periosteal edema, marrow edema |
| 4 | Fracture line present | Fracture line present |

***Treatment.*** Treatment will vary, depending on location of fractures and symptoms. For nondisplaced stress fractures, treatment includes local pain control, including physical therapy and nonsteroidal antiinflammatory drugs. Weight-bearing for normal activities is allowed. Eventually, return to athletic activity may begin if the child is pain free for 10 to 14 days.[38]

## KEY POINTS

- Pelvic avulsion fractures are usually treated conservatively unless fracture displacement is greater than 2 cm.
- In the setting of lateral patellar dislocation, the presence or absence of underlying patellofemoral dysplasia should always be noted.
- Identification of loose bodies in acute patellar dislocation has more impact on surgical management than identifying bone contusions and medial retinacular injuries.
- The Wrisberg variant of discoid lateral meniscus may occur in the setting of a meniscus of normal size and shape.
- Among throwing athletes, skeletally immature children tend to develop medial epicondylitis and medial epicondylar avulsion fractures, whereas skeletally mature children tend to suffer flexor tendon and ulnar collateral ligament tears.
- Femoroacetabular impingement treatment is predicated on both symptoms and imaging findings. Therefore the imaging diagnosis without supportive clinical symptoms may generate unnecessary orthopedic referrals.
